# High-performance thermoelectric silver selenide thin films cation exchanged from a copper selenide template†

Nan Chen,<sup>a</sup> Michael R. Scimeca,<sup>a</sup> Shlok J. Paul,<sup>a</sup> Shihab B. Hafiz,<sup>b</sup> Ze Yang,<sup>c</sup> Xiangyu Liu,<sup>a</sup> Fan Yang,<sup>c</sup> Dong-Kyun Ko<sup>\*b</sup> and Ayaskanta Sahu<sup>ID</sup><sup>\*a</sup>

Over the past decade, Ag<sub>2</sub>Se has attracted increasing attention due to its potentially excellent thermoelectric (TE) performance as an n-type semiconductor. It has been considered a promising alternative to Bi–Te alloys and other commonly used yet toxic and/or expensive TE materials. To optimize the TE performance of Ag<sub>2</sub>Se, recent research has focused on fabricating nanosized Ag<sub>2</sub>Se. However, synthesizing Ag<sub>2</sub>Se nanoparticles involves energy-intensive and time-consuming techniques with poor yield of final product. In this work, we report a low-cost, solution-processed approach that enables the formation of Ag<sub>2</sub>Se thin films from Cu<sub>2–x</sub>Se template films *via* cation exchange at room temperature. Our simple two-step method involves fabricating Cu<sub>2–x</sub>Se thin films by the thiol-amine dissolution of bulk Cu<sub>2</sub>Se, followed by soaking Cu<sub>2–x</sub>Se films in AgNO<sub>3</sub> solution and annealing to form Ag<sub>2</sub>Se. We report an average power factor (PF) of 617 ± 82 μW m<sup>–1</sup> K<sup>–2</sup> and a corresponding ZT value of 0.35 at room temperature. We obtained a maximum PF of 825 μW m<sup>–1</sup> K<sup>–2</sup> and a ZT value of 0.46 at room temperature for our best-performing Ag<sub>2</sub>Se thin-film after soaking for 5 minutes. These high PFs have been achieved *via* full solution processing without hot-pressing.

## Introduction

Burning of fossil fuels for energy and heat production is a major contributor towards climate change and global warming.<sup>1</sup> One of the largest energy consumers is the industrial sector which accounts for about 32% of total U.S. energy consumption with nearly 1933.2 PJ per year of energy dissipated as waste heat during manufacturing processes.<sup>2,3</sup> Of the rest of the energy produced, almost 50% goes into commercial and residential heating, ventilation and air conditioning (HVAC) operating costs where the majority of the energy is used for unnecessarily heating and cooling entire infrastructures such as ceilings, walls and unoccupied spaces.<sup>4</sup> Thermoelectric (TE) devices provide a two-prong approach to solving the energy and HVAC issues outlined above. A TE material has the unique potential to directly convert thermal energy into electricity and *vice versa*.<sup>5</sup> On one hand, operating in a waste heat recovery mode, TEs can absorb waste heat and convert it to usable electricity, which may

reduce the consumption of nonrenewable resources. On the other hand, flexible TE modules operating in heat pumping mode have the potential to be integrated with clothing for local temperature control<sup>6–8</sup> possibly replacing building wide HVAC systems and leading to unprecedented energy savings. Therefore, TE devices exhibit significant potential to alleviate global warming and environmental pollution issues. To gauge the performance of a TE material, the figure of merit commonly used is denoted as ZT, defined as  $S^2\sigma T\kappa^{-1}$ , where  $S$  is the Seebeck coefficient,  $\sigma$  is the electrical conductivity,  $T$  is the absolute temperature and  $\kappa$  is the total thermal conductivity.<sup>5,9</sup>  $S^2\sigma$  is also known as the power factor (PF). An efficient TE material requires maximizing the PF while minimizing thermal conductivity. However, it is challenging to simultaneously achieve high electrical conductivity, high Seebeck coefficient and low thermal conductivity in any traditional material due to parameter interdependency.<sup>10</sup> Nanostructuring has proven to be a valuable tool for adjusting the traditional relationships between electrical conductivity, Seebeck coefficient and thermal conductivity.<sup>11–13</sup> For example, energy filtering of cold electrons can help to overcome the Seebeck coefficient and electrical conductivity trade-off,<sup>14</sup> while the formation of nanocrystalline grains can decouple the relationship between electrical and thermal conductivity.<sup>15</sup> Many nanostructured TEs have been prepared *via* solution processing on flexible substrates with adaptable form factors that allow integration of these TE devices into a variety of applications that would otherwise be

inaccessible.<sup>16–18</sup> If flexible TE devices can be fabricated on fabrics, it would have implications in enabling temperature-regulating clothing that can reduce the energy and space consumption of household and building HVAC systems significantly.

Currently, bulk pellets of n- or p-type doped Bi<sub>2</sub>Te<sub>3</sub> and Sb<sub>2</sub>Te<sub>3</sub> materials dominate the commercial TE market due to their ideal balance between electrical and thermal properties.<sup>19</sup> Although these devices have good performances with *ZT* values around 1, they suffer from high manufacturing costs, toxicity, and rigidity thus limiting their use in applications that require flexible form factors. The TE community has already made substantial progress on nanostructured and solution-processable Bi<sub>2</sub>Te<sub>3</sub> and Sb<sub>2</sub>Te<sub>3</sub> materials to enhance performance and versatility while reducing manufacturing costs;<sup>18</sup> however, toxicity remains a large problem. To accomplish the goal of widespread flexible, integrated TE devices in clothing and other applications, toxic materials must be eliminated. Cu<sub>2</sub>Se has made rapid progress as a potential heavy-metal-free p-type material but a matching low-cost high-performance non-toxic n-type material is required for a working TE generator. In this regard, silver selenide (Ag<sub>2</sub>Se) has attracted significant interest, owing to its promising potential in TE applications.<sup>20,21</sup> Ag<sub>2</sub>Se is an n-type semiconductor with reported *ZT* values ranging from 0.32 to 0.99 at room temperature in bulk.<sup>10,18,22–31</sup> In addition, Ag and Se are less toxic than Bi, Pb, Sb and Te, and Se is approximately 10 times more abundant than Te.<sup>32</sup> Despite these promising advances, to maximize the TE potential of Ag<sub>2</sub>Se, nanocrystalline Ag<sub>2</sub>Se is required. Finally, to keep the final costs of the TE modules low, an ideal process would involve an inexpensive synthetic approach towards Ag<sub>2</sub>Se nanostructures, combined with a high-throughput solution-processing fabrication approach for widespread deployment on various substrates with flexible form factors.

Various reaction routes for directly synthesizing Ag<sub>2</sub>Se nanocrystals (NCs) have been reported,<sup>22,33–36</sup> but there exist few on nanostructured Ag<sub>2</sub>Se for TE applications. Perez-Taborda *et al.* fabricated Ag<sub>2</sub>Se thin films on glass substrates *via* pulsed hybrid reactive magnetron sputtering (PHRMS), reporting a PF of  $4655 \pm 407 \mu\text{W m}^{-1} \text{K}^{-2}$  at 376 K.<sup>37</sup> Despite the large PF, the power output required to run PHRMS would lead to high manufacturing costs.<sup>38</sup> Employing more cost-effective solution-synthesis techniques, Ding *et al.*, Xiao *et al.* and Pei *et al.* obtained Ag<sub>2</sub>Se NCs with PFs of  $987.4 \pm 104.1 \mu\text{W m}^{-1} \text{K}^{-2}$  at 300 K,<sup>6</sup> around  $544.5 \mu\text{W m}^{-1} \text{K}^{-2}$  at 405 K,<sup>30,39</sup> and  $1840 \mu\text{W m}^{-1} \text{K}^{-2}$  at 400 K respectively;<sup>40</sup> however, the use of hot pressing limits the true solution processability on flexible substrates and induces significant NC fusion. Our group has previously reported a facile one-pot colloidal synthesis of silver chalcogenide NCs using low temperature and less reactive precursors under atmospheric pressure.<sup>22,41–43</sup> This method resulted in stable Ag<sub>2</sub>Se NCs, but it is restricted to batch processing and the yield of the synthesis is relatively low (~4% yield).<sup>43</sup> An ideal synthetic route to overcome these challenges would be to use a high-yield technique with low-cost precursors to generate a nanostructured film. In this regard, a thiol-amine approach proposed by Webber *et al.* allows one to dissolve bulk

chalcogenide semiconductors in solvents such as ethylenediamine (en) and ethanedithiol (edtH<sub>2</sub>) and deposit as thin films with high throughput.<sup>44</sup> Unfortunately, not every chalcogenide (*e.g.* Ag<sub>2</sub>Se) is amenable to this dissolution-deposition technique. Although a number of hypotheses have been proposed in literature, none of them provide a detailed mechanism regarding the nature of dissolution of metal chalcogenides. The most convincing hypothesis involves the formation of the thiolatothiometallate anions counterbalanced by the enH<sup>+</sup> cations in the chalcogenide/en/edtH<sub>2</sub> system but this does not directly describe why some chalcogenides can be dissolved and some cannot.<sup>44–46</sup> An alternative approach that has been typically used in the semiconductor NC community is to take advantage of established protocols to synthesize common chalcogenide NCs and use cation exchange (CE) as a facile method to convert it into a high value product that cannot be synthesized directly.<sup>47</sup> CE has been demonstrated to be a versatile, efficient and convenient tool to expand the library of attainable materials with new and unique material phases, shapes and compositions.<sup>24,26,48,49</sup> CE transformation normally involves a two-step process, the first step being the synthesis of the base material as a template, and the second step being the exchange between the host and the guest cations within the crystal lattice.

In this report, we successfully demonstrated the fabrication of polycrystalline Ag<sub>2</sub>Se thin films from Cu<sub>2–x</sub>Se thin film templates that exhibit an average PF of  $617 \pm 82 \mu\text{W m}^{-1} \text{K}^{-2}$  with a *ZT* of 0.35 at room temperature. To demonstrate the applicability of our hypothesis, we start off with a template of Cu<sub>2–x</sub>Se thin films that was prepared *via* the method reported in the work of Lin *et al.*<sup>50</sup> The resulting Cu<sub>2–x</sub>Se thin films are not perfectly stoichiometric when synthesized under these chemical conditions, which is normal for the entire copper chalcogenides family.<sup>24,51</sup> Evidence shows that the vacancies in the lattice actually accelerate the exchange process as they provide alternative pathways for the diffusion of Ag<sup>+</sup> ions, even at low temperatures.<sup>24,52</sup> We then soaked our Cu<sub>2–x</sub>Se films into a Ag<sup>+</sup>-rich solution for various amounts of time and annealed our final samples afterwards as outlined in Fig. 1. We confirmed the transformation of copper selenide to silver selenide using X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), energy dispersive X-ray spectroscopy (EDS) and inductively coupled plasma mass spectrometry (ICP-MS) in addition to investigating the TE properties of the resultant films.

## Experimental

### Synthesis of Ag<sub>2</sub>Se thin films from Cu<sub>2–x</sub>Se template films

Copper(I) selenide (Cu<sub>2</sub>Se, >99.95%), ethylenediamine (H<sub>2</sub>NCH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>, >99%), ethanedithiol (HSCH<sub>2</sub>CH<sub>2</sub>SH, >98%), silver(I) nitrate (AgNO<sub>3</sub>, >99.9%), acetonitrile (C<sub>2</sub>H<sub>3</sub>N, anhydrous, 99.8%), acetone (C<sub>3</sub>H<sub>6</sub>O), isopropyl alcohol (C<sub>3</sub>H<sub>8</sub>O, 99%) and methanol (CH<sub>3</sub>OH) were purchased from Sigma-Aldrich. All the chemicals were used as received without further purification.

The following steps were performed in a nitrogen-filled glovebox. 100 mg of Cu<sub>2</sub>Se was weighed and transferred into a 5 mL glass vial. 2 mL of ethylenediamine (en) was measured and

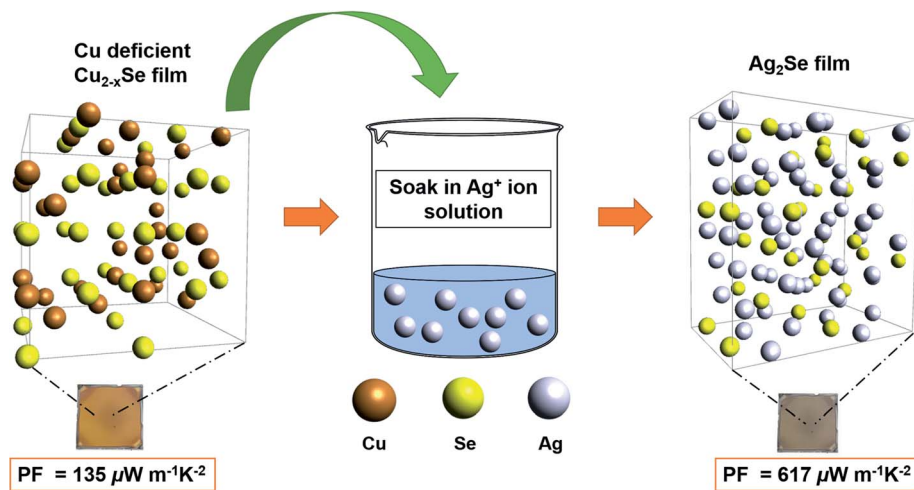

Fig. 1 Schematic describing the process in which a Cu-deficient  $\text{Cu}_{2-x}\text{Se}$  thin film transforms into an  $\text{Ag}_2\text{Se}$  thin film by fully immersing the  $\text{Cu}_{2-x}\text{Se}$  thin film into an  $\text{Ag}^+$ -rich solution for different amounts of time followed by annealing.  $\text{Ag}^+$  concentration gradient is established between the soaking solution and the thin film drives the  $\text{Ag}^+$  ions to diffuse into the  $\text{Cu}_{2-x}\text{Se}$  crystal lattice and replace the  $\text{Cu}^+$  ions. Electrically, this process results in a switching of majority carrier type from p-type ( $\text{Cu}_{2-x}\text{Se}$ ) to n-type ( $\text{Ag}_2\text{Se}$ ) and an increase in the average PF from  $135 \mu\text{W m}^{-1}\text{K}^{-2}$  to  $617 \mu\text{W m}^{-1}\text{K}^{-2}$ . The photographs show the  $\text{Cu}_{2-x}\text{Se}$  film (before soak) and the  $\text{Ag}_2\text{Se}$  film (after soak) on glass substrates.

transferred to the glass vial, followed by 0.2 mL of ethanedithiol ( $\text{edtH}_2$ ) to the same glass vial. The solution was stirred magnetically at  $35^\circ\text{C}$  for about 20 minutes until the solution turned dark brown.

The glass substrates ( $9.5 \text{ mm} \times 9.5 \text{ mm}$ ) were sonicated three times for 5–7 minutes in acetone, isopropyl alcohol and methanol respectively. To fabricate a  $\text{Cu}_{2-x}\text{Se}$  thin film with thickness ranges between 70–100 nm,  $35 \mu\text{L}$  of  $\text{Cu}_2\text{Se}$  thiol-amine solution was spun coat on a glass substrate at 1800 rpm for 60 seconds. The coated substrate was left on the hot plate to allow the solvent to dry at  $35^\circ\text{C}$  for 2 minutes. The temperature of the hot plate was ramped up to  $350^\circ\text{C}$  by increasing the temperature by  $50^\circ\text{C}$  every 5 minutes. The thin film was annealed on the hot plate for one hour after the temperature reached  $350^\circ\text{C}$ . After an hour, the hot plate was switched off which allowed the thin film to cool down to room temperature. All  $\text{Cu}_{2-x}\text{Se}$  thin films were prepared using the same procedures mentioned above.

To prepare for the  $\text{Ag}^+$  ion soaking process, 19 mg of  $\text{AgNO}_3$  was measured, transferred into the glovebox and dissolved in 10 mL of methanol in a glass vial to form a 0.01 M  $\text{AgNO}_3$  solution. 10 mL of methanol was prepared in a separate glass vial. Previously fabricated  $\text{Cu}_{2-x}\text{Se}$  thin films were held by a tweezer, soaked into the 0.01 M  $\text{Ag}^+$  ion solution for varying amounts of time and slowly transferred to the pure methanol solution for 45–60 seconds to wash out the excess  $\text{Ag}^+$  ions from the surface of the thin film. The  $\text{Ag}_2\text{Se}$  thin film was placed on the hot plate at  $50^\circ\text{C}$  to dry out the excess solvent and annealed at  $350^\circ\text{C}$  for 30 minutes to repair any cracks and/or release any trapped ions at the grain boundaries during the CE process. The procedure was repeated for each thin film.

### Materials characterizations

To characterize the morphology, structure and composition of the  $\text{Cu}_{2-x}\text{Se}$  template samples and the post-soaked  $\text{Ag}_2\text{Se}$

samples, we performed scanning electron microscopy (SEM), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), inductively coupled plasma mass spectrometry (ICP-MS) and TE measurements on our samples. We also performed electrical measurements *via* the standard four-probe van-der-Pauw method and Seebeck measurements using small Peltier units (CUI Inc.) to measure the induced TE voltage created by various temperature gradients across the sample. Electrical measurements and Seebeck measurements were run *via* a LabVIEW program along with Keithley 2400 sourcemeters and Keithley 2000 multimeters. Hall carrier concentrations were also obtained using an Ecopia HMS-5000 variable temperature Hall effect measurement system. Thermal conductivity data was extracted using the differential  $3\omega$  method using an SR865A lock-in amplifier from Stanford Research Systems (ESI, Fig. S1 and S2†). Film thickness measurements were analyzed *via* a Veeco Dektak 150 profilometer. Full details about the characterizations can be found in the ESI† along with ESI figures.

In addition, error bars were added to each plot in Fig. 6 to show the precision and reliability of our data. Aside from the instrumental errors, the major error for the electrical conductivity values came from the measurement of thickness (standard deviation =  $\pm 10 \text{ nm}$ ) using the profilometer. The detailed error analysis calculations are shown in the ESI† section.

## Results and discussion

In many CE reactions for semiconductors, Cd-based and Cu-based NCs have been used as ubiquitous nanocrystal templates to fabricate complex nanomaterials that are otherwise hard to obtain under standard conditions.<sup>48,49,53</sup> To form a thin-film NC template, we adopted a method developed by Webber *et al.* which demonstrated that bulk copper chalcogenides such as  $\text{Cu}_2\text{Se}$ ,  $\text{Cu}_2\text{Te}$  and  $\text{Cu}_2\text{S}$  can be dissolved in a thiol-amine solution mixture and be cast as thin films on

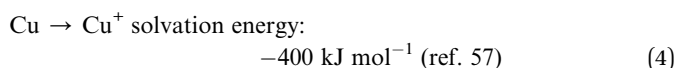

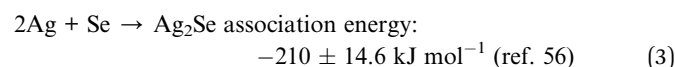

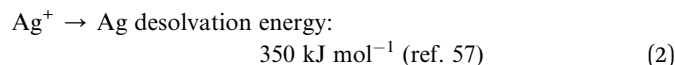

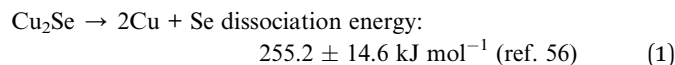

substrates.<sup>45,51,54,55</sup> However, bulk Ag<sub>2</sub>Se powder fails to do so at ambient conditions (see ESI, Fig. S3†).<sup>45,50</sup> To overcome this issue, we use an innovative combination of thiol-amine dissolution and CE techniques to realize a simple pathway to obtaining high-performance Ag<sub>2</sub>Se thin films.

We rationalize the CE using a mix of thermodynamic and kinetic parameters. The thermodynamic driving force of the CE reaction is determined by a number of factors including crystal lattice energy, dissociation and solvation energies, dislocation energies and interfacial strain energy.<sup>49</sup> To predict the likelihood of the transformation from Cu<sub>2</sub>Se to Ag<sub>2</sub>Se in bulk at room temperature, we conducted calculations on the dissociation and solvation energies during the CE reaction, as suggested in a report by Rivest *et al.*<sup>49</sup> The overall CE equation is described as,

The equation describes an isoalent system where Ag<sup>+</sup> ions are the incoming cations, Cu is the parent cation and Se is the parent anion in the NCs. The thermodynamics of the system can be described in terms of several elementary steps of the CE reaction using the approximate free energy values obtained from past literature, as shown in the following equations:

The net energy of the overall transformation is calculated to be:  $255.2 + 350 - 210 - 400 = -4.8 \text{ kJ mol}^{-1}$ . The negative value suggests that the CE reaction is spontaneous at room temperature, and hence is thermodynamically favorable. However, kinetic factors such as activation energy barriers and ion diffusivity also play an important role in determining the outcome of the reactions and the nature of the final products.<sup>24,49</sup> Cation exchanging on the nanoscale reduces the limitations stemming from the bulk solid-state exchange. The larger surface area of NCs reduces the sub-reaction activation energy barriers which exist mostly in bulk solid-state exchange, meaning that CE reactions in NCs could happen almost spontaneously. The high curvature surfaces of NCs and low coordination facets that serve as high-energy sites would also reduce the nucleation reaction barriers in NCs and facilitate nucleation.<sup>49</sup> Normally, a large excess of incoming cations creating a concentration gradient will be sufficient to drive the reaction at room temperature. Additionally, both Ag<sup>+</sup> and Cu<sup>+</sup> have high mobility due to their small ionic radii and are both soluble in common solvents such as acetonitrile.

Scanning electron microscopy (SEM) images presented in Fig. 2 show the quality of the thin film sample before and after the soaking process. No significant change in the morphology between the before-soaked Cu<sub>2-x</sub>Se and post-soaked Ag<sub>2</sub>Se polycrystalline thin films is observed with grain sizes on the order of tens of nanometers. While there are a few noticeable voids in the Ag<sub>2</sub>Se film, overall the films are continuous and give reliable TE measurements as will be discussed later. The grain size and morphology of the initial Cu<sub>2-x</sub>Se film and resultant Ag<sub>2</sub>Se film were mainly controlled by the annealing

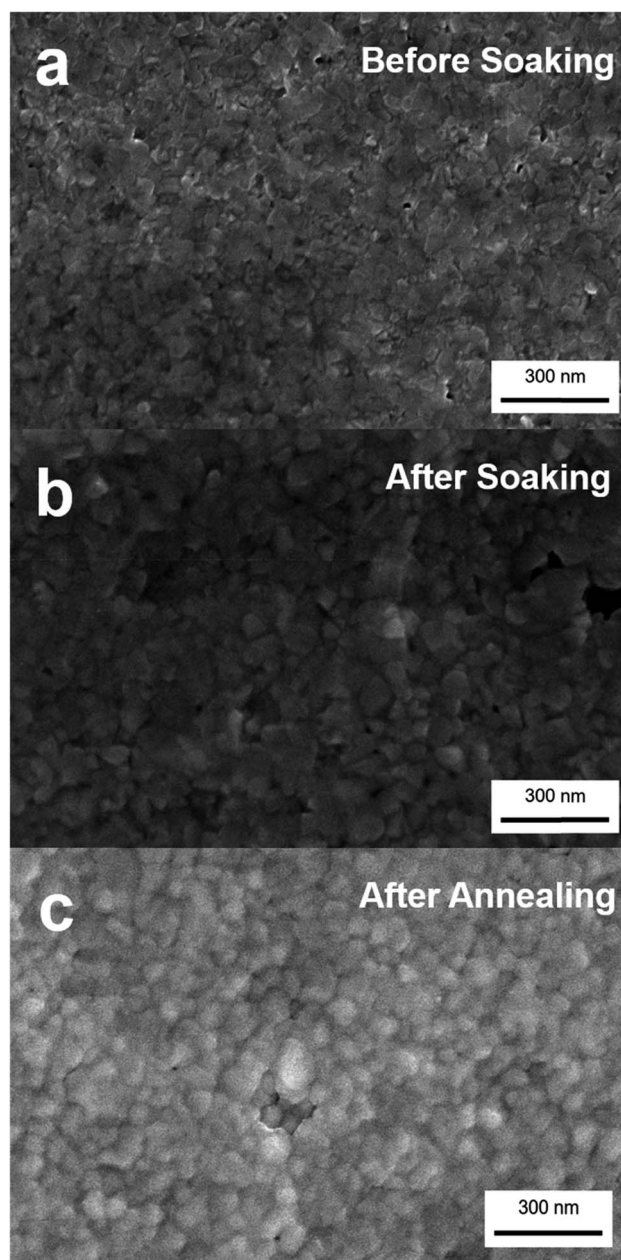

Fig. 2 Scanning electron microscope (SEM) images of (a) Cu<sub>2-x</sub>Se thin film sample before soaking (b) Ag<sub>2</sub>Se thin film after soaking and (c) the Ag<sub>2</sub>Se sample post annealing. The images demonstrate the nanocrystalline grain structure as well as the continuous void-free nature of the Cu<sub>2-x</sub>Se and the Ag<sub>2</sub>Se films. Annealing does not significantly affect the average grain size of the Ag<sub>2</sub>Se film.

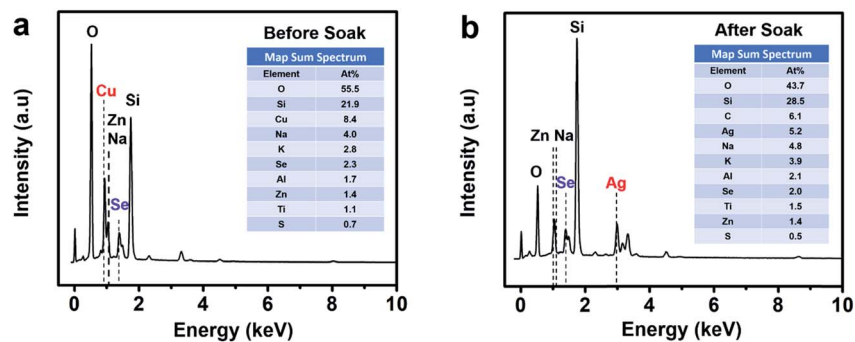

Fig. 3 Energy dispersive X-ray spectroscopy (EDS) of (a) a  $\text{Cu}_{2-x}\text{Se}$  sample on glass before soaking and (b) a  $\text{Ag}_2\text{Se}$  sample on glass after soaking and annealing. Before soaking, the sample shows peaks corresponding to Cu and Se elements, while after soaking the sample shows only Ag and Se peaks, indicating that the  $\text{Cu}_{2-x}\text{Se}$  sample has converted into  $\text{Ag}_2\text{Se}$ . The rest of the elements detected by EDS, including Si and O are from the glass substrate and trace amounts of Na, K, Al, and Zn are from glass impurities as well as a minute amount of sulfur from residual thiols.

temperature. We annealed our  $\text{Cu}_{2-x}\text{Se}$  samples after dissolution for one hour at  $350^\circ\text{C}$  (which gave us the best quality films) and our  $\text{Ag}_2\text{Se}$  samples after soaking at  $350^\circ\text{C}$  for 30 minutes. Once the initial  $\text{Cu}_2\text{Se}$  films are fabricated, annealing time does not seem to have a significant impact on grain size or domain size, as shown in the SEM images where there is no drastic change in grain size before and after annealing our  $\text{Ag}_2\text{Se}$  sample. The grain size we obtained for  $\text{Cu}_{2-x}\text{Se}$  and  $\text{Ag}_2\text{Se}$  is estimated to be between 30–50 nm based on the SEM data.

Energy dispersive X-ray spectroscopy (EDS) presented in Fig. 3 shows the thin film sample before soaking, revealing the presence of Cu and Se while the post-soaked sample indicates the presence of Ag and Se and the absence of Cu, clearly showing that most of the  $\text{Cu}^+$  ions were substituted during the soaking process for  $\text{Ag}^+$  ions in the thin film lattice. The rest of the elements such as O, Si, Na, K, Al, Zn originate from the glass substrate and impurities therein. We also detect a minute amount of sulfur from residual thiols in the samples.

To further confirm whether our  $\text{Cu}_{2-x}\text{Se}$  thin film sample was converted into  $\text{Ag}_2\text{Se}$  *via* ion exchange technique, we used X-ray photoelectron spectroscopy (XPS) to identify the presence of Cu and Se before soaking, and the presence of Ag and Se after soaking and annealing. We observe the two Cu peaks disappear as shown in Fig. 4a and the Se peak shifts to the right slightly as shown in Fig. 4c after CE. The Se peak shift may be attributed to the change of Se valence state due to the reduction of Cu vacancies and the occupancy of Ag ions within the lattice.<sup>51</sup> The Ag peaks appearing at  $\sim 369$  eV and at  $\sim 375$  eV illustrate

a strong presence of Ag within the thin film sample after soaking as shown in Fig. 4b.

To validate the structural transformation from  $\text{Cu}_{2-x}\text{Se}$  to  $\text{Ag}_2\text{Se}$  within the crystal lattice of our thin film sample, we performed X-ray diffraction (XRD) analysis on our  $\text{Cu}_{2-x}\text{Se}$  samples before and after soaking in a  $\text{Ag}^+$  salt solution. We compare the XRD data of our  $\text{Cu}_{2-x}\text{Se}$  sample with  $\text{Cu}_{1.95}\text{Se}$  and  $\text{Cu}_2\text{Se}$  reference files and the XRD data of our post-soak  $\text{Ag}_2\text{Se}$  sample with tetragonal and orthorhombic  $\text{Ag}_2\text{Se}$  reference files as shown in Fig. 5. The XRD data for the as-fabricated  $\text{Cu}_{2-x}\text{Se}$  sample closely resembles the  $\text{Cu}_{1.95}\text{Se}$  reference sample.<sup>58</sup> Compared to the peaks at  $26.3^\circ$  and  $43.6^\circ$  for the  $\text{Cu}_{1.95}\text{Se}$  reference,<sup>58</sup> the major peaks in our  $\text{Cu}_{2-x}\text{Se}$  are shifted slightly by  $0.5^\circ$  and  $1.2^\circ$  respectively, indicating that the unit cell in the  $\text{Cu}_{2-x}\text{Se}$  lattice shrinks when nanostructured. Post-soaked  $\text{Ag}_2\text{Se}$  samples are analyzed in a similar fashion as  $\text{Cu}_{2-x}\text{Se}$ . In the post-soaked sample, the  $\text{Cu}_{2-x}\text{Se}$  peaks at  $26.9^\circ$  and  $44.8^\circ$  disappear. The XRD peaks in our post-soaked  $\text{Ag}_2\text{Se}$  samples match some of the orthorhombic reference peaks and some of the 10 nm tetragonal  $\text{Ag}_2\text{Se}$  XRD peaks based on earlier reports from our group.<sup>22</sup> It is postulated that the phase of  $\text{Ag}_2\text{Se}$  relies on the crystallite size.<sup>61,62</sup> From our data, we observe that our post-soaked  $\text{Ag}_2\text{Se}$  thin film sample is a phase mixture of orthorhombic and tetragonal structures with the dominant phase being tetragonal.<sup>22</sup> This is expected due to the phase transition between tetragonal and orthorhombic phases occurring at a crystallite size of 40 nm which is around the average size of our grain sizes ( $\sim 30$ – $50$  nm) as seen in

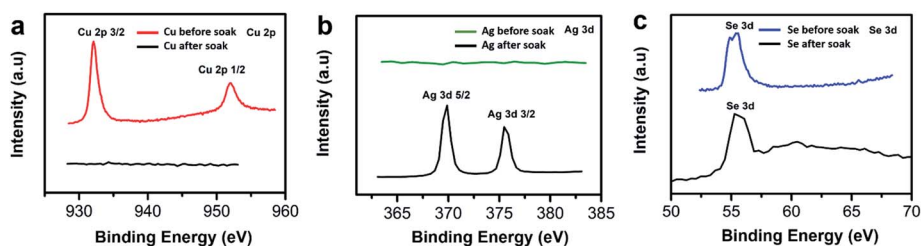

Fig. 4 X-ray photoelectron spectroscopy (XPS) images of (a) Cu peaks at 2p orbital in  $\text{Cu}_{2-x}\text{Se}$  sample before (red) and after (black) soaking, (b) Ag peaks at 3d orbital before (green) and after (black) soaking, (c) Se peaks at 3d orbital before (blue) and after (black) soaking.

Fig. 2.<sup>22,41,42</sup> The post-soaked sample XRD also confirms that, due to the absence of any detectable  $\text{Cu}_2\text{Se}$ -related XRD peaks, a complete exchange between  $\text{Ag}^+$  ions and  $\text{Cu}^+$  ions occurred during the soaking process.

The TE properties of the thin films were measured at room temperature. We tested several different soaking times: 1 min, 5 min, 10 min, 20 min, 40 min and 60 min. Results show that the TE properties remain mostly consistent across different soaking times. The  $\text{Cu}_{2-x}\text{Se}$  thin films with an average thickness of  $80 \pm 10$  nm exhibit an average electrical conductivity of nearly  $2.39 \pm 0.3 \times 10^5 \text{ S m}^{-1}$  at room temperature. The high electrical conductivity of the  $\text{Cu}_{2-x}\text{Se}$  thin film may be attributed to the high carrier concentration of holes due to Cu-vacancies. Post soaking in Ag-solution, all the samples exhibit a significant

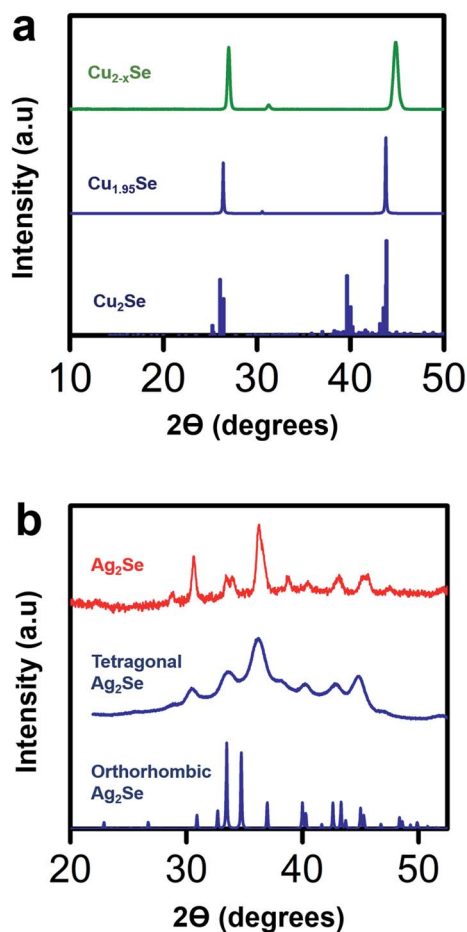

Fig. 5 (a) X-ray diffraction (XRD) data for a spin-coated  $\text{Cu}_{2-x}\text{Se}$  sample before soak (green), reference powder diffraction data for a  $\text{Cu}_{1.95}\text{Se}$  sample (blue, ICSD-243957)<sup>58</sup> and reference data for a perfectly stoichiometric  $\text{Cu}_2\text{Se}$  (blue)<sup>59</sup> with a low temperature  $\alpha$ -phase. As the XRD data of the  $\text{Cu}_{2-x}\text{Se}$  sample closely resembles that of the  $\text{Cu}_{1.95}\text{Se}$  sample, the Cu deficiency of the  $\text{Cu}_{2-x}\text{Se}$  sample is estimated to be roughly about  $x = 0.05$ . (b) XRD data for a  $\text{Ag}_2\text{Se}$  film (red) after soaking in  $\text{Ag}^+$  ion solution for 40 minutes and annealing at  $350^\circ\text{C}$  for 30 minutes, reference data for a tetragonal  $\text{Ag}_2\text{Se}$  film (blue)<sup>22</sup> and reference data for an orthorhombic  $\text{Ag}_2\text{Se}$  film (blue, ICSD-261822).<sup>60</sup> The XRD patterns show that the post-soaked annealed  $\text{Ag}_2\text{Se}$  film has a mixed phase of tetragonal and orthorhombic structures with a dominant tetragonal phase.

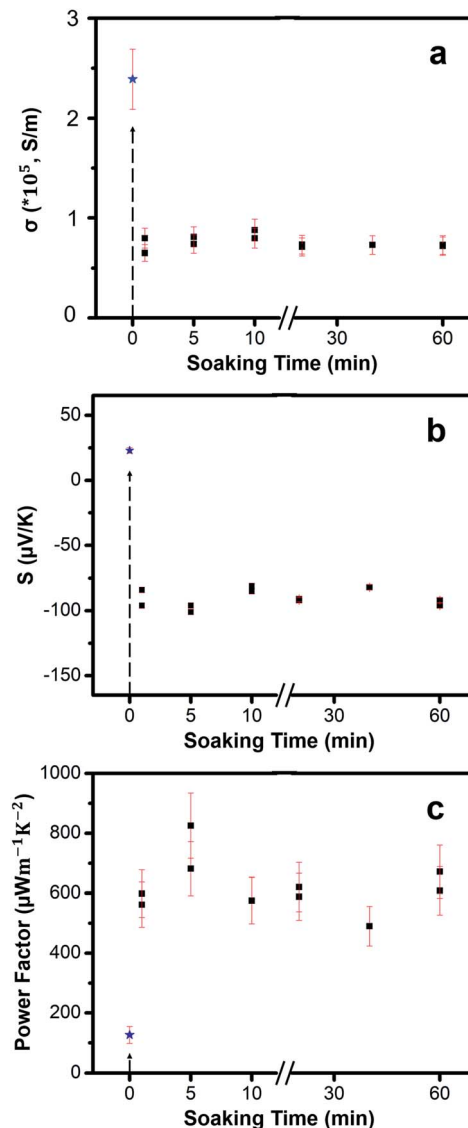

Fig. 6 (a) Electrical conductivity of as-fabricated  $\text{Cu}_{2-x}\text{Se}$  sample (blue star) and  $\text{Ag}_2\text{Se}$  samples (black squares) as a function of soaking time in  $\text{Ag}^+$  ion solution. The dotted line at 0 minutes indicates the electrical conductivity of the p-type  $\text{Cu}_{2-x}\text{Se}$  thin film. Our results show that the amount of soaking time does not significantly affect the electrical conductivity. (b) Seebeck coefficient of  $\text{Cu}_{2-x}\text{Se}$  sample and  $\text{Ag}_2\text{Se}$  samples as a function of soaking time in  $\text{Ag}^+$  ion solution. The sign of Seebeck coefficient changes from positive to negative indicating a transformation from p-type  $\text{Cu}_{2-x}\text{Se}$  to n-type  $\text{Ag}_2\text{Se}$ . (c) PF data as a function of soaking time. The average PF value measured from 11 samples is  $617 \pm 82 \mu\text{W m}^{-1} \text{K}^{-2}$  and the maximum PF obtained is  $825 \mu\text{W m}^{-1} \text{K}^{-2}$  after 5 minutes of soaking time.

drop in electrical conductivity due to the rapid diffusion of  $\text{Ag}^+$  guest ions into both the vacant sites and interstitial sites leading to early phases of transformation from p-type  $\text{Cu}_2\text{Se}$  to n-type  $\text{Ag}_2\text{Se}$ . Therefore, short soak times will result in mixed p-type and n-type transport. Rather than exchanging the  $\text{Cu}^+$  at the surface of the nanocrystalline grains, the  $\text{Ag}^+$  ions can also diffuse into  $\text{Cu}_{2-x}\text{Se}$  grains and initiate the CE at preferred regions called “reaction zones”.<sup>24,52</sup> After a longer soaking time, more “reaction zones” form, more CE reactions take place and

**Table 1** Soak time, Hall mobility, carrier density, Ag/Cu ratio (ICP) for selected samples that were soaked for different amounts of time in a Ag<sup>+</sup> ion solution

Soak time	Mobility [ $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$ ]	Carrier density [ $\text{cm}^{-3}$ ]	Ag/Cu molar ratio in Ag <sub>2</sub> Se sample
1 min	$2.80 \times 10^3$	$5.79 \times 10^{17}$	2.914
5 min	$3.62 \times 10^3$	$3.22 \times 10^{17}$	5.648
5 min	$2.64 \times 10^3$	$5.98 \times 10^{17}$	10.984
10 min	$1.24 \times 10^3$	$6.15 \times 10^{17}$	21.113
60 min	$3.68 \times 10^3$	$3.40 \times 10^{17}$	25.54

Cu<sup>+</sup> ions continue to be removed from the lattice. Overall, the electrical conductivities vary little over soaking time showing high consistency.

Immediately after soaking, we observe a sign reversal of the Seebeck coefficient (Fig. 6b) from positive (p-type) to negative (n-type), consistent with our thermodynamic analysis that the CE reaction occurs spontaneously to form n-type Ag<sub>2</sub>Se from p-type Cu<sub>2</sub>Se. Seebeck coefficient values stay mostly the same with an average value of  $-90 \pm 6.32 \mu\text{V K}^{-1}$  for various soak times. By combining electrical conductivity and Seebeck coefficient values, PF of the films were obtained, as shown in Fig. 6c. The PF values fluctuate slightly within a small range with an average value of  $617 \pm 82 \mu\text{W m}^{-1} \text{K}^{-2}$ . While the maximum PF value,  $825 \mu\text{W m}^{-1} \text{K}^{-2}$ , occurs at 5 min soak time we believe that the location and concentration of the residual Cu atoms in the post-soaked sample play a synergistic role in contributing to the higher electrical conductivity compared to all other post-soaked samples (Table 1). Future experiments will be directed to understand the exact role of the Cu-ions. After 60 minutes, the amount of Cu-ions in the sample saturate out at nearly 4% (Table 1). We hypothesize that longer exposure times might lead to back diffusion of Cu<sup>+</sup> ions into the Ag<sub>2</sub>Se lattice thus limiting the CE.

To observe how the concentration of Cu<sup>+</sup> ions vary with soaking time, we performed ICP-MS to obtain a quantitative analysis on how the Cu<sup>+</sup> ions are being removed over time. It is difficult to confirm with certainty that there is a complete exchange between Ag<sup>+</sup> and Cu<sup>+</sup> ions based on our ICP results. As seen in Table 1, the ICP results show that there exists a sizeable amount of Cu<sup>+</sup> ions in the post-soaked Ag<sub>2</sub>Se sample, but with an increase in the soaking time qualitatively the amount of Cu<sup>+</sup> ions in the sample decreases monotonically based on the increasing Ag/Cu ratio. The TE performance is not severely affected, however, suggesting that the Cu<sup>+</sup> ions may be loosely bound on the surface or trapped in grain boundaries rather than actively doping the material. This is also supported by Hall carrier concentration measurements which show a relatively constant carrier concentration and Hall mobility values across the post-soaked samples. While Hall measurements are not completely accurate for nano-grained polycrystalline samples, qualitatively we observe that all our samples show almost similar values. We suspect that the low carrier density could be attributed to the residual Cu atoms and the sulfur from the thiols as shown in the EDS data in Fig. 3. Further experiments

need to be conducted to explore the effect of these residual Cu atoms and sulfur on the TE properties.

Last but not the least, in order to quantify the *ZT* value for our samples, we conducted room temperature thermal conductivity measurements using the differential  $3\omega$  method and obtained a value of  $0.53 \pm 0.18 \text{ W m}^{-1} \text{K}^{-1}$  (details in ESI†). The total thermal conductivity ( $\kappa$ ) typically comprises of a lattice contribution ( $\kappa_l$ ) and an electronic contribution ( $\kappa_e$ ).  $\kappa_e$  can be approximated as  $LT\sigma$ , where  $L$  is the Lorenz number ( $\sim 1.8 \times 10^{-8} \text{ V}^2 \text{K}^{-2}$ ),  $T$  is the absolute temperature (300 K in our case) and  $\sigma$  is the electrical conductivity ( $72\,886 \text{ S m}^{-1}$  for the sample measured) which gives us a value of  $0.394 \text{ W m}^{-1} \text{K}^{-1}$  and thus a value of  $0.136 \text{ W m}^{-1} \text{K}^{-1}$  for  $\kappa_l$ . Compared to the bulk values of  $\kappa_l = 0.5 \text{ W m}^{-1} \text{K}^{-1}$ ,<sup>21</sup> our sample shows an almost 73% reduction in the lattice thermal conductivity values which is most likely due to the nano-grained structure (average grain sizes between 30–50 nm) of our thin film samples. Consequently, we obtain an average *ZT* value of around 0.35 with a peak *ZT* value of 0.46 at a 5 minute soak time. If the residual Cu atoms and sulfur could be removed or their concentration be reduced from our Ag<sub>2</sub>Se thin films, it would possibly drive up the *ZT* value to around 1. Compared to the *ZT* values in bulk powder ranging from 0.32 to 0.99, our average *ZT* value of 0.35 obtained from a completely solution-processed technique is competitive with bulk values without any need for hot pressing or spark plasma sintering.

## Conclusions

In conclusion, we report an efficient strategy for fabricating nanostructured Ag<sub>2</sub>Se thin films *via* an ion exchange technique between Cu<sup>+</sup> ions and Ag<sup>+</sup> ions at room temperature. Starting from a low-cost p-type Cu<sub>2–x</sub>Se template prepared by a thiol-amine dissolution process, n-type Ag<sub>2</sub>Se thin films were made by simply soaking the Cu<sub>2–x</sub>Se thin films into a Ag<sup>+</sup> ion solution while maintaining mostly the original morphology of Cu<sub>2–x</sub>Se thin films. The Seebeck coefficient of the thin films post-soaking switches from positive to negative values indicating the change in nature of carrier transport. The thermal conductivity of Ag<sub>2</sub>Se is measured to be  $0.53 \text{ W m}^{-1} \text{K}^{-1}$ . The average electrical conductivity of the post-soaked samples is around  $7.5 \times 10^4 \text{ S m}^{-1}$ . Based on the values of these three parameters, we obtain an average PF of  $617 \pm 80 \mu\text{W m}^{-1} \text{K}^{-2}$  and an average *ZT* of 0.35 at room temperature with an overall maximum PF of  $825 \mu\text{W m}^{-1} \text{K}^{-2}$ . Furthermore, the soaking

approach is a safe, solution-processable, economical fabrication technique which could be potentially useful in industrial scale-up production. Our results demonstrate that Ag<sub>2</sub>Se thin film materials can become one of the most promising n-type materials for use in a variety of TE applications at a large scale.

## Conflicts of interest

The authors declare no conflicts of interest.
