Single-nanostructure bandgap engineering enabled by magnetic-pulling thermal evaporation growth

Jinyou Xu, * Xingyu Wang and Richard Nötzel*

Realizing the substantial potential of bottom-up 1D semiconductor nanostructures in developing functional nanodevices calls for dedicated single-nanostructure bandgap engineering by various growth approaches. Although thermal evaporation has been advised as a facile approach for most semiconductors to form 1D nanostructures from bottom-up, its capability of achieving single-nanostructure bandgap engineering was considered a challenge. In 2011, we succeeded in the direct growth of composition-graded $\text{CdS}_{1-x}\text{Se}_x$ ($0 \leq x \leq 1$) nanowires by upgrading the thermal-evaporation tube furnace with a home-made magnetic-pulling module. This report aims to provide a comprehensive review of the latest advances in the single-nanostructure bandgap engineering enabled by the magnetic-pulling thermal evaporation growth. The report begins with the description of different magnetic-pulling thermal evaporation strategies associated with diverse examples of composition-engineered 1D nanostructures. Following is an elaboration on their optoelectronic applications based on the resulting single-nanostructure bandgap engineering, including monolithic white-light sources, proof-of-concept asymmetric light propagation and wavelength splitters, monolithic multi-color and white-light lasers, broadband-response photodetectors, high-performance transistors, and recently the most exciting single-nanowire spectrometer. In the end, this report concludes with some personal perspectives on the directions toward which future research might be advanced.

1. Introduction

1D semiconductor nanostructures (wires, belts, tubes) have been recognized as a more flexible choice than epitaxial thin

Jinyou Xu received a B.S. in Applied Physics (2008) and a PhD in Materials Science and Engineering (2014, with Prof. Anlian Pan) from Hunan University. He was a post-doctoral fellow (with Prof. Ernesto Joselevich) in the Department of Materials and Interfaces at Weizmann Institute of Science from 2014 to 2018. Since 2019, he has been a professor of Materials Physics

at the South China Academy of Advanced Optoelectronics in South China Normal University. His current research focuses on bottom-up one-dimensional semiconductor nanostructures, with major interest in their orientated growth, composition engineering, and scale-up fabrication of optoelectronic devices.

Xingyu Wang received his B.S. degree from the Department of Materials Science and Engineering at Lanzhou Tech University in 2015. Since 2017, he has been a PhD candidate (with Prof. Richard Nötzel) at the South China Academy of Advanced Optoelectronics in South China Normal University. His main research interests include the guided growth of 1D semiconductor nanostructures

on patterned substrates and their applications in optoelectronics.

films in terms of developing composition-engineered semiconductors with new or even tunable bandgaps owing to their higher tolerance of lattice mismatch between dissimilar semiconductors or between target nanostructures and supporting substrates.^{1–6} Moreover, 1D semiconductor nanostructures provide a class of versatile building blocks for “bottom-up” construction of nanoscale devices and systems^{7–10}—which are emerging as promising alternatives for further miniaturization of electronic circuitry and its components in the future, even though conventional “top-down” microfabrication employing photolithography continues to be the most prevalent technique at present. Realizing the substantial potential of bottom-up 1D nanostructures for the development of functional nanodevices, however, requires a predictable control over their composition, bandgap, interface, and alignment. In particular, one of the urgent tasks is to achieve various composition/bandgap engineering within single 1D nanostructures (hereafter referred to as “single-nanostructure composition/bandgap engineering”). For example, composition-graded nanowires (Fig. 1a and b)

Fig. 1 Schematic drawings of various composition-engineered 1D semiconductor nanostructures. Richard Nötzel received Diploma in Physics from the Technical University of Munich in 1989. From 1990 he stayed at the Max Planck Institute for Solid State Research in Stuttgart and received the doctoral degree in 1992. After working in Japan, Germany, The Netherlands, Spain and Italy, he joined the South China Normal University in 2017 as full professor. His work includes the direct growth

of nanostructured semiconductors for optoelectronic and electrochemical devices. For his research he received the Otto Hahn Medal of the Max-Planck Society, the NTT research award, and the Academy Award of the Berlin-Brandenburg Academy of Science.

enable a package of abundant tuneable bandgaps in an ultra-compact volume, therefore they can serve as wavelength-integrated nanoscale light sources.^{11,12} Axial hetero-nanowires (Fig. 1c) with a type-II energy band diagram have been suggested as a promising structure for nanoscale light-emitting diodes.¹³ Radial hetero-nanowires (Fig. 1d) with abruptly changed bandgaps along the nanowire radial axis provide an ideal configuration for the implementation of microscale photovoltaic cells since the coaxial structure resolves the mismatch between the shorter length scale for minority carrier diffusion and the longer length scale for light absorption by decoupling these directions.¹⁴ Lateral hetero-nanobelts (Fig. 1e) and composition-graded nanobelts (Fig. 1f) not only deliver abruptly and gradually changed bandgaps along the nanobelt width direction for broadband-response photodetectors but also provide a class of novel parallel optical cavities for monolithic multi-color lasers.¹⁵

To date, significant progress has been made in the growth of composition-engineered 1D nanostructures based on a number of bottom-up approaches. For instance, the hybrid pulsed laser ablation/chemical vapor deposition (LA-CVD) process enabled the block-by-block growth of single-crystalline Si/SiGe,¹⁶ GaAs/GaP, n-Si/p-Si and n-InP/p-InP superlattice nanowires.¹⁷ Metal-organic chemical vapor deposition (MOCVD) has been successfully employed for the growth of multi-quantum-well core/shell nanowire heterostructures,¹⁸ axial hybrid III-V/silicon nanowires,¹⁹ and so on. Molecular beam epitaxy (MBE) has been adopted for the growth of n-GaN/InGaN/p-GaN p-i-n hetero-nanowires,²⁰ GaAs/InAs core-shell nanowires,²¹ near full-composition GaAs_{1-x}Sb_x nanowires,²² composition-graded InGaAs²³ and InGaN²⁴ nanowires, GaN/Al_xGa_{1-x}N nanowires with embedded GaN nano-discs,²⁵ and so on. Atomically abrupt Si-Ge axial hetero-nanowires were synthesized in a solvent vapor growth system^{26,27} and inside a transmission electron microscope (TEM).²⁸ At present, MOCVD and MBE are still the limited and optimal solutions for those applications which require sub-monolayer growth control and atomically sharp interfaces,²⁹ although their success generally relies on costly instruments and sophisticated handling skills.

In contrast to the MOCVD and MBE growth, thermal evaporation provides a facile and cost-effective solution for semiconductors to form 1D nanostructures from bottom up by evaporating their bulk counterparts on the basis of the metal-catalytic vapor-liquid-solid (VLS)³⁰ or the non-catalytic vapor-solid (VS) mechanisms.³¹ To this end, the generality of thermal evaporation growth has been well proven with a growing list of 1D semiconductor nanostructures, including most II–VI and III–V semiconductors and their alloys,^{9,32–39} oxide semiconductors,^{40,41} perovskites,^{42,43} small-molecular organic semiconductors,⁴⁴ and so on. However, while having advantages of economical apparatus and simple handling skills, thermal evaporation growth was once considered very challenging in terms of achieving single-nanostructure composition engineering owing to the difficulty in adjusting the evaporating sources (or substrates), which are pre-sealed in the tube reactor during growth. In order to address this issue, we integrated a home-made magnetic pulling module into a conventional

tube furnace in 2011, accordingly achieving an *in situ* “source-moving” process by driving the magnet outside the tube during the growth. With this source-moving strategy, we succeeded in the direct growth of composition-graded $\text{CdS}_{1-x}\text{Se}_x$ ($0 \leq x \leq 1$) alloy nanowires for the first time.¹¹ Thereafter, the magic box of single-nanostructure bandgap engineering enabled by the magnetic-pulling thermal evaporation growth was opened and a growing list of composition-engineered 1D nanostructures^{12,15,45–50} was synthesized, providing diverse single-nanostructure bandgap engineering for a large variety of nano-optoelectronics. In this report, we aim to provide readers an overview of the recent advances in single-nanostructure bandgap engineering enabled by magnetic-pulling thermal evaporation growth over the past decade. Although significant similar progress has been achieved as well based on the MBE and MOCVD growth, as mentioned above, here we will not include such progress in view of the scope of this review.

2. Composition-graded alloy nanowires

The concept of compositional gradient of semiconductors dates back to the 1960s, when bulk single crystals of II–VI semiconductors with graded-bandgaps were prepared by two different vapor-phase methods with constant and variable charge temperatures,^{51–54} respectively. Later, this concept was extended to the nanoscience research community and a large number of 1D semiconductor nanostructures with graded compositions on a single substrate were grown with the assistance of temperature gradients of the heating apparatus,^{2,55} or spatial source reagent gradients^{1,56} or both,⁵⁷ such as $\text{Zn}_x\text{Cd}_{1-x}\text{S}$,³ $\text{CdS}_x\text{Se}_{1-x}$,^{2,55} InGaN ,⁵⁶ $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$,^{1,57} Co_mSi ,⁵⁸ $\text{Zn}_x\text{Cd}_{1-x}\text{Se}$,⁵⁹ $\text{Zn}_x\text{Cd}_{1-x}\text{Te}$,^{60,61} GaZnSeAs ,⁶² $\text{InAs}_x\text{P}_{1-x}$,⁶³ and $\text{Cd}_x\text{Pb}_{1-x}\text{S}$ ⁶⁴ graded alloy nanostructures on single centimeter-scale substrates. The alloy composition between adjacent nanostructures on the same substrate is continuously varied over a wide range along a certain direction of the substrate, a concept of single-chip graded bandgap engineering which was firstly proposed by Pan *et al.*⁵⁵ However, the composition of individual nanostructures remained at a certain stoichiometric ratio, which means no monolithic graded bandgaps within a single 1D nanostructure were achieved. In this part, we will only review the progress in single-nanostructure graded bandgap engineering as the space here is limited. For more information on single-chip graded bandgap engineering, please refer to the review contributed by Zhuang *et al.* in 2012.⁵

Unlike the impressive progress made in single-chip graded bandgap engineering, the progress in single-nanostructure graded bandgap engineering is still limited and only a few examples have been reported so far.^{20,65–68} Dong *et al.* observed a composition-graded $\text{ZnSe}_x\text{Te}_{1-x}$ segment in ZnSe – ZnTe hetero-nanowires generated by a solution–liquid–solid (SLS) growth mechanism.⁶⁵ Composition-graded NiSi nanowires were synthesized through a spontaneous chemical vapor growth.⁶⁸ Plasma-assisted MBE enabled the growth of composition-graded InGaAs ²³ and InGaN ²⁴ nanowires as well as sandwich-

like n-GaN/InGaN/p-GaN p–i–n hetero-nanowires with an indium composition gradient in the InGaN segments.²⁰ Axially graded $\text{Si}_{1-x}\text{Ge}_x$ nanowires reported by Yang and co-workers were fabricated by the kinetic control of the Au-catalytic decomposition of the precursors during chemical vapor synthesis.^{66,69,70} Composition-graded CuSi nanorod arrays with poor morphology and quality were synthesized by an oblique angle co-deposition technique.⁶⁷ In fact, none of these examples stemmed from conventional thermal evaporation growth before our pioneering work on composition-graded $\text{CdS}_{1-x}\text{Se}_x$ nanowires,¹¹ to the best of our knowledge. In 2011, our group and collaborators developed the first *in situ* “source-moving” thermal evaporation strategy by incorporating a home-made magnetic-pulling module into a conventional tube furnace, and accordingly achieved the growth of composition-graded $\text{CdS}_{1-x}\text{Se}_x$ nanowires, in which the S/Se elemental ratio (x) increased gradually from 0 on one end to 1 on the opposite end of the nanowires.¹¹ Thereafter, we further proposed a “substrate-moving” thermal evaporation strategy for the growth of composition-graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ ($0 \leq x, y \leq 1$) quaternary alloy nanowires with the assistance of a similar magnetic pulling module.¹² On the basis of these composition-graded nanowires, novel single-nanostructure graded bandgap engineering is achieved *via* the facile thermal evaporation growth for the first time.

2.1 Source-moving strategy

The source-moving setup consists of a horizontal tube furnace and a home-made magnetic source-pulling module, as shown schematically in Fig. 2a. Therefore, the solid reagents pre-sealed inside the quartz tube (“source”) can be moved into/out of the

Fig. 2 Composition-graded $\text{CdS}_{1-x}\text{Se}_x$ ($0 \leq x \leq 1$) ternary alloy nanowires. (a–f) $\text{CdS}_{1-x}\text{Se}_x$ nanowires with a single composition gradient: (a) schematic diagram of source-moving thermal evaporation growth; real-color optical photograph of (b) as-grown and (c) dispersed graded nanowires; (d) spatially resolved PL emission and corresponding spectra from a single graded nanowire; (e) TEM characterization; (f) position-dependent Se molar fractions and bandgaps. (g and h) $\text{CdS}_{1-x}\text{Se}_x$ nanowire with symmetric dual composition gradients: (g) position-dependent molar fractions; (h) real-color optical photograph of dispersed nanowires. heating zone on demand during high-temperature growth by driving the external magnet. For example, the evaporation rate of CdS (CdSe) powders in Fig. 2a is expected to decrease (increase) gradually by pushing the external magnet to the right side at a selected slow speed as a result of the symmetrical temperature gradient from the furnace center to its two ends. The changed evaporation rates of CdS and CdSe powders would deliver a gradually changed S/Se vapor ratio inside the tube, eventually leading to the growth of composition-graded $\text{CdS}_{1-x}\text{Se}_x$ nanowires on the Au-coated substrate *via* the well-known VLS mechanism.

Under illumination of a dispersive 405 nm laser, the emission color of each nanowire changes continuously from green at one end, through yellow and orange in the middle, to red at the other end (Fig. 2b and c), indicating a gradually varied chemical composition. Fig. 2d further shows that different emission colors can be extracted from different locations when the nanowire is locally illuminated with a focused laser beam. Corresponding spatially resolved PL spectra acquired along the nanowire length exhibit always a feature of a clean single narrow peak, with wavelength shift continuously from 505 nm at one end to 710 nm at the opposite end (left in Fig. 2d), further indicating that these nanowires are high-quality alloy nanowires with graded compositions. Besides, the spectra at the two ends are consistent with the spectra from the band-edge transitions of pure CdS and CdSe compounds, respectively, confirming the entire graded bandgap tunability ($0 \leq x \leq 1$) in these nanowires *via* a composition gradient. Neither apparent defects nor phase segregations are observed from the high-resolution TEM (HRTEM) image of a graded nanowire (Fig. 2e). Combined with the well-defined single set of diffraction spots in each selective-area electronic diffraction (SAED) pattern, one can conclude that these graded nanowires possess a high single-crystalline quality with a hexagonal crystal structure. The growth axis of these nanowires is identified to be [0002], along which their lattice spacing is compressed continuously from the wider CdS-rich end to the narrower CdSe-rich end (Fig. 2e). Fig. 2f shows that the Se molar fraction indeed increases linearly along the nanowire length, on the one hand. On the other hand, the bandgaps derived from the quantitative results of energy-dispersive X-ray spectroscopy (EDS) *via* the Vegard's law⁷¹ are well in agreement with the converted bandgaps from the peak energy of the PL spectra for each detected location, confirming that all these emissions originate from the band-edge transitions and that the gradually varied S/Se elemental ratio along the nanowire length is the only reason that causes the observed position-dependent PL peak shift.

The successful growth of composition-graded $\text{CdS}_{1-x}\text{Se}_x$ nanowires opens the magic box of single-nanostructure bandgap engineering based on the magnetic-pulling thermal evaporation growth. As an additional example, we thereafter succeeded in the growth of dual composition-graded $\text{CdS}_x\text{Se}_{1-x}$ alloy nanowires,⁴⁶ where the S/Se ratio gradually increased from the middle to both ends of the nanowires (Fig. 2g). Similar to the emission of $\text{CdS}_{1-x}\text{Se}_x$ alloy nanowires with a single composition gradient, the dual composition-graded nanowires exhibit an emission color symmetrically changing continuously

from red in the middle to green at both ends (Fig. 2h) as a result of the dual composition gradient. These dual composition-graded nanowires possess a high single crystalline quality as well, as confirmed by their HRTEM and SAED patterns.

2.2 Substrate-moving strategy

Inspired by the great success of the source-moving strategy, we further proposed the substrate-moving strategy for the growth of composition-graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ ($0 \leq x, y \leq 1$) quaternary alloy nanowires.¹² As schematically shown in Fig. 3a, here the Au-coated silicon substrate, instead of the solid precursors (CdSe and ZnS powders), is linked to the magnetic pulling module, thereby enabling an *in situ* "substrate-moving" process during growth by driving the external magnet. Besides, there are another two critical upgrades for the success of this substrate-moving thermal evaporation growth. One is that a fan cooling module has to be incorporated into where the substrate is placed in order to achieve a steep temperature gradient. The other is that the substrate has to be placed vertically in order to obtain a narrow temperature window across the whole substrate as much as possible. Interestingly, two types of composition-engineered nanowires are obtained by adjusting the moving speed and stay time of the substrate, as shown schematically in Fig. 3b. The first is composition-graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ ($0 \leq x, y \leq 1$) quaternary alloy nanowires by pulling the substrate from position A to B at a constant velocity of 5 cm min^{-1} . The other is multi-segment axial hetero-nanowires with abruptly changed

Fig. 3 Composition-graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ ($0 \leq x, y \leq 1$) nanowires. (a) Schematic diagram of substrate-moving thermal evaporation growth. (b) Schematic growth of full-color and tri-color nanowires. (c) SEM of as-grown nanowires. (d) TEM. (e) Position-dependent elemental molar fraction. (f) Real-color optical photograph of the dispersed nanowires under UV laser illumination. (g) Spatially resolved PL spectra acquired along a single nanowire (marked with a rectangle and crosses in panel (f)). (h) Position-dependent bandgaps calculated from the PL spectra (red circles) and the elemental compositions by the Vegard's law (black dots). Reproduced with permission.¹² Copyright 2011, American Chemical Society.

composition along the nanowire length. They are obtained by moving the substrate between selected positions as fast as possible and staying a certain time at each position as needed.

The composition-graded ZnCdSSe nanowires have a uniform diameter of ~ 80 nm and a length of up to ~ 30 μm (Fig. 3c and d). Spatially resolved EDS analysis indicates that any detected points along the nanowire length are composed of Zn, Cd, S, and Se elements. Fig. 3e reveals that Cd and Se increase gradually along the nanowire length while Zn and S are complementary to Cd and Se. Similar to the graded $\text{CdS}_x\text{Se}_{1-x}$ nanowires, graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ nanowires also have a high crystalline quality with the lattice spacing gradually varying along the growth axis. The most exciting result here is that these novel nanowires exhibit a rainbow-like emission colour under deep ultraviolet (UV) laser illumination, as shown beautifully in Fig. 3f. The red end corresponds to the Cd/Se-rich alloy, and the other grey end corresponds to the Zn/S-rich alloy with a bandgap or light emission extended into the UV region. Fig. 3g plots a series of spatially resolved PL spectra collected along the nanowire length. Each detected location has a single-band PL emission, with the peak wavelength gradually shifting from ~ 380 nm to ~ 700 nm, nearly covering the full visible spectrum. The local bandgap values can be derived from the PL spectra or calculated from the EDS quantitative results combined with Vegard's law for quaternary $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ alloys. Fig. 3h shows that the bandgaps calculated from the PL spectra and EDS are well consistent with each other, confirming that all the emissions originate from the band-to-band transitions.

The above three examples of composition-graded nanowires not only reach the goal of single-nanostructure graded bandgap engineering but also provide a novel material choice for the emerging nano-optoelectronic applications. First of all, they are expected to serve as ultra-compact light sources packed with abundant wavelengths in view of their nanoscale footprint and finely tunable bandgaps.^{11,12} In particular, the emission color of $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ nanowires covers the entire visible spectral range, and their nanoscale size is beyond the spatial resolution limit of the human naked eye. Consequently, they show high promise for use as monolithic white light sources. More details will be discussed in the Application section in this report.

It is worth mentioning that we made a great effort to grow composition-graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ nanowires by the source-moving strategy before we moved to the substrate-moving strategy. The possible reason why we failed in growing composition-graded $\text{Zn}_y\text{Cd}_{1-y}\text{S}_x\text{Se}_{1-x}$ nanowires *via* the source-moving strategy is that the ZnS and CdSe compounds possess very different vapor pressures at the same temperature.⁵² Although in-depth research has to be done before reaching any reliable conclusions, we assume, based on our experimental experience, that the source-moving strategy may be only applicable to the combination of compounds that share a similar equilibrium vapor pressure at equal temperature, such as the CdS–CdSe system, while the substrate-moving strategy is preferable for combinations of compounds with considerable difference of equilibrium vapor pressures at equal temperature, e.g. the ZnS–CdS, ZnS–CdSe, and ZnSe–CdSe systems.

3. Axial hetero-nanowires

It is well known that the most revolutionary applications of semiconductors (*i.e.* diodes and transistors) rely on rational semiconductor heterojunctions. Therefore, considerable effort has been dedicated to the growth of hetero-nanowires ever since the birth of semiconductor nanostructures. Axial hetero-nanowires, where the composition or dopant experiences abrupt variations along the nanowire length, are particularly important for developing a list of nanowire functional devices, such as photodetectors, light-emitting diodes, field-effect transistors, thermoelectric components, and so on.^{6,17,70,72} A prerequisite for the optimal performance of these devices is the formation of high-quality sharp heterointerfaces.²⁸ To date, most of the reported axial hetero-nanowires have been synthesized *via* other sophisticated approaches, rather than the facile thermal evaporation, as listed in the Introduction of this article.

On the basis of the great success in the growth of composition-graded nanowires, we moved forward to the growth of axial hetero-nanowires by upgrading the source-moving strategy to the so-called multistep source-switching strategy with the same magnetic-pulling principle.^{47,50,73} The difference is that the pulling process is done as fast as possible to enable a fast source switching. Additional key to success of this source-switching growth is that a distinct time duration has to be introduced before switching to the next evaporation source in order to remove the residual of the previous source material as much as possible. On the basis of this source-switching strategy, two different axial hetero-nanowires have been fabricated so far. One is the CdS–CdSse hetero-nanowires,^{46,50} the other is the GaSb–GaInSb hetero-nanowires.⁴⁷

With CdS and CdSe powders serving as the evaporating sources, dual-segment CdS–CdSse nanowires (Fig. 4a) and tri-segment CdS–CdSse–CdS nanowires with long (Fig. 4b) and short (Fig. 4c) CdSse segments are grown *via* the source-switching strategy by altering the growth parameters. The real-color photographs of these hetero-nanowires are shown in Fig. 4a–c, with green and red segments corresponding to the segments of CdS and CdSse alloys, respectively. The CdSse ternary alloy in these nanowires has a fixed S/Se ratio of ~ 0.5 , determined from EDS quantitative analyses, which is different from the gradually changed S/Se ratios in the graded nanowires. Fig. 4e shows a real-color emission photograph of a dual-segment hetero-nanowire, in which a sharp boundary between the green and red segment is clearly identified. Spatially resolved PL spectra (Fig. 4f) reveal that the green and red segments have a clean single-peak emission at 512 nm and 603 nm, respectively, with no obvious defect state-related emission, even around the hetero-interfaces. The spectrum from the junction (D3 in Fig. 4f) has two peaks with positions consistent with either the 512 nm green peak or 603 nm red peak, indicating that it originates from the two segments simultaneously, which is confirmed by 2D PL mapping. As shown in Fig. 4g, the 512 nm peak or 603 nm peak is only detected from the green and red segment, respectively, with a sharp boundary between them. The sharp boundary implies

(d and j) Reproduced with permission.⁴⁷ Copyright 2014, American Chemical Society.

that the elemental composition is suddenly changed at the junctions, which is confirmed by the high-angle annular dark-field (HAADF) STEM image around the boundary (Fig. 4h). The transition length from CdS to CdSse measured in the HAADF image is about 32 nm, which sets a new record of what can be reached by thermal evaporation growth, to the best of our knowledge. It is worth noting that the length of each segment in the tri-segment hetero-nanowires can be well controlled by adjusting the growth time. For example, the length of the middle CdSse segment has been reduced from 40 μm (Fig. 4b) to 300 nm (Fig. 4c and i) by reducing the growth time for the CdSse segment from 30 min to 2 min. This result suggests an improved controllability of thermal evaporation in terms of hetero-nanowire growth, although, unlike MOCVD and MBE growth, it remains a challenge to achieve sub-monolayer growth control and atomically sharp interfaces.

On the basis of the same source-switching strategy, GaSb–GaInSb p–n nanowires are also synthesized with high-purity GaSb and InSb powders serving as the precursors. As-grown GaSb–GaInSb hetero-nanowires have a length of up to 20 μm and a diameter ranging from 80 nm to 200 nm (Fig. 4d). Unlike the straight CdS–CdSse hetero-nanowires, GaSb–GaInSb hetero-nanowires have a regular kink structure with a bending angle of 120° (inset of Fig. 4d). The authors attribute this kink structure to the different growth temperatures for each segment. The mapping results (Fig. 4j) show that Ga and Sb are quite homogeneously distributed across the whole nanowire and In is almost completely confined in the top segment of the nanowire.

Considering that intrinsic GaSb is a p-type semiconductor and GaInSb alloy is an n-type semiconductor,^{74,75} the elemental analyses results prove that these nanowires are GaSb–GaInSb p–n heterostructures.

4. Lateral hetero-nanobelts

The source-switching thermal evaporation growth has further been extended to grow two different multi-lane hetero-nanobelts under modified growth conditions. One is the CdS–CdS_{0.4}Se_{0.6}–CdS tri-lane hetero-nanobelt, in which a CdS_{0.4}Se_{0.6} alloy nanobelt is sandwiched between two CdS nanobelts (Fig. 5a).⁴⁵ Under laser illumination, the middle CdS_{0.4}Se_{0.6} nanobelt and the two lateral CdS nanobelts exhibit red and green emission, respectively, thus each nanobelt looks like a colored tri-lane road, as shown in Fig. 5a. The other is exactly opposite, each nanobelt consists of a wide green CdS_{0.9}Se_{0.1} nanobelt in the middle and two narrow red CdS_{0.5}Se_{0.5} nanobelts on the two lateral sides (Fig. 5b).⁴⁸ In addition, Kim *et al.* reported the growth of similar CdS/CdSe lateral heterostructure nanobelts by a two-step physical vapor transport method.⁷⁶

Fig. 5c is the TEM morphology of the CdS–CdS_{0.4}Se_{0.6}–CdS nanobelt with a uniform width of $\sim 3 \mu\text{m}$. EDS spectra acquired from three different positions along the width direction and 2D elemental mapping (Fig. 5d) reveal that Cd is quite uniformly distributed across the entire nanobelt, while S is located more

Fig. 5 Lateral hetero-nanobelts. Real-color optical photograph of (a) CdS–CdS_{0.4}Se_{0.6}–CdS and (b) CdS_{0.5}Se_{0.5}–CdS_{0.9}Se_{0.1}–CdS_{0.5}Se_{0.5} hetero-nanobelts. concentrated on both lateral sides than in the central region, and Se almost completely occupies the central region of the nanobelt. The well-defined boundary in the elemental mapping images proves that these nanobelts are lateral heterostructures with CdS crystals forming both lateral lanes and CdS_{0.4}Se_{0.6} ternary alloy in the middle lane. The HRTEM image reveals that no grain boundary exists at the CdS/CdS_{0.4}Se_{0.6} hetero-interface (Fig. 5e), indicating the high quality of the heterojunction, which is reasonable since the lattice mismatch between CdS and CdS_{0.4}Se_{0.6} is very small.⁴⁵

The other CdS_{0.5}Se_{0.5}–CdS_{0.9}Se_{0.1}–CdS_{0.5}Se_{0.5} lateral nanobelts share a similar tri-lane microstructure. The high quality of these nanobelts is also confirmed by their spatially resolved PL spectra and 2D PL intensity mapping (Fig. 5f). The peak wavelength of the emission bands at the lateral sides (602 nm) and the central region (525 nm) is consistent with the near-band-edge energy of the CdS_{0.5}Se_{0.5} and CdS_{0.9}Se_{0.1} alloys, respectively. The PL spectra collected at the interface exhibit two peaks, coming from the emission of both the central and the lateral regions simultaneously. Similar to the case of graded nanowires, all lateral nanobelts exhibit a clean band-edge emission with no obvious trap-level related emission observed across the entire nanobelt, including at the interface region, further confirming the high quality of these nanobelts and few defects even at the strained interface.

In 2015, Ning's group succeeded in the growth of multi-lane ZnCdSse hetero-nanobelts *via* the multistep substrate-moving thermal evaporation assisted by magnetic force as well (Fig. 5g).¹⁵ The essence of this approach is to optimize the substrate temperature for the desired alloy composition by adjusting the substrate position along the axial temperature gradient in the tube reactor. Fig. 5g–k show schematically the whole growth procedure and the results from each step. The first step is the growth of Cd- and Se-rich red-emitting ZnCdSse nanobelts at position R3 with temperature $T_3 \approx 640$ °C. These nanobelts are then moved to position R1 with temperature $T_1 \approx 780$ °C by driving the connected iron rod with an external magnet, where they are transformed to a Zn- and S-rich blue-emitting ZnCdSse alloy with no appreciable change in morphology. The third step is the growth of the green-emitting lanes at position R2 with temperature $T_2 \approx 740$ °C by incorporating more Cd ions. Finally, the substrate is moved back to position R3 for the additional growth of the red-emitting lanes, resulting in the final multi-lane hetero-nanobelts capable of monolithic RGB light emission. The HRTEM images and the PL spectra (Fig. 5k) show that each lane of the nanobelt is a high-quality wurtzite monocrystal, with no visible defects or strain detected. Fig. 5l shows the morphology of a representative nanobelt used for chemical composition analyses, respectively. 2D mapping (Fig. 5m) results reveal that this nanobelt is composed of Zn, Cd, S and Se, and the concentration of these elements changes along the *c* axis. As one moves from the blue-emitting towards the red-emitting region, the concentrations of Cd and Se increase while those of Zn and S decrease. With this special nanobelt, a monolithic semiconductor laser capable of emitting over the full visible-color spectrum is demonstrated for the first time, which has a wide range of important applications,

such as solid-state lighting, full-color displays, visible color communications and multi-color fluorescence sensing. Details will be discussed later in this report.

Another unexpected product we obtained by this magnetic-pulling thermal evaporation growth is the lateral composition-graded nanobelts.⁴⁹ These special nanobelts are grown by the same source-moving thermal evaporation used for the growth of composition-graded nanowires but under different growth conditions. Elemental 2D mapping and line scanning results reveal that Cd is quite homogeneously distributed across the whole nanobelt, while S is gradually reduced and Se is gradually increased along the lateral direction. Under illumination of diffused laser light, each composition-graded nanobelt exhibits a gradually changed emission color from green to red along the ribbon width. The author attributes the formation of these composition-graded nanobelts to the polarization-induced asymmetric growth process.

5. Optoelectronic applications

The abovementioned examples of single-nanostructure bandgap engineering represent the latest advances in pursuing bandgap engineering at the nanoscale regime through the facile and cost-effective thermal evaporation growth. What is more important, a number of novel 1D semiconductor nanostructures are therefore obtained, providing a new material platform for both basic scientific research and nanodevice design. For example, composition-graded nanowires can directly serve as monolithic wavelength-tunable or multi-wavelength nanoscale light sources.^{11,12} Moreover, a growing list of functional components, including asymmetric light propagation,⁷⁷ wavelength-converted waveguides,⁷⁸ proof-of-concept wavelength splitters,⁷⁸ broadband-response photodetectors,^{79–81} wavelength-tunable lasers,^{82,83} field-effect transistors,⁸⁴ solar cells,⁸⁴ and single-nanowire spectrometers,⁸⁵ have been demonstrated based on these composition-graded nanowires. The axial hetero-nanowires show a high potential for performance improvement of nanowire photodetectors^{47,73} and threshold reduction of nanowire lasers.⁴⁶ The multi-lane nanobelts have been employed as both gain medium and parallel resonant micro-cavity for dual-color,^{45,86} multi-color^{49,87,88} and even monolithic white-light lasers.¹⁵ In this section, we will discuss these impressive optoelectronic applications in detail.

5.1 Monolithic white light sources

As stated above, the composition-graded nanowires integrate a list of position-dependent tunable bandgaps, making them promising wavelength-tunable or multi-wavelength nanoscale light sources. In particular, the PL from composition-graded Zn_yCd_{1–y}S_xSe_{1–x} nanowires covers the entire visible spectral range, therefore they have high potential to serve as trichromatic white-light sources since their nanoscale footprint is beyond the resolution of human naked eye. What is more interesting, the magnet-assisted substrate-moving growth allows one to control the length of each color segment by

altering the growth time, consequently adjusting the relative emission intensity of each primary color, which eventually enables a rational control over the color temperature. As an example, the left panels in Fig. 6a–d show the real-color micrographs of the dispersed nanowires from four different samples with different RGB segments. Corresponding PL spectra (right panels in Fig. 6a–d) reveal that the relative intensity of the three primary colors is indeed tuned in accordance with the length variation of each color segment. Under low-magnification observation, white light spots with different color-temperature combinations are directly recorded with a color digital camera. As shown in Fig. 6e, samples T1, T2 and T3 exhibit light blue, light yellow, and orange PL emissions, respectively, while sample T4 possesses a nearly ideal white light emission. The calculated CIE (International Commission on Illumination) chromatic coordinates of samples T1–T3 are located at the edge of the white area in the CIE diagram, while that of sample T4 is located at the center of the white area (Fig. 6f), demonstrating the realization of nearly ideal white light emission from these graded nanowires by carefully adjusting the relative intensity of the three primary colors.

5.2 Photonic waveguides

Similar to optical fibers used for optical information communication in daily life, semiconductor nanowires have a two-dimensional confinement for visible light in their cross-section owing to their high refractive index contrast to their surroundings. In addition, semiconductor nanowires fabricated

by thermal evaporation generally undergo a high-temperature process which offers them advantages of high single-crystalline quality, smooth surfaces, and nearly perfect geometry. Therefore, semiconductor nanowires have been utilized as excellent optical micro-cavities for light propagation and oscillation.^{89–92} In particular, the graded composition achieved in individual nanowires introduces not only a graded bandgap profile, but also a gradually changed dielectric constant along the nanowire length, which deserves special attention in terms of optical waveguiding. As a matter of fact, an unusual asymmetric light propagation has been observed in single composition-graded CdSe nanowires from the perspective of guided light intensity, while from the perspective of guided light wavelength, a proof-of-concept wavelength splitter has been proposed based on the nanowire branch structure made of a composition-graded nanowire trunk and several composition-homogeneous nanowire branches.

Fig. 7a and b show, respectively, the SEM view and real-color emission photograph of a composition-graded CdSe nanowire. When the nanowire is independently excited at the nanowire ends with the same focused laser beam (input, Fig. 7c and d), the output light at the opposite ends has the same color but significantly different intensity. The PL spectra acquired at the output ends (Fig. 7e) further confirm that the light intensity contrast, C , at the two output ends is up to 0.95, demonstrating an excellent capability of asymmetric light propagation. Such a high intensity contrast is even close to the ideal contrast ($C =$

1) expected for a diode behavior, suggesting the potential for developing all-optical diodes.^{93–95} Theoretical studies suggest that the excellent asymmetric light propagation observed in these graded nanowires originates from the different propagation mechanisms along opposite directions. In the case of forward propagation toward the bandgap-increasing direction (Fig. 7c), the nanowire acts as a passive optical cavity for the input light (the PL coupled into the narrow-bandgap end) because the photon energy is smaller than the bandgap energy of any other positions along the nanowire. The input light will transmit through the nanowire cavity mainly by total internal reflection, exactly like how light transmits in a transparent optical fiber. Therefore, the propagation loss (both the optical intensity and the photon energy) is dominated by the band-tail absorption (induced by structural disorder) and the leakage caused by non-perfect geometry, which is very small for high quality nanowires. In the case of backward propagation toward the bandgap-decreasing direction (Fig. 7d), however, the nanowire acts as an active optical cavity for the input light (the PL coupled into the wide-bandgap end). The input light travels through the nanowire cavity by the incessantly repeated band-to-band re-absorption and re-emitting processes. The main contribution to propagation loss comes from the nonradiative loss involved in each band-to-band absorption and emitting process, which is orders of magnitude higher than the propagation loss for the forward passive waveguide.

These nanowire-based asymmetric optical waveguides have some advantages, such as cost-effective setup, simple fabrication process, tunable working wavelengths, ultra-low operating power and nanoscale footprint, compared with previous all-optical diode designs based on planar chiral structures,⁹⁶ liquid crystal heterojunctions,⁹⁷ photonic crystals,⁹⁸ absorbing multilayer structures,⁹⁹ concentration-gradient fluorescent dyes,⁹⁵ asymmetric optical resonators,¹⁰⁰ and so on.^{93,94} However, it is worth noting that the guiding light inside the graded nanowires actually is the coupled PL emission induced by the input laser beam, instead of the original laser light. Therefore, this nanowire asymmetric optical waveguide can only serve as the so-called active optical waveguides at present, which is a fatal flaw for a lot of practical applications that usually require passive optical waveguides (where the guiding light is the original input light), such as the all-optical diodes required for the next generation of all-optical computing and processing. Nevertheless, the composition-graded nanowires still hold the possibility of realizing passive asymmetric optical waveguides by employing the gradient of dielectric constant along the nanowire length induced by the composition gradient.

The above discussion also indicates that the photon energy (wavelength) of the guided light in single composition-graded nanowires shifts continuously as it travels along the bandgap-decreasing direction. Therefore, single composition-graded nanowires can function as nanoscale wavelength converters. What is more interesting, this wavelength-converted waveguide behavior has been further used for development of a proof-of-concept nanoscale wavelength splitter. As shown in Fig. 7f, the proposed wavelength splitter consists of a nanowire-based

branched structure, where the CdS branches are physically linked to the graded CdSSe backbone using the fiber-based micromanipulation incorporated in optical microscopy. When the green end of the graded CdSSe nanowire is locally excited with a focused laser beam (Fig. 7g), a small part of the PL emission from the excited end will couple into the nanowire body and further travel to the opposite end. The wavelength of the traveling light within the graded nanowire trunk will continuously increase as the propagation proceeds. Meanwhile, the wavelength-converted light inside the trunk can partially transmit into the branches through side-by-side coupling⁹⁰ at each junction and further transmit passively along the CdS branches, in which additional wavelength shift is negligible since the CdS nanowire branches have a larger bandgap than that of any of the junctions in the graded nanowire trunk. In Fig. 7g, light spots with different colors and intensities are observed at each branch end (positions 2–4) as well as the opposite end of the graded nanowire (position 5). Corresponding intensity-normalized PL spectra in Fig. 7h confirm that light of different wavelengths has been extracted successfully from different CdS ends, therefore realizing the function of a wavelength splitter. The structure and involved fabrication steps of these nanowire-based wavelength converters and proof-of-concept wavelength splitters are much simpler than those of previously proposed schemes by other groups, such as photonic crystal,¹⁰¹ diffraction grating,¹⁰² or dielectric-loaded plasmonic waveguides.¹⁰³ They will have great potential applications for optical information processing and communication in a compact photonic integrated system.^{18,101}

5.3 Nanoscale lasers

1D semiconductor nanostructures with perfect geometry and smooth surface are ideal optical micro-cavities (*i.e.* Fabry–Pérot or whispering-gallery mode) in view of the high dielectric constant of semiconductors. Meanwhile, they provide the necessary gain media required for light to reach lasing thresholds. Therefore, they have been suggested as promising candidates for developing nanoscale lasers.¹⁰ Since the first demonstration of ZnO nanowire lasers in 2001 by Yang *et al.*,⁸⁹ a large number of 1D nanostructure-based lasers have been investigated. Most of them are optically pumped lasers made of individual composition-homogeneous 1D nanostructures, such as the well investigated II–VI, III–V family and their alloys, and the brand new perovskite nanostructures.¹⁰⁴ In principle, the lasing properties (*i.e.* lasing modes, quality factors, thresholds) of 1D semiconductor nanostructures are determined by their sizes, bandgaps, and geometry. Therefore, the single-nanostructure bandgap engineering in these composition-engineered 1D nanostructures is expected to play a key role in their lasing behavior. For example, the composition-graded CdSSe nanowires are capable of defining tunable lasing wavelengths over a wide range.^{82,83,88} In contrast, the dual composition-graded CdSSe nanowires are considered as more perfect optical resonant cavities, reducing the nanowire lasing threshold because they can effectively suppress the band tail induced self-absorption.⁴⁶ The multi-lane lateral hetero-

nanobelts provide monolithically integrated cavities in a parallel configuration, which allows light with different wavelengths to lase simultaneously, therefore realizing dual-color,⁴⁵ tri-color,⁴⁹ and even monolithic RGB white-light¹⁵ lasers from individual 1D semiconductor nanostructures.

5.3.1 Graded nanowire lasing. Fig. 8a–d shows the typical lasing properties of a single composition-graded CdSSe nanowire when optically pumped with a pulsed laser.⁸³ Unlike the gradually changed PL color along the nanowire length under

continuous wave (CW) laser illumination (Fig. 8b), the optically pumped lasing wavelength (637 nm) fixes in the red emission band of the narrow-bandgap end (Fig. 8c). The mechanism behind this phenomenon has been discussed above for the asymmetric optical waveguide. In brief, the graded nanowire always acts as a passive cavity for the red emission from the narrow-bandgap end and active cavity for the green emission from the wide-bandgap end. The latter case introduces a much higher optical loss because the green emission will undergo incessantly repeated band-to-band re-absorption and re-emitting processes as it travels along the bandgap-decreasing direction. Therefore, the red emission can start to lase with a lower threshold than the green emission.

Nevertheless, it is interesting to investigate whether single graded nanowires could lase at different colors simultaneously since they naturally integrate abundant tunable bandgaps in one ultra-small cavity. Such a goal first came true by looping the wide-bandgap end of a graded nanowire to form a relatively isolated nano-ring cavity for the green emission,⁸³ as illustrated in Fig. 8e. The nano-ring cavity in this configuration provides a strong feedback for the green emission from the wide-bandgap end,^{105,106} hence significantly reducing the re-absorption of the green emission by the straight nanowire tail with smaller bandgaps. In the meantime, the orange emission from the narrow-bandgap end can still propagate in the entire nanowire. As a result, the green emission can oscillate in the nano-ring cavity with sufficient gain and low loss to reach the lasing level, while the orange emission can still oscillate to lase in the cavity defined by the two end-facets of the nanowire. More interestingly, this configuration enables a color-tunable laser by pumping the straight and looped segments separately with modulated laser intensities. As shown in the dark-field images (Fig. 8e), the output color at the junction was tuned from green (B1) to yellow-green (B2) to yellow (B3) to orange (B4) by simply adjusting the relative intensities of the two pump beams. The corresponding lasing spectra (right side in Fig. 8e) confirm that the intensity of the green and orange lasing peaks is well modulated by adjusting the pumping intensities, which eventually leads to the tunable lasing color.

Another way to extract the integrated different lasing wavelengths from these composition-graded nanowires was reported by Yang *et al.* in 2014.⁸² As shown in Fig. 8f–h, tuned laser colors from red to green with tunable wavelengths over a wide range of 119 nm are achieved by cutting a single composition-graded CdSSe alloy nanowire along the bandgap-increasing direction step-by-step. In contrast, if the nanowire is step-by-step cut along the bandgap-decreasing direction, its sharp lasing modes are always located in the broad PL peak from the CdSe-rich end (Fig. 8i). The free spectral range of these lasing modes shows a linear relationship with L^{-1} , where L is the nanowire length after each cutting, indicating the well-defined Fabry-Pérot cavity properties originating from the reflection at the two end facets of the nanowire.^{89,91} Therefore, further cutting the nanowire into even shorter lengths may end up with single-mode lasing, which is another active research topic in the field of nanowire lasers.

Fig. 8 Composition-graded nanowire lasers. (a) Dark-field optical photograph and (b) real-color image of a composition-graded CdSSe nanowire. Scale bars are 30 μm . (c) PL spectra under a single excitation pulse with increasing peak power density. (d) Integrated intensity of 637 nm lasing peak versus excitation power density. (e) Color control of a looped wire dual-color laser. Left is the dark-field image of the looped nanowire. Scale bar, 10 μm . Right is the normalized lasing spectra acquired from the middle panels. (f) Real-color image of a composition-graded CdSSe alloy nanowire with six cut points determined by the localized PL spectra. (g) Real-color images and (h) lasing spectra of the nanowire after being cut at point 1 to point 6 sequentially. The colorful spots shown in each spectrum correspond to the real-color image of the end emission of each nanowire at pump density above the threshold. (i) Lasing spectra obtained by cutting the nanowire along the bandgap-decreasing direction step-by-step. (j and k) Pumping power-dependent PL spectra of symmetrically composition-graded nanowires and composition-homogeneous CdSSe alloy nanowires, respectively. (l) Integrated intensity of the lasing peaks at 581.5 nm and 594.3 nm versus excitation power density. (a–e) Reproduced with permission.⁸³ Copyright 2013, American Chemical Society. (f–i) Reproduced with permission.⁸² Copyright 2014, American Chemical Society. (j–l) Reproduced with permission.⁴⁶ Copyright 2013, American Chemical Society.

As stated above, the red laser from the CdSe-end of the composition-graded CdS_{1-x}Se_x nanowire also indicates that a passive optical cavity is more favorable than an active optical cavity in terms of reducing the lasing threshold of nanowires. Such a deduction is further proven by the investigation of the lasing behavior of symmetrically composition-graded CdS_{1-x}Se_x alloy nanowires⁴⁶ as well as tri-segment axial hetero-nanowires.⁵⁰ As shown in Fig. 8j–l, the symmetrically composition-graded CdS_{1-x}Se_x nanowires start to lase at a threshold of $\sim 50 \text{ kW cm}^{-2}$, which is several times lower than the threshold of the composition-homogeneous CdS nanowire lasers ($\sim 200 \text{ kW cm}^{-2}$). As a result of the symmetrically increased bandgaps from the middle to the two ends, the nanowire is optically transparent for the light emitted from the middle segment that has the narrowest bandgap (red emission). In this case, the propagation loss of the red emission is expected to be much smaller than that in homogeneous nanowires because both the band-to-band absorption and the self-absorption induced by the band tails^{92,107} are eliminated during oscillation between the two nanowire end facets. Owing to the same reason, similar results are obtained when the middle narrow bandgap segment of the tri-segment axial hetero-nanowires is pumped to lase.⁵⁰

5.3.2 Multi-lane nanobelt lasing. The abovementioned nanowire lasers suggest that postgrowth treatment (*i.e.* end looping or cutting) is involved in order to extract multiple lasing wavelengths from individual composition-graded nanowires owing to the inevitable bandgap re-absorption of the higher energy photons along the bandgap-decreasing direction, although graded nanowires assemble rich tunable emission wavelengths. In contrast, the multi-lane hetero-nanobelts offer a novel side-by-side parallel optical micro-cavity, which can exclude the bandgap re-absorption significantly.^{15,45,86,87} Consequently, multi-wavelength lasing is highly expected from single multi-lane hetero-nanobelts without any postgrowth treatment.

Room-temperature dual-color lasing was first observed from individual CdS–CdS_{1-x}Se_x–CdSe tri-lane hetero-nanobelts,⁴⁵ as can be seen in the pumping power-dependent lasing spectra (Fig. 9a). The 607.9 nm red and 517.9 nm green lasing peaks originate from the middle CdS_{1-x}Se_x lane and the two lateral CdS lanes, respectively. The lasing threshold of the red emission ($\sim 80 \text{ kW cm}^{-2}$) is a lot lower than that of the green emission ($\sim 200 \text{ kW cm}^{-2}$). Although the threshold of a semiconductor laser is determined by a series of factors, such as the optical gain of materials and the amount of gain materials,⁹¹ here the inevitable re-absorption of the green emission by the middle CdS_{1-x}Se_x lane is the main reason that caused the difference in lasing thresholds. More interestingly, the lasing peak at the longer side of the wavelength can be tuned by adjusting the S/Se ratio in the middle CdS_{1-x}Se_x lanes, as shown in Fig. 9b. Fan *et al.* reported similar results in 2013 as well.⁸⁶

On the basis of lateral composition-graded CdS_{1-x}Se_x nanobelts, multi-color lasers with three groups of lasing modes at 519 nm (green), 557 nm (orange), and 623 nm (red), respectively, have been reported at room temperature (Fig. 9c).⁴⁹ In-depth studies revealed that the red lasing mode originates from the passive Fabry–Pérot cavity^{89,91} resonance between the two end facets of the longer length direction. The orange and green lasing modes,

however, in accordance with the passive and active Fabry–Pérot modes, oscillate between the two lateral facets along the width direction, respectively.

The most exciting achievement of monolithic multi-color lasers is the first realization of a monolithic white-light laser from individual ZnCdS_{1-x}Se_x multi-lane hetero-nanobelts.¹⁵ Three power adjustable beams are focused into long, narrow, parallel stripes to pump one of the three segments each. Fig. 9d shows the optical properties of such a multi-lane hetero-nanobelt under different pumping conditions. By pumping one, two and all three lanes up to their lasing thresholds, the author demonstrated independent lasing of each RGB color, simultaneous two-color lasing of any two of the three primary colors, and finally simultaneous RGB mixed white color lasing. Fig. 9e presents the lasing spectra for all the seven cases, while Fig. 9f shows the calculated chromaticity for these lasing spectra on a CIE1931 color diagram. The chromaticity of the carefully balanced white lasing is very close to that of the white point CIE standard white illuminant D6546. The corresponding far-field photograph in Fig. 9g confirms the following: (1) independent red, green and blue lasing can be achieved by pumping each

color lane individually (g2–g4); (2) yellow, cyan and magenta mixed lasing emissions are produced by pumping two of the segments (g5–g7); (3) simultaneous RGB lasing emission from a single multi-segment hetero-nanobelt can be mixed together to render white-like color (g8). This color mixing demonstration provides an experimental proof-of-concept for the use of multi-color lasing structures for illumination and display applications (Fig. 9h).

5.4 Photodetectors

Another intensively investigated application of 1D semiconductor nanostructures is the photodetector (or optical sensor) considering the fact that the electrical conductivity of semiconductors usually increases in accordance with the incident light intensity. In principle, the photoconductivity involves several successive or simultaneous physical processes:¹⁰⁸ (1) absorption of incident light; (2) exciton generation by the incident light with photon energy larger than the nanostructure bandgap, which determines the spectral response of the photoconductor; (3) carrier (electrons and holes) separation due to an applied electrical field, which induces the photocurrent; (4) exciton recombination at the surface and in the bulk of the nanostructures, which leads to photocurrent degradation; (5) carrier trapping and releasing by defect centers, which determine the rise time and decay time when the incident radiation is introduced and withdrawn, respectively. They are all closely related to the bandgap diagram of the nanostructures, therefore the abovementioned single-nanostructure bandgap engineering induced by the engineered composition is expected to bring additional impact on their photoconductivity characteristics.

The first example is a monolithic wavelength-selective (multispectral) photodetector by taking advantage of the graded bandgaps along the nanowire length axis.⁷⁹ This multispectral photodetector consists of individual graded CdSse nanowires with 4 parallel electrodes deposited (Fig. 10a). By connecting adjacent electrodes, three photodetector cells (PD1, PD2, PD3) are integrated in a series configuration, each covering a different bandgap band. As a result, each detector is expected to have its unique response to a different spectral range. Fig. 10b plots the photocurrent as a function of incident wavelength. The response cutoff wavelengths extrapolated for PD1–PD3 at forward bias and PD3 at reverse bias are 540, 570, 600, and 630 nm, respectively. The rectification ratio, defined as the ratio of forward current to backward current, is closely related to the excitation wavelength. As plotted in Fig. 10c, the rectification ratio of each detector exhibits a single peak feature, with peak wavelengths at 550, 570, and 600 nm, respectively, which correspond to the response cutoff wavelengths in Fig. 10b. Although a similar tunable wavelength response range is implementable based on CdSse nanowire arrays with a composition gradient along a single substrate,¹⁰⁹ here the tunable ranges are monolithically integrated into a single nanowire. Besides, the integrated number of photodetector units can be increased by simply adding more parallel electrodes onto the graded nanowires, hence increasing the selectivity of the photodetector. Such a monolithic multispectral system greatly

increases the sensitivity of photodetectors beyond what single spectral photodetectors are capable of.

The change of the conductivity induced by incident irradiation depends upon not only the bandgap absorption of the semiconductor, but also the number of free carriers produced per absorbed photon and the mobility of these carriers.^{108,110} The abruptly changed bandgap in 1D axial hetero-nanostructures is expected to enhance the separation of photogenerated carriers. Fig. 10d depicts schematically the construction of a photodetector made of a single CdS–CdS_{0.49}Se_{0.51} axial hetero-nanowire. Under the illumination of laser beams of different wavelengths with the same intensity, the conductance of the CdS–CdS_{0.49}Se_{0.51} axial hetero-nanowire

is indeed increased significantly, on the one hand. On the other hand, the increment depends on the wavelength being used (Fig. 10e). Fig. 10f further reveals that two response bands with peak positions at 512 nm and 603 nm, respectively, are recognized for this axial hetero-nanowire detector, which is much broader than the single response band at 512 nm observed for the homogeneous CdS nanowire detector. The two response bands are expected results since the CdS and CdS_{0.49}Se_{0.51} segments in the same nanowire possess a stronger photon absorption ability for these two bands owing to their band-to-band absorption. Besides, the photocurrent of axial hetero-nanowire detectors is always higher than that of CdS nanowire detectors, indicating improved photoconductivity in the investigated spectral band (from 350 nm to 700 nm). The author ascribed this improved photoconductivity to the broadened absorption bands in the hetero-nanowire and the re-absorption of the CdS emission by the CdS_{0.49}Se_{0.51} segment with a narrower bandgap. In addition, the rise time and fall time of the CdS–CdS_{0.49}Se_{0.51} axial hetero-nanowire detector are reduced to 68 μs and 137 μs, respectively, which are at least 1 order of magnitude shorter than those of the CdS nanowire detector (1.6 ms and 3.7 ms, respectively).

On the basis of CdS_{0.5}Se_{0.5}–CdS_{0.9}Se_{0.1}–CdS_{0.5}Se_{0.5} lateral hetero-nanobelts, a high performance photodetector is also demonstrated (Fig. 10g).⁴⁸ Similar to the axial hetero-nanowire detector, this detector exhibits increased photoconductivity compared to the homogeneous CdS nanobelt detector in a broad spectral range from 350 nm to 700 nm (Fig. 10h). The rise time and fall time of this hetero-nanobelt detector are 30 ms and 90 ms (Fig. 10i), respectively, 1 order of magnitude shorter than the case of the CdS nanobelt detector (280 ms and 550 ms, respectively). Although the hetero-nanobelt detector has a longer rise and fall time than the hetero-nanowire detector, the responsivity ($1.16 \times 10^3 \text{ A W}^{-1}$) and gain (10^4), are 1 and 2 orders of magnitude higher than those of the hetero-nanowire detector (1.18×10^2 and 3.1×10^2), respectively. As suggested by the Rose model,^{111–114} there is a tradeoff between the gain and the response speed of semiconductor detectors since both gain and response speed are determined by the lifetime of the photo-generated carriers.

Until now, most photodetectors made of 1D semiconductor nanostructures exhibit a notable response to a certain spectral band in the visible range. Progress in developing infrared photodetectors from 1D nanostructures, however, is limited. On the basis of the GaSb–GaInSb p–n hetero-nanowires, we reported a near-infrared nanowire photodetector that works at room temperature.⁴⁷ As shown in Fig. 10j, all the *I*–*V* curves acquired for different incident infrared light wavelengths but same intensity show a well-defined rectification characteristic owing to the formation of a p–n junction in the GaSb–GaInSb hetero-nanowire. Compared with the electrical conductance under dark conditions, the electrical conductance of the nanowire increases dramatically under light illumination. Fig. 10k further shows that the photodetector exhibits a dual-band spectral response as well. The peak wavelengths of these two bands are located at 1550 nm and 1950 nm, in consistence with the band-to-band charge generation processes of the GaSb

and Ga_{0.9}In_{0.1}Sb segments, respectively. Fig. 10l indicates that this near-IR photodetector exhibits features of a high external quantum efficiency of 10^4 , a high responsivity of 10^3 A W^{-1} and a response time as short as 2 ms. It is worth pointing out that the strongest response band at 1550 nm is exactly the wavelength that is most widely used in optical communication systems. Therefore, these photodetectors may be compatible with the existing optical communication systems. Besides, the nanoscale footprint of these devices offers them great potential for future on-chip integrated nanosystems.

5.5 Field-effect transistors and solar cells

Similar to the case of 1D nanostructure photodetectors, most of the early reported field-effect transistors (FETs) and solar cells are built up from individual composition-homogeneous nanostructures that are randomly selected from the growth substrate.^{115–119} The impact of engineered composition in single 1D nanostructures has rarely been investigated.^{70,74} On the basis of composition-graded CdS_{1–x}Se_x alloy nanowires, Li *et al.* carried out the initial study on their FETs and solar cells. The FET is made of single composition-graded CdS_{1–x}Se_x alloy nanowire with a back-gate configuration. The acquired output characteristics reveal that this FET has a pronounced gate-dependent *I*_{ds}–*V*_{ds} effect and n-type conductivity. From the linear region of the transfer characteristics, the threshold gate voltage, *V*_{th}, and the transconductance, *g*_m, are determined to be –8.2 V and 18.6 nS, respectively. Consequently, the calculated electron mobility is $1.5 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and the concentration is $2.1 \times 10^{17} \text{ cm}^{-3}$. The on–off current ratio of such FETs is up to 10^7 . In addition, a CdS_xSe_{1–x} nanowire-network Schottky solar cell was fabricated and characterized under air-mass (AM) 1.5 G illumination. This device exhibits a current density (*J*_{sc}) of 13.1 mA cm^{-2} , an open-circuit voltage (*V*_{oc}) of 0.21 V, a fill factor (FF) of 28%, and an energy conversion efficiency (*η*) of 0.77%. These results are comparable to or even higher than the values measured for pure CdS¹¹⁷ and CdSe¹¹⁸ nanowire/nanobelt cells. The monochromatic incident photon-to-electron conversion efficiency (IPCE) spectrum shows that the solar cell maintains a high photo-electron response in the whole visible range. However, such a nanowire-network Schottky solar cell has been far from perfect so far. The energy conversion efficiency is still quite low and the dispersed nanowires are too disordered to reach the upper limit of the theoretical performance. Possible strategies for further performance improvement will be discussed in the Conclusion section.

5.6 Single-nanowire spectrometer

The latest exciting optoelectronic application of composition-graded nanowires is the single-nanowire spectrometer, reported last year by Yang *et al.* In their report, a composition-graded CdS_xSe_{1–x} nanowire covered from 1.74 eV to 2.42 eV in bandgaps (Fig. 11a) was firstly transferred from the growth substrate onto a Si/SiO₂ substrate and served as the active element of the spectrometer. An array of In/Au parallel electrodes (top, Fig. 11b) with identical spacing was then deposited on the graded nanowire to form a good electrical contact. After

Fig. 11 Spectrometer based on single composition-graded $\text{CdS}_x\text{Se}_{1-x}$ nanowires. (a) PL real-color digital image of a selected composition-graded $\text{CdS}_x\text{Se}_{1-x}$ nanowire and corresponding PL spectra collected from the circle-marked regions (spot size $\sim 5 \mu\text{m}$). Scale bar, $20 \mu\text{m}$. (b) Fluorescent micrograph (top) of a nanowire spectrometer, incorporated into a packaged chip (bottom). Scale bar, $10 \mu\text{m}$. (c) Time response measured between two neighboring electrodes at the red (CdSe) end of the nanowire under intensity-modulated incident light (490 nm , 0.3 mW cm^{-2}) at a bias of 0.5 V . Dotted lines indicate 10 and 90% of peak value, as used for calculating the rise (1.5 ms) and fall time (3.5 ms). (d) Normalized spectral responses $R_i(\lambda)$ of each constituent unit in the nanowire spectrometer, with cutoff wavelengths shifting continuously along the nanowire length. (e) Operational scheme of the nanowire spectrometer. (f) Measurement and reconstruction of a single spectral peak at 560 nm using a 30- and 38-unit device, relative to the same signal measured by a conventional spectrometer (Thorlabs CCS100, 0.5 nm wavelength accuracy). Arrows indicate the FWHM. (g–k) Spectral imaging at the micrometer scale: (g) operational scheme of cell mapping; (h) photograph of the cell-mapping apparatus; (i) micrograph of a naturally pigmented red onion cell surrounded by transparent cells. Scale bar: $50 \mu\text{m}$; (j) absorption spectral images of the onion cell at selected wavelengths. incorporating the graded nanowire into a packaged chip (bottom, Fig. 11b), a single-nanowire spectrometer was successfully constructed for the first time. With such a simple configuration, each segment of the graded nanowire between two neighboring electrodes functioned as an ultra-compact photodetector. Under illumination of adequate light, each cell showed a good photo-response characteristic with typical response and recovery time of $\sim 1.5 \text{ ms}$ and 3.5 ms , respectively (Fig. 11c). In principle, photocurrent or photo-response only emerges when the incident photon energy is larger than the bandgap energy of the semiconductor materials. As a result of the graded bandgaps between adjacent photodetector cells, the response cutoff wavelengths and normalized spectral responses $R_i(\lambda)$ of the photodetector cell shifted continuously along the nanowire (Fig. 11d) under the same radiation. Therefore, the incident light spectrum can be reconstructed by taking into account the pre-calibrated photon-response and signal discrepancy of each detector unit (Fig. 11e). The minimum reconstructed FWHM achieved by the nanowire spectrometer

with 38 detector units is 7 nm (Fig. 11f), which is comparable with the FWHM measured using a conventional spectrometer (Thorlabs CCS100, 0.5 nm wavelength accuracy). At present, the spectrometer can well resolve two peaks around 570 nm separated by 15 nm . Despite a reduction in footprint of about two to three orders of magnitude, such a resolution is comparable to that of other visible-range spectral reconstruction microspectrometers, and commercially available centimeter-scale systems. Furthermore, the authors demonstrated an *in situ*, micrometer-scale spectral imaging, which has long been a great challenge across fields such as cytobiology and biomedicine, using their nanowire spectrometer on the basis of a shift register strategy (Fig. 11g–k). As an example, a red onion cell membrane, featuring naturally colored cells surrounded by transparent cells, was mounted onto the sample holder and positioned over the nanowire spectrometer with a gap of several micrometers (Fig. 11g and h). Under the illumination of white light, the nanowire spectrometer scanned across the x - y plane with fixed mapping steps (Fig. 11i). The scanning results provided simultaneously the intensity maps at fixed wavelength (Fig. 11j) and the reconstructed absorption spectra for different points on the onion cell membrane (Fig. 11k), suggesting that this spectrometer has high potential to obtain spectral images at the cellular level.

6. Concluding remarks and future perspectives

In summary, the past ten years have witnessed great progress in single-nanostructure composition/bandgap engineering by upgrading conventional thermal evaporation systems with a home-made magnetic-pulling module. Several different magnetic-pulling strategies have been proposed for bottom-up growth of diverse composition-engineered 1D semiconductor nanostructures, consequently offering various single-nanostructure bandgap engineering desired for future nano-optoelectronics. The first is the *in situ* “source-moving” strategy, which enabled the growth of CdSSe ternary alloy nanowires with a linear composition gradient or symmetrical dual composition gradients along the nanowire length, as well as CdSSe ternary alloy nanobelts with a composition gradient along the nanobelt width. The second is the *in situ* “substrate-moving” strategy, which allowed the growth of composition-graded ZnCdSSe quaternary alloy nanowires and multi-lane ZnCdSSe hetero-nanobelts. The third is the multi-step “source-switching” strategy, which let us succeed in the growth of axial hetero-nanowires and tri-lane CdSSe hetero-nanobelts. On the basis of these composition-engineered 1D semiconductor nanostructures, a number of laboratory nano-devices have been proposed for optoelectronic applications, including ultra-small monolithic wavelength-tunable light sources, monolithic white-light sources, asymmetric light propagation, wavelength converters and splitters, color-tunable nano-lasers, low-threshold nanowire lasers, monolithic dual-color, multi-color and even white-color nanostructure lasers, monolithic wavelength selective and broadband-response

photodetectors in the visible and IR spectral range, transistors, solar cells as well as the very recent exciting single-nanowire spectrometer.

Despite the great progress in the growth and promising optoelectronic applications of composition-engineered 1D semiconductor nanostructures based on this magnetic-pulling thermal evaporation strategy, many opportunities and challenges remain for the future. First and foremost, site-controlled horizontal alignment is necessary in order to further realize the substantial potential of these novel 1D nanostructures. For example, composition-graded nanowires on a single chip have recently been suggested as a fascinating material platform for developing the so-called spectrum-splitting photovoltaic system^{120,121}—which enables optimized absorption of different solar spectral components by a combination of the matched bandgaps available in these graded nanowires and the assistance of dispersive optical elements (such as prisms).¹²² In this regard, site-controlled horizontally aligned composition-graded nanowire arrays (Fig. 12a) are highly anticipated in order to construct such spectrum-splitting photovoltaic systems for further improvement of the energy conversion efficiency of nanowire solar cells, as schematically shown in Fig. 12b. The great news is that considerable progress in site-controlled growth of horizontally oriented semiconductor nanowires through the facile thermal evaporation has been made by suitably choosing the substrate and growth conditions over the past two decades. To date, a growing list of semiconductor nanowires have been successfully grown on either flat surfaces through the guiding effect of the substrate lattices^{123–129} or faceted surfaces with pre-formed aligned nano-features (*i.e.* nanogrooves, nanosteps) by the so-called “graphoepitaxy”,^{9,32–40} where nanowires are guided by the aligned orientation of the nano-features. Very recently, the generality of guided growth has been further applied to the growth of self-aligned core-shell

nanowires with controlled growth sites and shells, allowing a scale-up fabrication of nanowire photodetectors with both high-gain and ultrafast response.¹⁴⁴ With these ideas in mind, there will be a great chance for success in the site-controlled growth of composition-engineered 1D semiconductor nanostructure arrays by combining the magnetic-pulling thermal evaporation strategy with the in-plane guided growth mechanism. Second, controlled growth of p–n hetero-nanowire horizontal arrays for light emitting diodes (Fig. 12c) and n–p–n hetero-nanowire horizontal arrays for transistors remains a challenge, which deserves even more research enthusiasm. Third, it is worthwhile to make efforts to extend the general synthesis strategy to the growth of narrow-bandgap III–V semiconductors for the purpose of photodetector applications in the near and deep IR spectral range. Last but not least, the principle of this magnetic-pulling thermal evaporation is not limited to the growth of composition-engineered 1D semiconductor nanostructures. As a matter of fact, this strategy has been successfully applied to the growth of composition-modulated 2D layered nanomaterials,¹³⁰ such as composition-graded atomic layer $\text{MoS}_2(1-x)\text{Se}_{2x}$ (ref. 131) and $\text{WS}_2(1-x)\text{Se}_{2x}$ (ref. 132) nanobelts, as well as WS_2 – WSe_2 and MoS_2 – MoSe_2 atomic layered heterostructures,¹³³ and so on.

From the perspective of technology, some optimization work is anticipated in order to further improve the capability of composition control of thermal evaporation growth. For example, it remains a substantial challenge to grow nanowire superlattices based on thermal evaporation because thin nanowires are usually too delicate to survive multiple sequential growth steps, which however are necessary for the formation of nanowire superlattices. In principle, block-by-block growth of nanowire superlattices requires an effective minimization of undesired homogeneous nucleation of new crystal seeds to ensure exclusive heterogeneous epitaxial growth at the two ends of the existing nanowires. Such a goal has been achieved in the robust growth of superlattices from 2D atomic crystals by introducing a reverse gas flow during the temperature-swing stage in the sequential vapor deposition growth process.¹³⁴ In this regard, incorporating the reverse flow strategy into the magnetic-pulling thermal evaporation system to enable block-by-block growth of nanowire superlattices is another research direction worthwhile to make an effort in the near future. Last but not least, further improvement of alignment quality (*i.e.* nanowire density, length uniformity, industrial-scale)^{135,136} is essential toward the next-step large-scale fabrication of optoelectronic devices and systems based on bottom-up 1D semiconductor nanostructures.
