Aptamer-functionalized nanomaterials for biological applications

Qiaoli Ren,^{†,a} Lu Ga,^{†,b} Zhili Lu,^c Jun Ai ^{†,a} and Tie Wang ^{†,d}

Aptamers have attracted the attention of many researchers because of their high stability, high affinity and high selectivity. Over the past decades, considerable intensive exploration and research has been carried out in this area. These studies have led to the emergence of functionalized nanomaterials, which have suggested a more diverse range of potential applications. However, despite the many exciting and remarkable developments emerging at the moment, several challenges and issues remain to be addressed. Based on currently reported aptamer-functionalized nanomaterials (AFNs), this review highlights potential applications for AFN platforms in catalysis, detection, cellular analysis, imaging, and targeted drug delivery. We also focus on explaining controllable syntheses and the unique dynamic properties of AFNs. Finally, we discuss progress and the challenges associated with AFN applications in this field.

1. Introduction

With the rapid development of modern biology in the 20th century, the structures of proteins, antibodies, nucleic acids,

polysaccharides, lipids and other macromolecules have been elucidated successively.^{1–5} Follow this trend, the 21st century has been the century of life science. Aptamers are strands of oligonucleotides (RNA or ssDNA) or amino acid fragments with a special tertiary structure, which are selected *in vitro* from large random libraries by a process called systematic evolution of ligands by exponential enrichment (SELEX).^{6,7} Aptamer of SELEX has a high affinity and specificity to non-nucleic acid targets, such as peptides, proteins, drugs, organic and inorganic molecules, or even whole cells. Nucleic acid aptamers (RNA or ssDNA) have been suggested repeatedly as promising emerging therapeutic agents and recognition elements. A single strand of DNA or RNA, usually 10–100 nucleotide residues, was obtained by amplification or screening from the synthetic DNA/RNA library. Even RNA or ssDNA aptamers acting on the same target have

Qiaoli Ren is currently a Master student at the Inner Mongolia Normal University (with Professor Jun Ai). And during this period, she is also a joint Master student at the Institute of Chemistry, Chinese Academy of Sciences (with Professor Tie Wang). She is currently focused on research into photochromic materials and biosensor construction.

Qiaoli Ren

Lu Ga obtained her BSc degree in Chemistry in 2000 and her MS degree in Medical Chemistry in 2005 from Inner Mongolia Normal University and Inner Mongolia Medical University. At present, she is an associate professor and works at Inner Mongolia Medical University. Her current research is focused on Mongolian medical nanomaterials.

different sequences and tertiary structures.⁸ The chemical properties of aptamers are based on nucleic acid molecules, which has the obvious advantage that they are small in size, non-toxic, easy to synthesize, easy to modify chemically with various functional groups, have low immunity, allow identification of diverse targets, and show easy surface immobilization in biological applications. In fact, aptamers are so superior in terms of their advantages over antibodies that they have been considered ideal substitutes for antibodies. Furthermore, as a new type of functional molecular probe, they have overtaken the decades-long dominant position of antibodies in molecular recognition.^{9,10} Aptamers have found more and more applications in life science, chemistry and other fields, including diagnostic and therapeutic tools, biosensor probes, and drug discovery and release. Of all these areas of research, the field of life science mainly focuses on the treatment and diagnosis of diseases. Researchers are currently trying to develop adaptations that specifically identify targets in diseases such as cancer and viral infections.

Nanotechnology is a type of technology platform that is being more and more widely applied.^{11–16} The term describes the use of technology for design, synthesis, characterization and application at the nanoscale. Control at the nanoscale and manipulation of basic molecular structures allows for the regulation of the macroscopic chemical and physical properties of materials and devices. As the fields of materials science, chemistry and engineering have evolved over the past few decades, nanotechnology is still being developed in all areas where the small scale plays a crucial role in determining fundamental properties. To date, nanotechnology has been widely used in the fields of physics, engineering, chemistry, biology and medicine.^{17–19}

With the rapid development of nanotechnology and biotechnology over recent decades, it is now possible to combine these two exciting fields to realize new possibilities. The wide range of biological applications of different nanomaterials in biological analysis, diagnosis and biomedical treatment has aroused great interest.^{20,21} Even though some progress has

been reported in the field of aptamer-functionalized nanomaterials (AFNs), this is such a promising field that further effort and exploration is required. This review will systematically explain controllable syntheses, dynamic properties, and potential applications of AFNs. Finally, we will also offer some perspectives on the challenges facing future advancements in this field.

2. Aptamer-functionalized nanomaterials

To fully realize the potential of nanomaterials in biological applications, they must be biocompatible and able to target specific biomolecules in order to ensure selective sensing, imaging and drug delivery in complex environments such as living cells, tissues, animals and humans.²² The immobilization of functional aptamers to nanoscale or microsized carriers is a powerful way to build new multi-functional materials with desirable properties. In general, nanomaterials can be easily adapted for functionalization through covalent bonding or non-covalent action.^{23,24} This modification aims to improve detection sensitivity and selectivity, reduce analysis time and improve the specificity of binding to target objects. Nanomaterials are commonly used as a substrate for fixing aptamers or as markers for signal amplification because of their ability to absorb cellular components and metabolites, which can be modified by aptamers to cells. Therefore, the use of nanomaterials in medicine represents a breakthrough in the development of materials because the materials are designed to interact with the human body at a cellular scale with a high degree of specificity. Nanomaterials, involving quantum dots, nanoclusters (NCs), nanowires, nanosheets and nanotubes, are characterized by at least one dimension in the nanometer range.^{25,26} (i) Quantum dots have the advantages of traditional organic fluorophores, including light stability, chemical stability, narrower emission spectra and wider excitation spectra. In addition, their surface can be easily modified by chemicals or biopolymers.

Jun Ai

Jun Ai obtained his BSc and MS degree in Chemistry in 2000 and 2004, respectively, from Inner Mongolia Normal University and Inner Mongolia University. He then worked in Inner Mongolia Normal University and at present he is a professor. In 2009, he joined Prof. Erkang Wang's group, and received his PhD degree in analytical chemistry in January 2013 from Changchun Institute of Applied Chemistry, Chinese Academy of Sciences. His studies are centered on biosensor construction and fabrication of functional nanobiomaterials.

Tie Wang

Tie Wang is a professor at the Institute of Chemistry, Chinese Academy of Sciences (ICCAS). He received his BSc degree from Xi'an Jiaotong University in 2002 and his PhD degree from Changchun Institute of Applied Chemistry, Chinese Academy of Sciences in 2007. He then worked as a postdoctoral fellow at Rensselaer Polytechnic Institute, Troy, NY, and the University of Florida, Gainesville, FL. He joined ICCAS with the award of the "Thousand Youth Talents Plan" in 2013. In 2019, he was awarded "outstanding youth of the national fund council". His research focuses on nanoparticle assemblies and their applications.

This is an advantage that most of bulk materials do not have. (ii) Nanoclusters, such as gold and silver, are a new class of fluorophores. Au and Ag NCs have an appealing set of features that complement the properties of organic dyes and quantum dots. They also have desirable photophysical properties and low toxicity suitable for biological applications. (iii) Nanowires typically exhibit better mechanical properties than bulk materials as their size decreases. As size is reduced, strength and toughness become greater. (iv) There are only a few reports on aptamer-functionalized nanosheets currently, most of which are graphene nanosheets. (v) Nanotubes, such as single-wall carbon nanotubes (SWCNTs), have a high aspect ratio, high surface area and excellent material properties, including electrical conductivity, thermal conductivity and mechanical strength, which offer a wide range of opportunities and potential applications in biology and medicine. Nanomaterials can be broadly divided into two categories: nanoparticles and nanobulk materials. Nanoparticles are microscopic particles at the nanoscale, defined as particles less than 100 nm in at least one dimension, or materials made of them as basic units. Nanobulk materials are blocks formed by particles with a size of \sim 1–100 nm. The term describes a one-, two- or three-dimensional systems constructed and composed on a nanoscale as a basic unit according to certain laws, in which the crystal size, crystal boundary width, precipitation phase distribution, pore size and defect size are all of the order of nanometers. Nanoparticles have unique properties compared with bulk materials in terms of optical, thermal, electrical, magnetic, mechanical, and chemical properties. Because their basic structural units are on the nanoscale, nanomaterials have special properties compared with traditional bulk materials, such as quantum size effect, small size effect, surface effect and macroscopic quantum tunneling effect. Furthermore, in the case of DNA, it usually requires the use of cationic transfection agents to achieve cell absorption.^{27,28} However, it is these substances that penetrate into cells making it difficult to perform biological sensing in the living body, and also causing damage to the nucleus. To address this obstacle, nanomaterials, such as metals, carbon, silicon or magnetic materials, have been used as DNA carriers or assistants. By combining the inherent features of nanomaterials with the specific recognition ability of aptamers, a range of nanomaterial-aptamer conjugates have proven their

utility in multiple areas. Aptamers can be used to perform a variety of functions, across two main directions: (1) based on their specific binding to target molecules, aptamers have great potential in biomedical applications, such as drug delivery and the development of new therapeutic systems. (2) The properties of aptamer means that they play an important role in the development of new biosensors. So far, nanomaterials such as metals, magnetism, silica, hydrogels and carbon materials have helped many advances in biology. These nanomaterials typically have a large surface area and have unique dimensions and shapes, as well as physical and chemical properties associated with their composition, including surface plasmon resonance (SPR), fluorescence, magnetism and/or load capacity. The cross-linking of these properties has allowed researchers to synthesize AFNs as needed, as summarized in Table 1.

This shows that the two areas of nanotechnology and biotechnology may have broader prospects by complementing each other. To date, noble metal nanoparticles in these nanomaterials have been reported and have shown particular potential in achieving these tasks due to their unique chemical and physical properties, simple synthesis, good biocompatibility and easy integration with biomolecules. It is well known that aptamer-coupled Au nanomaterials or Ag provide a powerful platform for targeted recognition, detection and treatment.^{41–47} In 2004, Willner *et al.* reported that catalytic amplification of aptamer-functionalized Au nanoparticles (AuNPs) amplifies the optical detection of aptamer-thrombin complexes in solution and on the surface.⁴⁸ Since then, the Liu group were the first to report aptamer-functionalized AuNPs as probes in a dry-reagent strip biosensor for protein analysis.⁴⁹ More recently, Xu *et al.* have reported the rapid identification of lipopolysaccharide using the different binding affinities between two aptamer-functionalized AuNPs.⁴⁵

In addition, nanomaterials are fascinating in terms of their composition-, size-, and shape-dependent properties. For example, mesoporous silica nanoparticles (MSN) were designed as promising carriers due to their unique characteristics, such as high loading capacity, biocompatibility, high thermal stability, uniform porosity, adjustable pore size (2–10 nm), and easy functionalization of internal and external surfaces.⁵⁰ Therefore, silica nanoparticles have also become an important platform for biomedical

Table 1 Specific categories of functionalization of several functionalized nanomaterials

Aptamer-nanomaterials	Immobilization and features	Application	Ref.
Magnetic nanoparticles (e.g. Fe_3O_4 , g- Fe_2O_3)	Specificity and magnetism (high throughput separation capabilities)	Used as imaging agents Magnetic fluid hyperthermia therapy	29 30

applications and biological analysis. Dinarvand and co-colleagues developed aptamer-functionalized polyethylene glycol coated superparamagnetic iron oxide nanoparticle (SPION)/mesoporous silica core-shell nanoparticles for simultaneous targeted cancer therapy and magnetic resonance imaging for the development of nanomaterials with thermal diagnostic capabilities.⁵¹

Precise control the structure of metal nanomaterials is also of great significance for the development of advanced nanobiological technologies. Some assembly techniques have been shown to provide methods for the immobilization of nanoscale particles and to obtain highly dispersed nanomaterials.^{52,53} Countless functional aptamers were constructed by coupling interactions linking the building blocks or by modulating their agreement pattern. The breakthrough related to the assembly of functionalized nanomaterials with synthetic aptamers which allowed a series of new physical and chemical properties to emerge, including mechanical, wetting, optical, magnetic and electrical properties. Therefore, the functional performance of AFN assemblies has allowed practical applications to be expanded and improved.⁵⁴

Numerous studies have shown that aptamers, DNA/RNA-zymes or aptazymes can generally induce assembly of nanomaterials.^{55–58} To date, the DNA molecule is probably the most widely used novel biomolecular material designed to regulate structure and self-assemble. DNA-based sequence-oriented functional features may include specific recognition properties, catalytic functions, reactions to enzymes or sequence-specific binding of proteins; these unique functional oligonucleotides are widely used to develop DNA-based sensors, construct DNA machines and assemble DNA nanostructures.⁵⁹ Some studies have shown that DNA can mediate surface functionalization, shape-controlled synthesis, and collaborative assembly of nanoparticles, such as specific biological probes. In 2013, two different self-assembly methods for the preparation of red or yellow nucleic acid stable Ag NC nanowires were reported.⁶⁰ As shown in Fig. 1, they used two different approaches to prepare functional template nanowires, including the hybridization-polymerization reaction or the hybridization chain reaction. This study confirmed that DNA provides a functional template for the deposition of orderly and stable Ag nanowires, which led to the production of DNA nanowires, which have adjustable luminescence functions. This research laid the foundation for the development of multiple DNA (or aptamer) analysis schemes based on luminescent nucleic acid stable Ag NC nanowires, and other sequence-specific metals (e.g., Au, Cu) can also be implemented. In addition, one study recently described double-stranded DNA molecules (dsDNA) designed to be anchored on AuNPs to regulate the crystallization of gold atoms from the surface of AuNPs to the end of DNA; mainly driven by the distribution gradient of the gold precursor. Furthermore, star-like AuNCs (nanometer stars) can be synthesized by single or multiple branches under the guidance of linear dsDNA.⁶¹ This study reports that DNA, as a molecular regulator of nanocrystalline growth, makes possible the synthesis and design of metal nanocrystalline in biomedical imaging, optical antenna and biomolecular sensors. Modification of nanoparticles by specific

aptamers has advantages in different application fields. The properties of aptamer-modified nanoparticles can be used in biosensors. If cell-specific aptamers are used, the resulting conjugates can be used for cell targeting, targeted drug delivery and so on.

3. Properties of aptamer-functionalized nanomaterials

Systems based on AFN composites not only have the dual properties of aptamers and nanomaterials, but also have many new properties, such as high affinity, strong degradation and high cell uptake between functionalized nanomaterial complexes and targets. The properties of these functionalized nanomaterials may play a key role in biomedical applications; for example, the efficient self-delivery to cancer cells is the first condition for exploring the intracellular environment.^{62,63}

3.1 Large specific surface area and abundant, easily accessed metal sites

With decrease in particle size, the specific surface area of nanomaterials increases greatly, and the number of surface atoms has also increased substantially as a proportion of the total number of particles. An increase in the total number of surface atoms will lead to an increase in the coordination unsaturated properties of surface atoms, which will result in a large number of suspended bonds and unsaturated bonds. Surface defects also increase. Therefore, nanomaterials have higher catalytic activity compared with large-scale catalysts. Gold, for example, has long been considered a low-activity catalytic material, but when gold is dispersed to the nanometer level, it can show high catalytic activity. AFNs also possess these properties, having a large surface area and depending on the unique size and shape, as well as the physical and chemical properties of the composition.⁶⁴ Many different materials can attach biomolecules, such as aptamers, through a variety of surface chemical reactions. One reason for the specific fixation of the aptamer on the surface of the nanostructure may also be that the large surface area of the material increases the density of the aptamer on the material, thus increasing the area of interaction between the aptamer and the target analyte. Another major reason is that the combination of the intrinsic properties of nanostructured materials with the binding properties of immobilized aptamers provides possibilities for a variety of applications.

3.2 Conformational flexibility

In general, aptamers can change their secondary structure after being combined with the target, folding into a unique secondary or three-dimensional structure, giving them high affinity and specific binding abilities toward their corresponding targets.⁶⁵ Target binding can induce significant conformational changes in aptamers, and based on these conformational changes, targets can be detected. Many efforts have been made to design and build

various logic gates. Based on the conformational flexibility, this has led to a breakthrough that enables most logic devices that could previously perform only one operation to perform the operation of multiple universal logic devices. Our group hypothesized that two or more different sizes of fluorescent transmitters can be formed by undergoing structural changes in a single DNA template in some cases. We reported cationic K^+ , H^+ , which induced a hair clip DNA template (called HP26) into structural change, regulating the preparation HP26-stabilized Ag fluorescence behavior as shown in Fig. 2.⁶⁶ This study suggested the idea of constructing more logic devices by changing the specific sequence of DNA stabilizers to construct logic devices.

3.3 High affinity and specificity

The high affinity and specificity of aptamers toward targets is generally achieved by a combination of molecular shape complementarity, hydrogen-bonding interactions, and stacking

interactions.⁶⁷ Based on the specific binding properties of an aptamer, Yao and co-workers reported a method used to detect three different chemicals; adenosine, dopamine and 17β -estradiol.⁶⁸ In the study, Ru complexes and quantum dots (QDs) were used as fluorescent probes. Ru complexes can quench the fluorescence of QDs, and QDs also preferentially bind to the adaptive DNA, resulting in an increase of the fluorescence of QDs. When the aptamer is specifically bound to the target, the Ru complex is in an unbound state, so the fluorescence of QDs is quenched. This method has the advantages of requiring no label, having low cost, high selectivity and repeatability, which make it significant.

3.4 Biocompatibility

Biocompatibility is the degree that a material is compatible with the human body after implantation. That is, whether it will cause toxic effects on human tissues.⁶⁹ Biomaterials are an

important technology, allowing the development of tissue engineering, while their respective biocompatibility and host reaction are key factors for the use of biomaterials in tissue engineering. However, because important concepts around biological reactions, infections, surface interactions and material properties are still poorly understood, this limits the application of medical materials. Therefore, biocompatibility is urgently needed for further development, not only because of its importance in interdisciplinary science but also because of its importance in medicine and various other applications.⁷⁰ In addition, materials interact with tissues through cell adhesion, and the biocompatibility of materials is also closely related to cell adhesion.⁷¹ Therefore, the first problem to be solved in developing new materials and modifying surfaces to create devices that are responsive to the environment is surface biocompatibility. At present, many methods of improving biocompatibility by surface modification have been reported. but there are still many challenges to overcome. Surface biocompatibility is important; for example, the properties of bulk materials need to be carefully considered when selecting biomaterials for specific purposes. Other functions such as self-cleaning, intelligent healing, self-repair, control of degradation and function are also important. In addition, the toxicity of these materials requires further study.

4. Applications of aptamer-functionalized nanomaterials

Due to the unique size and structure of functionalized nanomaterials, they have many physical and chemical properties that traditional materials do not, including a surface effect and small size effect, quantum size effect and macroscopic quantum

tunneling effect, for example. Combining nanomaterials with aptamers can effectively improve selectivity and sensitivity of AFNs.

4.1 Catalysts

Some molecular recognition components, generally including nucleic acid enzymes and proteins, have catalytic properties. For example, catalytic DNA is a kind of functional DNA with catalytic properties. These components can catalyze different kinds of chemical and biological reactions, including cleavage of nucleic acid substrates, small molecule decomposition, nucleic acid ligation, nucleic acid structure rearrangement and porphyrin metalation. Because of its unique catalytic properties and extensive catalytic action, catalytic DNA has been widely used in biosensors, disease diagnosis and nano-structure assembly.

DNAzyme is one of the most widely used synthetic functional nucleic acids, which can simulate the catalytic activity of enzymes, and had attracted extensive research in the past 20 years. To date, several strategies for the regulation of catalytic DNA activity have been proposed.⁷² Guo *et al.* reported thermosensitive catalytic systems in which the surfaces of AuNPs are simultaneously modified with a thermoresponsive polymer, poly(*N*-isopropylacrylamide) (pNIPAM), and catalytic DNA.⁷³ The system is designed to regulate the catalytic activity of DNA by changing the temperature. The results show that the catalytic activity in the designed catalytic system is greatly affected by temperature. A thermosensitive pNIPAM on the surface of AuNPs enables controlled catalytic activity over a narrow temperature range. The catalytic DNA/pNIPAM/AuNP

system has little catalytic activity at temperatures lower than the pNIPAM critical solution temperature (LCST). When the temperature rises above LCST, it shows high catalysis.

However, the relatively high cost of DNAzymes limits its broad potential applications, particularly in everyday sensing applications and in mass production based on DNAzyme catalysis. In addition, most DNAzyme-based sensing or catalytic systems require homogeneous reactions in aqueous solutions, which makes the recovery of these biocatalysts difficult. Therefore, the development of renewable and recyclable DNAzyme-based catalysts is of great significance. Based on this vision and previous works, the Guo group also reported high catalytic and recyclable DNAzyme functionalized pNIPAM microgels, prepared by one-step precipitation polymerization. pNIPAM/DNAzyme microgels have high catalytic activities in aqueous solution at room temperature.⁷⁴ When the temperature is higher than the critical solution temperature of pNIPAM, the catalyst will become hydrophobic and separate from the reaction mixture, which is conducive to the

recovery of the catalyst. This strategy will pave the way for building low-cost, high-performance DNA biocatalysts for biometrics and biosensors, and may help in the development of low-cost DNA-based catalysts and purification technologies. As shown in Fig. 3, these pNIPAM/DNAzyme microgel catalysts maintained an initial catalytic activity of 80–91% after eight cycles.

In addition, DNA also has been reported as a template. The Huang group developed a simple, one-step strategy for the rapid synthesis of DNA template copper nanoparticles (Apt-CuNPs), showing selective targeting and high catalytic activity of peroxides, and it can be used to detect thrombin as shown in Fig. 4.⁷⁵ Interestingly, Apt-CuNPs were rapidly oxidized to Apt-CuO/Cu₂O NPs, showing intrinsic peroxidase activity in the presence of H₂O₂. Using Mucin-1 binding aptamer-templated CuO/Cu₂O NPs, they finally applied the sensing platform to detect Mucin-1-overexpression in tumor cells. This study suggests that the Apt-T_n can be used as a universal template for the preparation of enzyme-like CuO/Cu₂O

NPs for the detection of proteins and the labeling of tumor cells when using appropriate aptamers.

4.2 Imaging

In order to understand cell function, pathology, disease diagnosis and drug discovery, it is important to be able to monitor the distribution of biomolecules within cells. Cell imaging is a useful approach in understanding the spatial distribution of biomolecules in cells. Imaging using nanomaterials as contrast agents visualizes structures and helps clinicians describe and recommend appropriate treatments.^{76,77} We previously reported the water-soluble DNA encapsulated Ag NCs with near-infrared (NIR) fluorescence, which can be used for simultaneous targeted cancer imaging and enhanced photothermal therapy (PTT) or photodynamic therapy (PDT) due to the synergistic effects between the photodynamic agent and NIR Ag NCs.⁷⁸ In the study, AS1411 was reasonably connected with the DNA scaffold of the Ag NC, retained its secondary structure, and effectively loaded photosensitizer. The binding affinity of AS1411 to the nucleolin with high fluorescence of Ag NCs provided opportunities for their application in the intracellular imaging and nuclear staining. In addition, Li *et al.* reported the reconfigurable bioinspired framework nucleic acid (FNA) nanoplatform, dynamically manipulated in living cells for subcellular imaging.⁷⁹ They built an FNA logic device on the nano-scaffold of a DNA triangular prism. By using an i-motif and an ATP-binding aptamer (ABA) incorporated into the DTP scaffold, this FNA device logically responds to the changes of lysosomal pH and ATP levels modulated by external stimuli. Once two tetrahedral DNA nanostructures enter the acidic lysosomes of living cells, they assemble into a heterodimer structure to form a larger framework, which allows subcellular imaging under the action of endogenous ATP. Recently, the authors also reported a lysosomal recognition FNA nanometer device as shown in Fig. 5.⁸⁰ The i-motif and ATP-binding aptamers bind to the DNA triangular prism as logical control units. Once inside the lysosomal vesicles, FNA devices respond to lysosomal pH and ATP by folding i-motif and ATP-binding aptamers and inducing structural changes in FNA and releasing the reported structures of subcellular imaging. This work addresses the challenge of how to control their activation within a specific cell interval.

Cell-type-specific imaging is also reported in intracellular imaging. Zhu *et al.* propose a simple one-pot method for the synthesis of AS1411 functional AgNCs with good fluorescence properties as shown in Fig. 6.⁸¹ They demonstrated that AS1411 functionalized AgNCs could be internalized into MCF-7 human breast cancer cells and specifically stain the nuclei red. Due to the simple synthesis process and the ability to identify specific targets, this fluorescent platform has the potential to expand the application of AgNCs in biosensors and bioimaging.

Aptamers have been proven to be promising molecular probes for *in vivo* cancer imaging. However, the application of aptamers *in vivo* may be limited by the lack of physiological temperature affinity in human plasma and the degradation of aptamer nucleases; some aptamers-functionalized nanomaterials also have been developed for *in vivo* imaging. Zhang *et al.* assembled a three-way junction (3-WJ) RNA-human epidermal growth factor receptor 2 (HER₂)apt-siMED1 nanoparticle to target HER₂-overexpressing human breast cancer *via* an HER₂ RNA aptamer to silence MED1 expression, and found that these ultra-compact RNA nanoparticles were very stable under RNase A, serum and 8 M urea conditions.⁸² In *in situ* xenograft mouse models, these biosafety nanoparticles effectively target and penetrate tumors that overexpress HER₂ after systemic administration.

4.3 Pesticide detection

The application of traditional analytical techniques is limited due to the long time consumption, large reagent consumption, complex sample preparation and expensive instrumentation. Therefore, it is of great importance to realize a sensitive, fast and simple detection method. Biosensors with an adaptive recognition unit are called aptamer sensors. Since the aptamer has many unique features, such as unique characteristics and chemical structure, they are widely used to detect biomarkers or factors associated with food, medicine, disease and cancer cells in analytical fields, and are an ideal choice for analysis equipment and technology. Aptamers can bind to different targets such as metal ions, small molecules, proteins, live cells, viruses and bacteria with high affinity and specificity. The use of nanomaterials that are functionalized with aptamers for the selective and sensitive detection of analytes such as small

molecules, metal ions, proteins, and cells has been demonstrated.^{83–85} Nanomaterials add signal transduction, as well as signal amplification. Some researchers have proposed that the use of multiple molecules (aptamers, small molecules, polymers, and biopolymers) to prepare functionalized nanomaterials should be a worthwhile attempt to overcome non-specific interactions of pristine aptamers and stabilize functionalized nanomaterials while maintaining their biological functions.⁸⁶ Replacement of nucleic acid aptamers or DNA sequences may lead to the application of this sensing strategy for different target detection. Lin and co-workers reported a chemiluminescence assay with dual signal amplification, which was developed based on multi-DNAzymes-functionalized AuNPs using *in situ* rolling circle amplification (RCA) for the ultrasensitive detection of thrombin on a microchip.⁸⁷ The linear range of

thrombin chemiluminescence detection was good, ranging from 1 to 25 pm, and the detection limit was as low as 0.55 ppm. Furthermore, multi-channel microchips improve the reaction efficiency and shorten the detection time. Lu *et al.* reported biosensing based on label-free aptamers and AuNPs for the detection of *Escherichia coli* (*E. coli*) O157:H7 and *Salmonella typhimurium*. The target bacteria binding aptamer was adsorbed on the unmodified AuNP surface to capture the target bacteria. The detection was carried out by inducing the appropriate aggregation of the target bacteria. The color of the aptamer changed from red to purple under high salt conditions.⁸⁸ Pollution due to pesticides has caused wide public concern, because of the extensive use of pesticide in agriculture in order to increase crop yields and improve the quality of agricultural products. The biosensors can achieve the highly sensitive and rapid detection of pesticides without complex sample

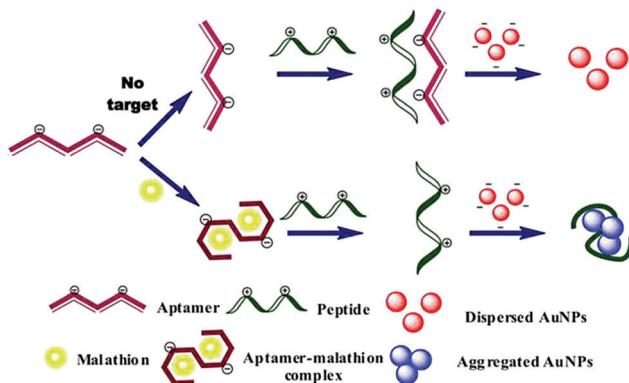

Fig. 7 Schematic illustration of colorimetric assay for malathion based on aptamer, cationic peptide and AuNPs. The AuNPs remain red in the absence of malathion due to the interaction of aptamer and peptide, whereas in the presence of malathion, the color of the particles becomes blue as the aptamer binds to malathion and the peptide is free to aggregate the particles. Image reprinted from ref. 91 with permission. Copyright 2016 Elsevier.

preparation.^{89,90} Over the past few decades, a great deal of work has been done to develop qualitative/quantitative methods for the detection of chemical contaminants in food. The Wangoo group reported a study using aptamers, cationic peptides and unmodified AuNPs to detect malathion, a toxic organophosphorus pesticide widely used in agriculture, as shown in Fig. 7.⁹¹ When attached to the appropriate body, the peptide disassociated the AuNPs, giving them a red color. However, when the aptamer binds to malathion, the peptide can still be used to cause the aggregation of nanoparticles and turn the suspension blue. The method used optical changes of AuNPs to detect malathion colorimetry. It was found that the method was linear, with a detection limit of 1.94 pM in the range of 0.01–0.75 nM.

4.4 Lab on a chip

In situations where medical diagnosis and food safety require quick and on-site results, electrochemical biosensors and associated on-chip laboratory equipment are the preferred analytical systems for environmental protection, process control, wastewater treatment and life science discovery research.⁹² To date, reports have also highlighted that lab-on-a-chip (LOC) biosensors have great application potential because they can be miniaturized and automated. They also have the potential to be fast and very sensitive. Some samples may require a more complex preparation process in order to separate or enrich the target analytes with a minimum of distractors before reaching the sensor unit, ultimately improving the analytical performance. LOC is a platform that allows integration of these modules, providing a robust automation system for the required applications. Because a LOC system can perform the complete analysis of a sample, the components of each system are selected based on the analysis. LOC systems typically contain microfluidic channels for sample transport. On the basis of analyzing the problem, the microfluidic system and LOC system are combined. The most important characteristics of the analytical LOC system are the sample preparation, separation and detection.

Recently, Primiceri *et al.* reported that biochips can be used to quantify two of the most common food-related pathogens; *Listeria monocytogenes* and *Staphylococcus aureus*. They all come from suspension of bacterial stationary phase broth culture. The detection limit of *L. monocytogenes* was 5.00 CFU ml⁻¹, and the detection limit of *S. aureus* was 1.26 CFU ml⁻¹.⁹³ Their platform could be a promising real-time medical device for clinical and food diagnostics, but also for biosafety purposes. Malhotra *et al.* reported the preparation of a label-free chip impedance laboratory (iLOC) for low density lipoprotein (LDL) detection from protein (bovine serum albumin) and an apolipoprotein-B-functionalized carbon nanotube nickel oxide (CNT–NiO) nanocomposite, as shown in Fig. 8.⁹⁴ The cytotoxicity of CNTs, NiO nanoparticles and CNT–NiO nanocomposites synthesized in the presence of lung cancer A549 cell lines was studied using the 3-(45-dimethylthiazol-2-yl)-25-diphenyl tetrazolium bromide (MTT) method. CNT–NiO nanocomposites showed higher cell viability at concentrations of 6.5 g ml⁻¹ compared with those using single CNTs. Cell viability and proliferation studies showed that the toxicity of CNTs increased with concentration. This iLOC shows excellent sensitivity of 5.37 kΩ (mg dL)⁻¹ and a low detection limit of 0.63 mg dL⁻¹ in a wide concentration range (5–120 mg dL⁻¹) of LDL. The binding kinetics of antigen–antibody interaction of LDL molecules reveal a high association rate constant (8.13 M⁻¹ s⁻¹). Thus, this smart nanocomposite (CNT–NiO)-based iLOC has improved stability and reproducibility, which has implications toward *in vivo* diagnostics.

4.5 Nanomedicine

Nanomaterials can protect the aptamer from the digestion of nucleases, so the AFNs can be used as drug or gene carriers. Drug-carrying nanoparticles can sustain drug release, prolong drug action time and improve target delivery.⁹⁵ They can even improve the target location effect.⁹⁶ Compared to bulk materials, nanoparticles are more likely to penetrate membrane cells and travel along nerve cell synapses, blood vessels, and lymphatic vessels. At the same time, nanoparticles accumulate selectively in different cells and certain cell structures. The use of nanoparticles for highly permeable drugs provides effectiveness.

Drug delivery is an important part of medical treatment. Compared with AFNs, aptamers without modification are more easily degraded by nucleases *in vitro*, and as a small molecule, it is easily filtered by the kidneys. By loading the nanomaterials, it can overcome the inherent shortcomings of these aptamers. Most modifications to the aptamers aim to improve affinity, potency and metabolic stability.⁹⁷ A key attribute of therapeutic aptamers is the ability to adjust pharmacokinetic characteristics by regulating metabolic stability and by adjusting renal clearance and distribution rates. There have been several reviews on the discovery of aptamers, their general pharmacological properties, and even recent advances in improving the properties of aptamers.^{98–103} Among them, AFNs are being developed as a promising platform for targeted therapy and diagnosis, finding a way to overcome the problem.

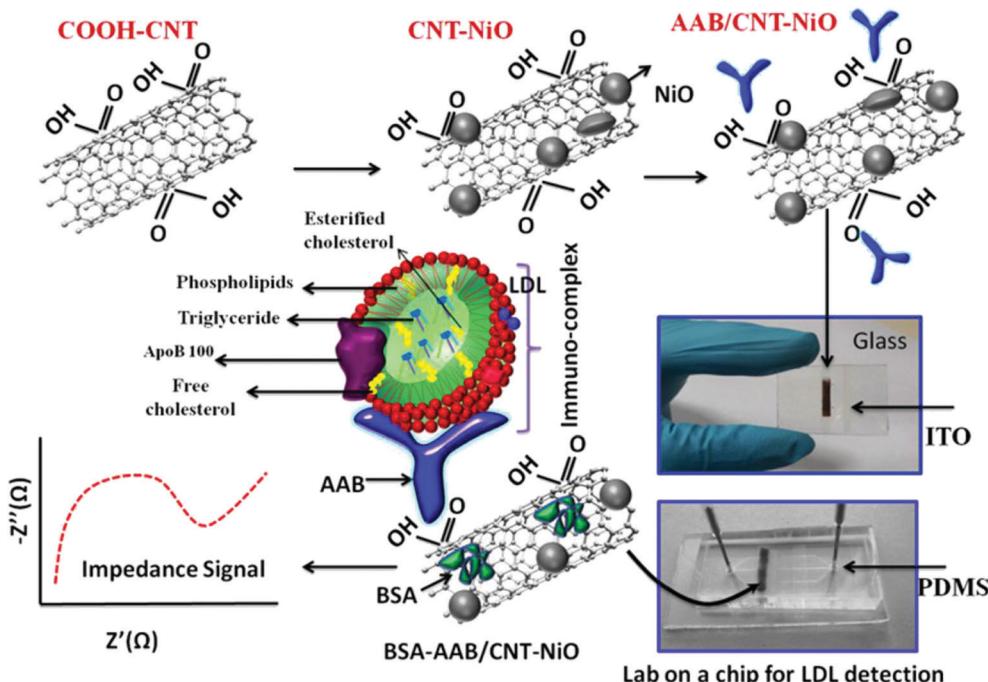

Fig. 8 Schematic representation of the lab-on-a-chip fabrication for LDL detection. Image reprinted from ref. 94 with permission. Copyright 2015 American Chemical Society.

A prominent application of AFNs is cell targeting. There are numerous aptamers currently available for various cellular targets. Targets can be cell-surface binding proteins, viruses, *etc.* With nanomaterials as drug carriers, they can be used together with detection instruments or devices, such as fluorescence. Nanomaterials can improve drug stability and reduce toxicity and side effects. At present, the development of a multi-functional nano-platform has been used in biomedical research.^{104,105} Aptamer-guided nanomedicine shows great promise without affecting the homeostasis of the physiological environment or the integrity of the nearby tissue in targeted cancer therapies. In the case of delivery, nanoparticle-based carrier systems have a unique ability to cross biological barriers. Therefore, nanoparticles can leak into the tumor through its localized blood vessels and be retained due to poor lymphatic drainage in the tumor microenvironment. Tan *et al.* reported a study on how the physiological environment affects targeting to investigate the loss of such targeting. Aptamer-functionalized AuNPs were selected as models and exposed to human serum to simulate the physiological environment.¹⁰⁶ Liposomes are considered to be one of the most successful nanoplatforms for drug delivery due to their similarities with the structure and function of cell membranes, and have been used to transfer a variety of small molecules, genes, and even nanoparticles.^{107,108} MSN is a kind of surface porous structure material. When MSN is used as a carrier, internally packaged drugs are released by using different pore inhibitors and respond to different stimuli, including pH, temperature, light, enzyme and competitive binding.^{109,110} Aptamer-modified fluorescein molecules or other materials can be applied to imaging localization, and the aptamer can be used for therapy. Because of the advantages

of non-toxicity, rapid targeting and rapid diffusion through blood circulation, this can increase the certainty of diagnosis, treatment and clinical analysis. Furthermore, AFNs have been widely used in tumor therapy and have attracted extensive attention. Different approaches, including chemotherapy, photodynamic therapy, gene therapy and immunotherapy, have been reported in terms of therapy. Shen *et al.* presented the aptamer-functionalized Fe_3O_4 @carbon@doxorubicin NPs (Apt- Fe_3O_4 @C@DOX), and its application results in cancer synergistic chemotherapy (PTT).¹¹¹ It has a strong ability to transform 808 nm NIR light into heat, according to energy spectrum analysis of drug release, meaning that the aptamers act as markers that allow the cancer cells to target DOX to attack a chemotherapy drug. The diversity of aptamer targets and the ease of modification are thought to make this strategy attractive for cell-based delivery and therapy. Chen *et al.* developed a novel aptamer-targeted light-response drug delivery system, namely the non-covalent assembly of the cy5.5-as1411 aptamer on the surface of GO coated doxorubicin loaded mesoporous silica nanoparticles (MSN-Dox@GO-Apt) for light-mediated drug release and aptamer-targeted cancer therapy.¹¹² The two switches of MSN-Dox@GO-Apt are respectively controlled by the appropriate body targeting and light triggering. The Cy5.5-AS1411 ligand provides MSN-Dox@GO-Apt with nucleoside specific targeting and real-time indication by turning off the Cy5.5 fluorescence recovery function. In the absence of laser light, GO acts as a gatekeeper, preventing the load of GO from leaking, and controlling its release under laser light. When the GO coating falls off under laser light, the “switch” photosensitive drug delivery system is activated, inducing chemotherapy. Interestingly, with increased laser power, the synergistic effect of chemotherapy and photothermal therapy on a single

Fig. 9 Schematic illustration of GO-wrapped DOX-loaded MSN- NH_2 bound with Cy5.5-labeled AS1411 aptamer and the corresponding NIR light-controlled intracellular drug release. The two “off-on” switches of MSN-Dox@GO-Apt were controlled by aptamer targeting and light triggering, respectively. Image reprinted from ref. 112 with permission. Copyright 2015 Royal Society of Chemistry.

MSN-DOX@GO-Apt platform was more effective than mono-therapy in killing cancer cells, providing a new approach to cancer treatment (Fig. 9).

However, despite many exciting and dramatic developments emerging at the moment, these functional nanomaterials still face many challenges in the further clinical application of cancer therapy. One of the most important issues is the potential long-term safety of nanomaterials. In particular, non-biodegradable inorganic materials remain in the body for a long time after administration. In addition, the future of cancer treatment is likely to rely on the combination of a series of different treatments, including surgery, chemotherapy, radiation therapy, gene therapy, as well as heat and light power therapy. As a result, the development of multi-functional nanocarriers that can combine different therapeutic mechanisms to treat tumors brings great opportunities for a new generation of cancer therapies.

4.6 Chemiluminescence

Aptamer-functional nanomaterials with chemiluminescence properties have attracted increasing attention from researchers due to their excellent chemiluminescence properties, good stability and reproducibility. Currently, due to the incomplete recognition of the binding site and conformation change of the target ligand after binding, it is difficult to observe the marker site, and even labeling or modification reduces the binding affinity between the target and its adapter, thus reducing sensitivity and creating other problems. Facing this kind of challenge, chemiluminescence (CL) has attracted the attention of many researchers.

CL is an effective and powerful analytical technique with extremely high sensitivity and other advantages, such as simple

instrumentation. CL does not need an external light source to generate a signal. In fluorescent assays, aptamers can serve as recognition moieties and control the distance between quenchers. In recent years, a few aptamer-based sensing platforms have been proposed to use in CL detection. For example, Li *et al.* reported a label-free, aptamer-based chemiluminescent biosensor, which relies upon the catalytic activity of unmodified AuNPs on the luminol- H_2O_2 CL reaction, and the interaction of unmodified AuNPs with the aptamer.¹¹³ Wang *et al.* developed a highly specific and sensitive CL aptamer sensor for sulfamethazine (SMZ) by taking advantage of the supernormal selectivity of a new selected aptamer.¹¹⁴ Finally, the aptamer sensor was applied to milk samples, and the accuracy was better. In addition, AS1411 is a versatile bioassay aptamer, which has been applied to the chemiluminescence detection of nucleosides on the surface of HeLa cells. In view of this condition, our group previously carried out a study and proposed a new method to prepare AS1411 G-quadruplex and folic acid-double-targeted fluorescent gold nanocomposite (AF-D-AuNP) with DOX.¹⁰⁴ In this study, AF-D-AuNP cover support AS1411 was successfully developed and shows significant potential in the early detection of cancer due to its high light bleaching. Sancenón and co-workers developed a novel sensing nanometer probe for the selective sensitive detection of As(III) based on the combination of aptamer and MSN.¹¹⁵ The sensing mechanism depends on the specific interaction between the capped-shaped aptamer (ARS-3) and As(III). The efficiency of the sensor has been verified under environmental conditions, showing great potential in As(III) monitoring. The prepared nano-probe showed a remarkable limit of detection of 0.9 PPB. The authors believe that the method is simple and easy to use and has potential applications (Fig. 10).

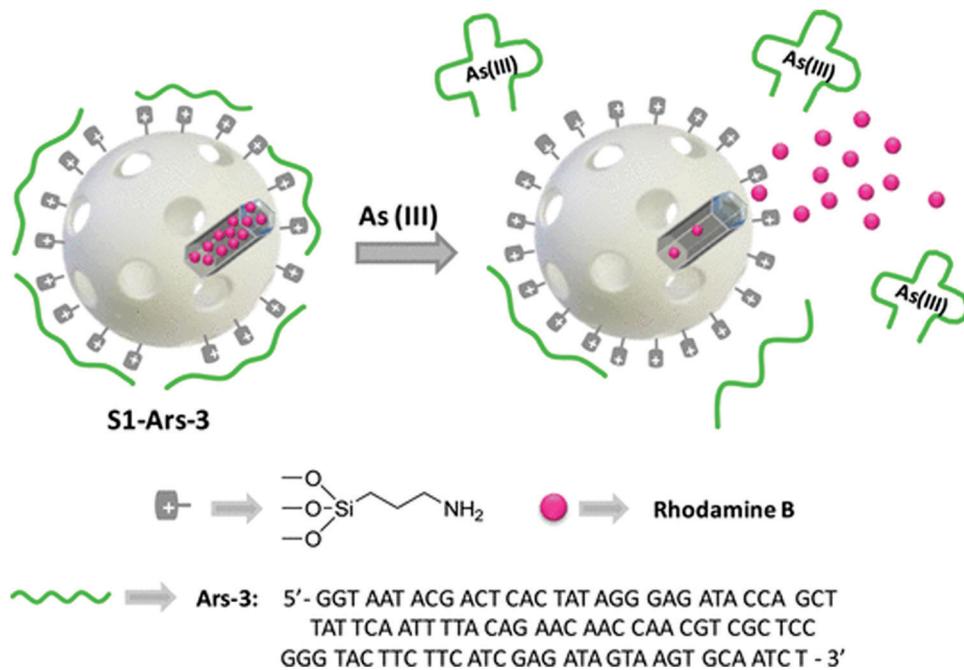

Fig. 10 Representation of the gated material S1-Ars-3 functionalized with aminopropyl moieties and capped with Ars-3 aptamer. Delivery of the entrapped dye (rhodamine B) is specifically accomplished in the presence of As(III). Image reprinted from ref. 114 with permission. Copyright 2014 American Chemical Society.

5. Conclusions and perspective

An aptamer is an oligonucleotide sequence that can be specifically bound to a target object, easily synthesized *in vitro*, and modified by various simple chemicals. Because the aptamers are non-immunogenic and non-toxic, and the types of target aptamers are not restricted, they can be used in the diagnosis and treatment of diseases in the field of biological applications. Based on all these advantages, AFNs have become increasingly important molecular tools for diagnosis and treatment. In this review, we discuss the development of AFNs in catalytic, biosensing, imaging, targeted drug delivery and cancer cell treatment. Despite the many exciting and compelling developments that are emerging at the moment, several challenges and important issues still need to be addressed further: (1) To develop further synthetic strategies for the preparation of AFNs. Since the immobilization of the aptamer may interfere with its combined properties, the aptamer density, aptamer orientation, surface charge and steric hindrance should be considered. (2) To improve efficiency *via* optimizing the AFN. Its main purpose is to solve the problem of optimal binding performance after the aptamer is fixed on the carrier. (3) To explore novel physical-chemical properties of AFN structures. Further consider combining materials of different dimensions (one-, two-, three-) to construct unique properties. (4) To promote the development of practical applications of AFNs; for example, to solve the problem of toxicity of AFNs. So far, various efficient and practical AFN engineering technologies have been developed. These nanoscale devices have proven to be ideal tools for various biological applications, with good

biocompatibility, high endocytosis efficiency and high affinity for target analytes. In the future development of nanomaterials, increasing attention will be paid to the preparation of new nanomaterials and the improvement of aptamer properties.
