Two novel ACE inhibitory peptides isolated from longan seeds: purification, inhibitory kinetics and mechanisms†

Atthasith Nuchprapha,^a Supawee Paisansak,^a Papassara Sangtanoo,^b Piroonporn Srimongkol,^b Tanatorn Saisavoey,^b Onrapak Reamtong,^c Kiattawee Choowongkomon^d and Aphichart Karnchanatat  ^b

Angiotensin converting enzyme (ACE) inhibition offers a useful means of managing hypertension, because ACE inhibitors (ACEIs) are known to serve as agents with antihypertensive properties in addition to generating positive metabolic and cardioprotective outcomes. However, current ACEIs are linked to adverse consequences, and so there is a requirement for effective but safer compounds, which might be achieved through chemical synthesis or the isolation of naturally obtained bioactive molecules. Protein hydrolysates with ACEI activity can be produced by the combined pepsin and pancreatin proteolysis (to mimic gastrointestinal digestion) of longan seed protein. This study examined longan seed protein hydrolysates, obtained from a sequential 3 h digestion with pepsin and then pancreatin. The resulting hydrolysate underwent sequential ultrafiltration membrane fractionation with a 10, 5, and 3 kDa molecular weight cut-off (MWCO). The permeate derived from the <3 kDa MWCO demonstrated the highest ACEI activity. This permeate subsequently underwent separation by reverse-phase high performance liquid chromatography to give the main fractions on the basis of differing elution times. The ACEI IC_{50} values for these fractions were then identified. Quadrupole time-of-flight tandem mass spectrometry was employed to determine the peptide mass for the major peak (F_5), which was shown to be Glu–Thr–Ser–Gly–Met–Lys–Pro–Thr–Glu–Leu (ETSGMKPTEL) and Ile–Ser–Ser–Met–Gly–Ile–Leu–Val–Cys–Leu (ISSMGILVCL). These two peptides were stable over a temperature and pH range of –20 to 90 °C and 2–12, respectively, for 60 min. From the Lineweaver–Burk plot, both peptides inhibited ACE non-competitively. Molecular docking simulation of the peptides with ACE supported the formation of hydrogen bonds by the peptides with the ACE active pockets. This research indicates that it may be possible to use both of these peptides or longan seed protein hydrolysates in order to create ingredients for functional foods, or to produce pharmaceutical products, capable of lowering hypertension.

1. Introduction

Hypertension, or high blood pressure, accounts for more than 20 million visits to doctors annually. The condition afflicts all age groups, although the elderly tend to be more significantly

affected, with the incidence rising in those over 50 years old. It is believed to be the most common of all the cardiovascular disorders, with around a billion people globally affected to some degree, and is a significant contributor to both morbidity and mortality. There are no recognizable symptoms, and so it can be difficult to diagnose hypertension, which makes management of the condition difficult.¹ Numerous cardiovascular diseases (CVD) have been linked to hypertension, including arteriosclerosis, congestive heart failure, end-stage renal diseases, coronary heart disease, stroke, and myocardial infarction. In addition, it can also be a cause of abnormal renal function and ultimately lead to renal failure.^{2,3}

Blood pressure can be regulated by angiotensin I-converting enzyme (ACE; EC 3.4.15.1) *in vivo* operating *via* the renin–angiotensin system (RAS) along with the kallikrein–kinin system (KKS). Within the RAS, the release of the vasoconstrictor angiotensin II from the cleavage of the C-terminal dipeptide from angiotensin I is performed by ACE. Meanwhile, in the KKS,

ACE serves to inactivate the vasodilator bradykinin by removing the two C-terminal dipeptides.^{4,5} As a result, ACE-inhibitors (ACEIs) can be employed for the purpose of reducing blood pressure. There are several synthetic ACEIs that have been employed to treat hypertension in human patients, but the drawback is that they can induce various side effects, including coughing, hypotension, heightened serum levels of potassium, and abnormalities of the fetus.^{6,7} Accordingly, it is essential to develop new ACEIs that will provide safe and effective hypertension treatment and, because of the need for safety, there is growing interest in ACEI peptides that can be derived from food.⁸⁻¹⁰

Both the food and non-food sectors are taking an increased interest in proteins derived from plant sources. In the food sector, proteins from soy, legumes, and wheat gluten are very appealing, and the agricultural industry is of interest to other sectors who wish to investigate the extraction of proteins from agricultural by-products. Plant processed waste is often rich in proteins, and so there is an increasing interest in developing nutritional supplements or nutraceuticals from this type of waste, since it can offer strong nutritional qualities along with a number of important amino acids.¹¹ Agricultural by-products might be readily converted into products with applications in other industries. One advantage of using such agricultural by-products to useful ends is that the environmental issues associated with the disposal of such by-products can be eliminated.¹²

Thai fruit is ingrained in the country's cultural identity. Fruit is both plentiful and geographically widespread in Thailand,¹³ and is highly valued as a healthy food product. However, when fruit is processed by the food industry, such as during the canning or drying process, there are waste by-products, including seeds. Those seeds are usually disposed of if they are without value, or are sometimes sold as fuel at minimal prices. Earlier studies, however, have shown that useful nutrients can be stored in seeds.¹⁴ One such example is the longan (*Dimocarpus longan* Lour.), which is a Chinese evergreen plant from the Sapindaceae family. Many tropical countries grow this tree for the fruit and so studies have been conducted to assess whether it offers potential pharmacological benefits to human health, especially through the antimicrobial and antioxidant properties of its seeds.¹⁵⁻¹⁷

Previous works have focused on non-edible seeds from lychee (*Litchi chinensis* Sonn.), which produce a protein hydrolysate offering anti-inflammatory activity,¹⁸ but it is important to determine the active ingredient(s) in such protein hydrolysates, since the findings may be of interest in the both the pharmaceutical sector and food industry. When plant proteins are digested *in vitro* with pepsin and pancreatin, it may be the case that bioactive peptides are produced that can play effective roles in developing certain food products. These enzymes, which are required in the process of human gastrointestinal digestion, might prove informative when considering the production of bioactive peptides when these proteins are digested. Accordingly, this study sought to examine the generation of ACEI peptides resulting from the

digestion of longan seed protein isolates with pepsin and then pancreatin.

The enriched ACEI peptides from the longan seed source was performed *via* membrane filtration and RP-HPLC followed by mass spectrometry sequencing for identification. It was also considered possible that the purified peptide might undergo binding at the ACE active site, if the outcomes of molecular docking experiments are interpreted correctly. It is demonstrated that longan seeds, which have hitherto found few applications, might prove to be nutritionally valuable by yielding bioactive peptides that could treat hypertension. The results obtained in this research study may augment the current information available in the database detailing medicinal plants.

2. Materials and methods

2.1 Materials

The longan seeds used in this study were provided by the Malee Group Public Company Limited (Nakhon Pathom, Thailand). Having obtained the samples, they were held in cold (4 °C) and dark conditions until used. The ACE (E.C. 3.4.15.1) from the lungs of rabbits was supplied by Sigma Chemical Co. (St. Louis, MO, USA). The same supplier also provided the acetonitrile (ACN), bovine serum albumin (BSA), captopril, hippuric acid, hippuryl-L-histidyl-L-leucine (HHL), pancreatin from porcine pancreas, pepsin from porcine gastric mucosa, and trifluoroacetic acid (TFA). All materials used in the study were of analytical grade.

2.2 Preparation of crude protein from longan seeds

The preparation process followed the guidance of Saisavoyey *et al.*¹⁸ commencing with the cleaning and blending of 1.5 kg of longan seeds using 5 L of phosphate buffered saline (PBS; 20 mM phosphate buffer with 0.15 M NaCl pH 7.2). At first, a mixer was employed, followed by overnight stirring at 40 °C with a magnetic stirrer. Filtration was performed using a double-layered cheesecloth in order to obtain a suspension that could be isolated from the liquid. The filtrate was clarified by centrifugation (15 900 × g, 30 min, 4 °C) before harvesting of the supernatant. Ammonium sulfate was then introduced to 80% saturation and left overnight with stirring at 4 °C followed by centrifugation (15 900 × g, 30 min, 4 °C) to harvest the insoluble pellet. The pellet was solubilized in PBS, dialyzed against excessive quantities of double deionized water, and then freeze dried in order to generate the required crude protein.

2.3 Amino acid composition in crude protein from longan seeds

The AOAC 994.12 (ref. 19) and 988.15 (ref. 20) techniques were employed to determine the crude protein amino acid content, whereby 25 mg (dry weight) of longan seed crude protein was dissolved in 5 mL of 6 M hydrochloric acid (HCl) and heated for 24 h at 110 °C. Then 10 µL of 2.5 mM L-amino-n-butyric acid in 0.1 M HCl was added as an internal standard followed by

deionized water to a volume of 250 μ L. This was heated at 55 °C for 10 min prior to analysis using reversed-phase high-performance liquid chromatography (RP-HPLC) with a Hyper-sil GOLD column C18 (4.6 mm \times 150 mm, 3 μ M). Elution was performed with a sodium acetate buffer at pH 4.9 and 60% (v/v) ACN at 0.3 mL min $^{-1}$. The amino acid content was then established by ALS Laboratory Group (Thailand) Co., Ltd., Suan Luang, Bangkok, Thailand.

2.4 Hydrolysis of crude protein by pepsin and pancreatin

Following the technique of Inthuwanarud *et al.*²¹ the crude proteins obtained from the longan seeds served as the substrate for forming the protein hydrolysate. The crude protein preparation (1 mg mL $^{-1}$) was added to pepsin to a final substrate: enzyme concentration ratio of 20 : 1, while the pH was set at 2.5 using 1 M HCl. Hydrolysis was performed for 3 h at 37 °C with shaking at 180 rpm. The activity was then halted by raising the pH to 7.5 through the introduction of 1 M (NaOH). This procedure was then repeated except using pancreatin instead of pepsin, and the reaction was halted by heating at 80 °C for 20 min. The hydrolysates were clarified by centrifugation (15 900 \times g, 30 min, 4 °C) and the supernatant was evaluated for ACEI activity. These enzymic processes are broadly similar to those which would occur naturally inside the human gastrointestinal tract.

2.5 Fractionation of the hydrolysate *via* ultrafiltration

Suttisawan *et al.*²² noted that ultrafiltration can be employed to fractionate pepsin and pancreatin hydrolysates using a high-performance ultrafiltration cell (Pellicon XL Filter; Merck Millipore, Billerica, MA). In this study, three molecular weight cut-off (MWCO) membranes were sequentially employed (10, 5, and 3 kDa MWCO) to create four fractions (>5–10, 3–5, and <3 kDa). Having clarified the fractions by centrifugation (15 900 \times g, 30 min, 4 °C), they were then passed through the 10 kDa MWCO membrane first, recycling the retentate into a second 10 kDa MWCO membrane fractionation. The permeate derived from the 10 kDa membrane was then passed *via* the 5 kDa membrane, recycling the retentate into a second 5 kDa MWCO membrane fractionation. This sequence was then repeated with the 3 kDa MWCO membrane, thus lowering the potential for smaller molecular weight fractions to contaminate the larger fractions.

2.6 Assay of ACEI activity

The technique described by Yodjun *et al.*²³ was used to measure the ACEI activity, whereby 50 μ L of the crude protein derived from longan seeds was combined with an equal amount of ACE (25 mU mL $^{-1}$) and underwent pre-incubation for 10 min at 37 °C. The next step then involved re-incubation for 30 min using 150 μ L of substrate (10 mM HHL in PBS) at 37 °C. The reaction was stopped by the addition of 250 mL of 1 M HCl. The resulting hippuric acid was extracted in 500 μ L of ethylacetate with centrifugation at 15 900 \times g, and 4 °C for 15 min, whereupon 200 μ L of the upper layer was placed in a new test tube at room temperature and evaporated in a vacuum. Once the

hippuric acid had subsequently been dissolved in 500 μ L of double deionized water, the absorbance was measured at 250 nm (A_{250}) using a UV-spectrophotometer. The amount of hippuric acid released in the assay mixture was then determined from the A_{250} value by comparison to a standard curve derived from known hippuric acid concentrations. Captopril was used as the positive control. The equation $100 \times [(C - B_i) - (S - B_s)/(C - B_i)]$ was employed to assess the percentage ACEI activity, where C represents the A_{250} of the control, S indicates the A_{250} of the sample, B_s denotes the A_{250} of the peptide only sample, and B_i indicates the A_{250} of the blank inhibitor. The IC₅₀ value, as the peptide concentration of hydrolysate required to obtain a 50% ACEI activity, was calculated by non-linear regression using the GraphPad Prism Version 6 software (GraphPad Software Inc., La Jolla, CA, USA).

2.7 Assessment of protein content

Bradford's procedure^{24,25} was used to determine the protein content, using BSA as the standard at 5, 10, 15, and 20 μ g mL $^{-1}$ in order to plot the calibration curve. A 50 μ L aliquot of each two-fold sample dilution in deionized water was added to each of three wells in a microtiter plate, followed by the addition of 50 μ L of Bradford's reagent to each of the wells, shaken to mix for 5 min and left to stand for 10 min. The optical density at 595 nm was then measured using an ELISA plate reader and converted to the protein concentration using the linear equation derived directly from the standard curve.

2.8 RP-HPLC

The peptide solution offering the best ACEI activity after ultrafiltration underwent further separation by RP-HPLC (Spectra System, Thermo Fisher Scientific) using a Luna 5U C18 100 A° column (4.6 \times 250 mm, Luna 5 μ M; Phenomenex, Torrance, CA). Samples were filtered through a nylon membrane of 0.45 μ m (Whatman, GE, Buckinghamshire, UK) and loaded into the column at 20 μ L (protein concentration of 1.0–1.50 mg protein per mL). Elution was performed at 25 °C with a three-phase linear gradient of 100 : 0% (v/v) A : B declining to 90 : 10 over 15 min, to 65 : 35 over 30 min, and to 55 : 45 over 40 min with a flow rate of 0.7 mL min $^{-1}$. Mobile phase A was 0.1% (v/v) TFA, while B was 70% (v/v) ACN in 0.05% (v/v) TFA. Chromatographic analysis was performed using ChromQuest Software (Thermo Fisher Scientific). Assessment of the peptide peaks at 280 nm was based upon leaving the baseline until returning to the baseline.

2.9 Liquid chromatography-quadrupole time-of-flight electrospray-ionization tandem mass spectrometry (LC-Q-TOF-ESI-MS/MS) and *de novo* peptide sequencing

The RP-HPLC fraction (F_5) with a strong ACEI activity and sufficient yield was subject to LC-Q-TOF-ESI-MS/MS analysis to identify the peptides after calibrating the tool to identify peptide chains in the mass range of *m/z* 50–25 000 (Model Amazon SL, Bruker, Germany). The evaluation was performed with *de novo* sequencing, while Mascot was used in the analysis of all of the MS data. The sequences which were obtained were

then compared with findings available through the NCBI database using BLASTp.

2.10 Synthesis of peptides

For the two peptides whose sequences were obtained *via* the MS analysis (Section 2.9) their synthesis was performed using a 433A Synergy solid phase peptide synthesizer (Applied Biosystems, CA). The synthetic peptides Glu-Thr-Ser-Gly-Met-Lys-Pro-Thr-Glu-Leu (ETSGMKPTEL) and Ile-Ser-Ser-Met-Gly-Ile-Leu-Val-Cys-Leu (ISSMGILVCL) were first verified through analytical MS (Model Finnigan™ LXQ™, Thermo Fisher Scientific Inc., MA) along with the use of a Surveyor HPLC. These pure synthesized peptides were then screened to confirm and characterize their ACEI activity (Section 2.6) for comparison with that of the peptide fraction obtained from RP-HPLC fractionation (Sections 2.8 and 2.9).

2.11 Peptide properties

For the design of future research, it is important to understand the ACEI peptide properties. It is possible to locate useful parameter scans in the online database. Toxicity analysis of the peptides were performed using the ToxinPred server (<http://crdd.osdd.net/raghava/toxinpred/>), while the online Innovagen server was used to assess peptide solubility (<http://www.innovagen.com/proteomics-tools>).

2.12 Temperature influence on ACE inhibitory activity

Temperature can also affect the ACEI activity, and was evaluated by incubating TSGMKPTEL and ISSMGILVCL in 20 mM phosphate buffer at pH 7.2 at various temperatures (–20 to 90 °C using 10 °C increments) for 60 min. The samples were then cooled to 4 °C before examination of the residual ACEI activity (Section 2.6). The uninhibited mixture, set as 100% inhibition, was used to normalize the attained activities for the positive control, while the negative control was a maximum inhibited mixture (attained how?). Inhibitory activities are reported as relative to the uninhibited mixture activity. All assays had ACE.

2.13 Influence of pH upon ACE inhibitory activity

The pH stability and pH optima for the ACEI activity were assessed through the incubation of ETSGMKPTEL and ISSMGILVCL in buffers at similar levels of salinity but with pH values varying in the range of 2–14 using 20 mM glycine–HCl (pH 2–4), sodium acetate (pH 4–6), potassium phosphate (pH 6–8), Tris–HCl (pH 8–10), and glycine–NaOH (pH 10–12). The respective peptide–buffer mixture was left to stand at room temperature for 60 min before the ACEI activity was ascertained (Section 2.6) and compared to the negative or positive controls and reported as the relative percentage ACEI activity. All assays had ACE.

2.14 Kinetic parameter estimation

The hydrolysis rate for HHL by ACE over a range of HHL concentrations of 0–5.0 mM was measured while varying the concentrations of ETSGMKPTEL and ISSMGILVCL. The data underwent double-reciprocal analysis using the Lineweaver–

Burk plot in order to establish the Michaelis–Menten constant (K_m), the maximum velocity (V_{max}), and the mode of ACE inhibition. The Dixon plot was used to assist in determining the inhibitor constant (K_i) by serving as a representation of the Lineweaver–Burk plot slope.

2.15 Molecular docking of ETSGMKPTEL and ISSMGILVCL at the ACE binding site

Molecular docking was performed using the Hermes 1.10.1 software. The Protein Data Bank (<http://www.rcsb.org/pdb/home/home.do>) provided details of the three-dimensional (3D) crystal structure for a human ACE–lisinopril complex (1O8A.pdb), which had a binding site with a radius of 6 Å capable of serving as the receptor for this research study. Discovery Studio 2.0 software was used to prepare the molecular structures for each of the ETSGMKPTEL and ISSMGILVCL peptides.²⁶ Prior to docking, preparation of the model receptor ACE molecule was performed by removing all of the water molecules, and adding the hydrogen atoms to the receptor model. Molecular docking evaluation was performed by assessing the Goldscore, ChemScore, ChemPLP, and ASP. The binding energy and fitness scores provided the detail to determine the most suitable pose for each of the residues. The hydrogen bonds (H-bonds) were identified with the Discovery Studio 2.0 software (specify the cut-off criteria used to accept a H-bond), along with the nature of the various interactions between the ACE molecules and the peptide residues (hydrophobic, hydrophilic, electrostatic, van der Waals, or coordination interactions).

2.16 Statistical analysis

Each experiment was performed in triplicate, and the findings are presented as the mean \pm one standard error of the mean (SEM). Analysis was performed using SPSS 11.5 statistical software. Hypotheses were tested using one-way ANOVA and the least significant difference (LSD) test accepting significance at the $P < 0.05$ level.

3. Results and discussion

3.1 Longan seeds' amino acid composition

Food proteins that offer suitable levels of amino acids can also potentially be used for antihypertensive purposes. For each specific peptide, the particular function is established by the type of the constituent amino acids along with the R-group differences. In general, longan seeds offer aromatic amino acids in addition to hydrophobic aliphatic amino acids (Table 1), including methionine, isoleucine, alanine, leucine, and proline, which are able to support the ACEI ability of food proteins. Daskaya-Dikmen *et al.*²⁷ stated that a strong ACEI activity is clearly linked to hydrophobic amino acid residues in peptides, especially at the C-terminal position. Moreover, those peptides that contain proline are understood to resist enzyme digestion in the intestines, and can easily reach the blood circulatory system. Manoharan *et al.*²⁸ suggested that the proline found in the C-terminal position of the peptides could bind effectively to ACE molecules. Furthermore, the ACEI drugs that are commercially available, such as captopril and enalapril,

^a Findings appear in the form of mean ± SEM ($n = 3$).

have proline as a part of their structure.²⁹ From analysis of the amino acid composition it was apparent that longan seeds might contain peptides which offer strong ACEI activity.

3.2 Hydrolysis of longan seed protein isolates using pepsin–pancreatin

Pepsin is a proteolytic enzyme released in the stomach, while the pancreas inside the small intestine produces pancreatin, which contains elastase, trypsin, and chymotrypsin proteases. The peptides produced by extensive pepsin–pancreatin digestion are, therefore, likely to be formed by and resistant to human gastro-intestinal digestion and may be absorbed by digestive epithelial cells in the small intestine. This indicates their potential bioavailability to perform their normal biological activities.³⁰ The longan seed protein isolates underwent hydrolysis with pepsin–pancreatin and then were screened for ACEI activity. The longan seed protein isolates that had not been hydrolyzed did not demonstrate any ACEI activity, but rather ACEI activity was only detected after the enzymatic hydrolysis. The pepsin–pancreatin hydrolysate presented an ACEI activity with an IC_{50} value of $1.74 \pm 0.006 \text{ mg mL}^{-1}$ (Table 2). Previously, ACEIs were reported in the protein hydrolysates of peas and whey but at a much greater ACEI activity with IC_{50} values of 0.070 and 0.041 mg mL^{-1} , respectively.³¹ Further ACEI inhibitory activity was reported from cowpea protein hydrolysates, but with IC_{50} values in the range of 0.04–170.6 (Flavourzyme hydrolysate), 24.3–123 (Alcalase hydrolysate), and 44.7–112 (pepsin–pancreatin hydrolysate) $\mu\text{g mL}^{-1}$.³² Meanwhile, the IC_{50} values for chickpea desi and chickpea kabuli proteins, which had undergone hydrolysis by simulated *in vitro* gastrointestinal processes, were $140 \pm 1 \text{ } \mu\text{g mL}^{-1}$ and $229 \pm 1 \text{ } \mu\text{g mL}^{-1}$ respectively.³³

Table 2 Summary of the inhibitory activity of ACE, listing the IC_{50} values, for crude extract, crude protein, protein hydrolysate, and four different fractions of longan seed protein hydrolysate obtained via pepsin–pancreatin hydrolysis (10, 5, and 3 kDa MWCO membrane-filtered)^a

Molecular weight (kDa)	ACE inhibitory activity (IC_{50} ; mg mL^{-1})
Crude extract	>5.00
Crude protein	>5.00
Protein hydrolysate	1.74 ± 0.006^c
>10	$1.37 \pm 0.017^{b,c}$
5–10	$0.95 \pm 0.006^{a,b}$
3–5	$0.43 \pm 0.011^{a,b}$
<3	0.25 ± 0.004^a

^a The findings appear in the form of mean ± SEM ($n = 3$). Those mean values which are shown with a different superscript in each column exhibit significant differences ($P < 0.05$).

3.3 Ultrafiltration

Peptides can be separated on the basis of their molecular weight (as 3D size) by ultrafiltration. This approach is a relatively simple, reliable, and efficient means of preparing samples for RP-HPLC. Using 10, 5 and 3 kDa MWCO ultrafiltration membranes sequentially, the longan seed protein hydrolysate ($IC_{50} = 1.74 \pm 0.006 \text{ mg mL}^{-1}$) was separated into four size fractions of >10 kDa, 5–10 kDa, 3–5 kDa, and <3 kDa, and then each was screened for ACEI activity. The <3 kDa fraction showed the greatest ACEI activity with an IC_{50} value of $250 \pm 4 \text{ } \mu\text{g mL}^{-1}$ (Table 2). It is possible for smaller peptides to pass through the wall of the intestines to enter the bloodstream if they survive the process of gastrointestinal digestion. Because these peptides in this study were obtained after extensive (assumed complete) pepsin–pancreatin digestion they are likely to be stable to human digestion and so able to exert their inhibitory influence even after they have reached the bloodstream.

That these small peptides display ACEI activity in part may reflect that there is a tiny groove in ACE which prevents large polypeptides from accessing the active site. The MW of the hydrolysate is lower than that of the strongest ACEI peptides derived from the tuna frame hydrolysate generated by pepsin (MW of 2482 Da and IC_{50} value of $11.3 \text{ } \mu\text{M}$). The findings reported by Arise *et al.*³⁴ were similar, in that the smallest groundnut protein hydrolysate (MW < 1 kDa) revealed the greatest ACEI activity, where a five-fold improvement in the ACEI purity was achieved following sequential ultrafiltration. Wan Mohtar *et al.*³⁵ described the winged bean (*Psophocarpus tetragonolobus*) protein hydrolysate in the context of the four proteolytic enzymes (flavourzyme, alcalase, bromelain, and papain) after ultrafiltration at a MWCO of 10, 5 and 2 kDa, where the <2 kDa fraction provided the greatest level of ACEI activity (IC_{50} values of 0.003 and 0.130 mg mL^{-1}). Accordingly, the MW < 3 kDa fraction of the longan seed hydrolysate was further fractionated by RP-HPLC.

3.4 RP-HPLC fractionation of the <3 kDa MWCO fraction of longan seed hydrolysate

The <3 kDa MWCO peptide fraction was further fractionated by RP-HPLC using a RP-C18 column with gradient elution. Fig. 1

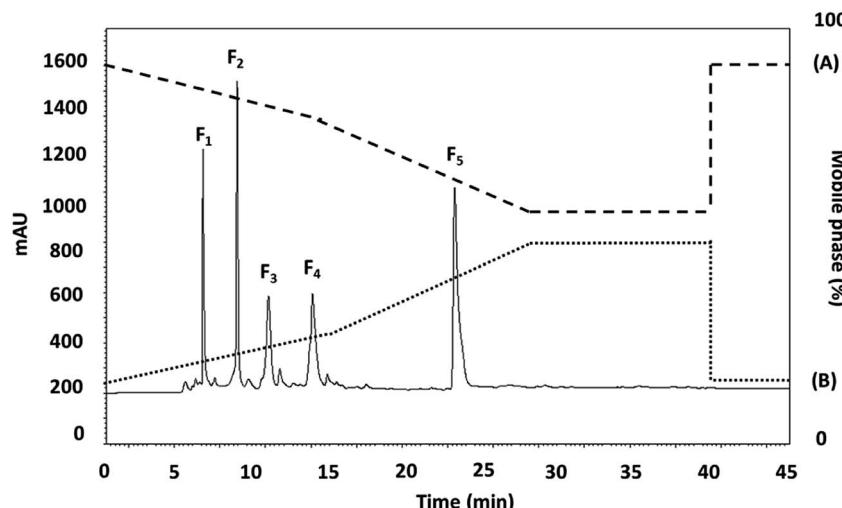

Fig. 1 The RP-HPLC profile of the active fraction (<3 kDa) obtained from longan seeds protein hydrolysate.

presents the chromatographic profile, where five main fractions were obtained on the basis of their hydrophobicity. The fractions (F_{1-5}) were collected and lyophilized, whereupon the peptide concentration and ACEI activity of each fraction was assessed. The F_2 and F_3 subfraction yields were not high enough to accurately measure the ACEI IC_{50} value, while those for fractions F_1 , F_4 , and F_5 were 24.57 ± 0.015 , 37.36 ± 0.007 , and $18.22 \pm 0.029 \mu\text{g mL}^{-1}$, respectively. The F_5 sub-fraction was then subjected to peptide amino acid sequencing through the use of Q-TOF-ESI-MS/MS analysis.

It was previously reported for chickpea protein hydrolysates that the peptides that were the last to be eluted from the RP-HPLC had the highest ACEI activity.³⁶ One argument is that ACEI peptides have a high level of hydrophobic amino acids, and so have a greater retention time within the hydrophobic chromatography column. For example, it is very important that ACEI peptides have hydrophobic qualities, often seen at the peptide N-terminal, and hydrophilic peptides are incompatible with the active ACE site, and so have almost no ACEI activity as a consequence. Accordingly, if hydrophobic amino acids are removed, the inhibition capability of ACE might be adversely affected because of the heightened affinity for active ACE sub-sites of the hydrophobic peptides.³⁷

3.5 Identification of peptide sequences in fraction F_5

The amino acid sequences for identification of the peptides in the RP-HPLC F_5 sub-fraction, which had ACEI activity was

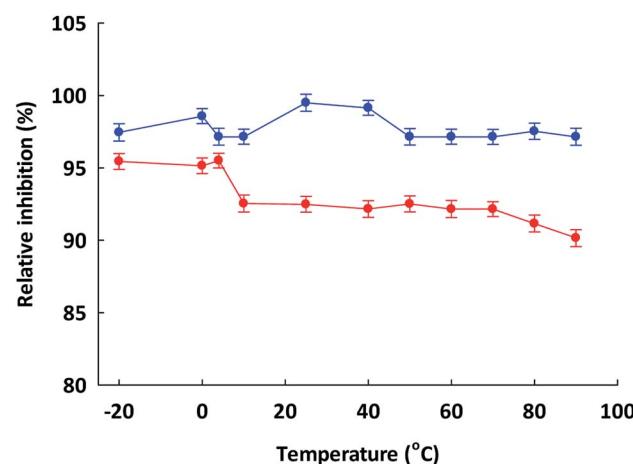

Fig. 2 Indication of the thermostability of (●) ETSGMKPTEL and (●) ISSMGILVCL. The assay was carried out using 20 mM phosphate buffer at pH 7.2 at different temperatures for 60 minutes. The data are presented in the form of mean + 1 SEM and were obtained from experimentation performed in triplicate.

determined using LC-MS/MS ESI Q-TOF *de novo* sequencing aided by searching the MASCOT database. The *de novo* sequencing process resulted in 100% identification on the basis of the Sapindaceae family as the peptides Glu-Thr-Ser-Gly-Met-Lys-Pro-Thr-Glu-Leu (ETSGMKPTEL; 1092.22 Da) and

Table 3 The physicochemical attributes of the two peptides along with the *de novo* peptide sequencing algorithm

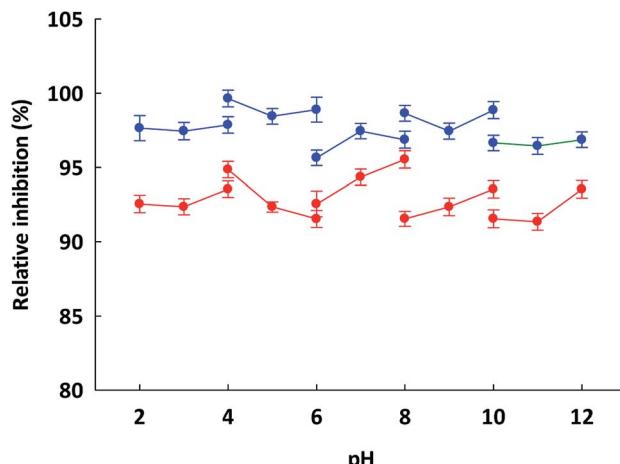

Fig. 3 Indication of the pH stability of (●) ETSGMKPTEL and (○) ISSMGILVCL. The assay was carried out using a number of different buffer systems, each at 20 mM: glycine–HCl (at pH 2.0–4.0), sodium acetate (at pH 4.0–6.0), potassium phosphate (at pH 6.0–8.0), Tris–HCl (at pH 8.0–10.0) and glycine–NaOH (at pH 10.0–12.0) at different temperatures for 60 minutes. The data are presented in the form of mean + 1 SEM and were obtained from experimentation performed in triplicate.

Ile–Ser–Ser–Met–Gly–Ile–Leu–Val–Cys–Leu (ISSMGILVCL; 1035.33 Da) (see Fig. S1†).

These two peptide sequences were then commercially synthesized and their ACEI activity was evaluated. The findings confirmed that both synthesized peptides had an ACEI activity with an IC_{50} value of $2.15 \pm 0.016 \mu\text{M}$ and $3.88 \pm 0.004 \mu\text{M}$ for ETSGMKPTEL and ISSMGILVCL, respectively. In the case of ETSGMKPTEL, a 100% (10/10) amino acid sequence identity to 6-phosphogluconate dehydrogenase (partial – all from *D. longan*) was found, with 88% similarity to the kelch repeat-containing protein of *D. longan*. The ISSMGILVCL peptide showed similarity to a ferredoxin (partial), and the NBS-LRR disease-resistant protein NBS11 (100%), with 80% similarity to the glutathione transferase from *D. longan*. These peptides can be investigated for specific conflict sites, and might be able to replace polymorphic regions with proteins possibly derived from divergent sub-units.

The BIOPEP database was used to search for possible ACEI activity from the peptides identified in the study through comparison with previously identified sequences (Table 3). A majority of the peptides identified had sequences which contained peptides with potential ACEI characteristics. In the case of those peptides derived from longan seed protein hydrolysate, the relevant sequences were quite short, with just 10 amino acids. These findings matched those reported by Natesh *et al.*,³⁸ who showed by crystallography that large peptide molecules cannot access the active ACE sites. It is not yet, however, fully understood how peptide structures affects the relationship with ACEI activity, as the structure–activity relationship of ACEI peptides has yet to be fully established. When considering different peptides and their ACEI activity, there is some correlation between structure and activity. For example, the C-

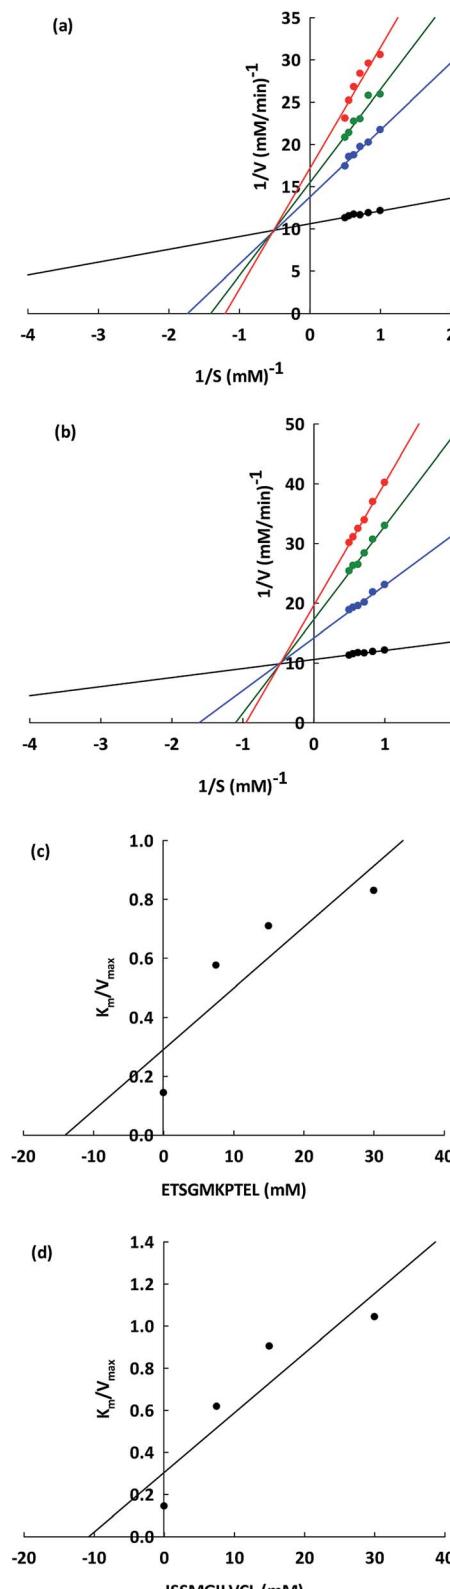

Fig. 4 The Lineweaver–Burk plot of (a) ETSGMKPTEL and (b) ISSMGILVCL for ACE inhibition. ACE activities were assessed with and without both peptides (●) control; (●) 7.5; (●) 15; (●) 30 mM. $1/V$ and $1/S$ indicate the reciprocals of velocity and substrate. The Dixon plot is shown to measure the inhibitor constant (K_i) for (c) ETSGMKPTEL and (d) ISSMGILVCL.

terminal tripeptide sequence has a powerful influence on the binding to ACE, while branched aliphatic amino acids at the N-terminal end are the most suitable to increase the peptide binding activity to ACE.²⁵

3.6 Peptide properties

To prepare functional peptides it is first necessary to understand their properties and stabilities. Data provided by the Innovagen server indicated that ISSMGILVCL exhibits poor solubility in water (Table 3). However, in this research we noted that ISSMGILVCL presented a good solubility in water at concentrations up to 5.0 mg mL^{-1} (4.8 mM, above the IC_{50} value of $3.88 \mu\text{M}$), and thereafter the solubility decreased as the concentration rose. The hydrophobicity of ISSMGILVCL is due to the existence of hydrophobic amino acids, including Ile, Met, Gly, Leu, and Val. Hydrophobicity can support the peptide binding to the hydrophobic active ACE center, thereby leading to improved inhibitory activity.

In assessing stability, the pH of the peptides was measured along with the thermal stability. The ACEI activity of both peptides was also stable to heat, at up to 90°C for 60 min (Fig. 2), and a broad pH range of 2–12 for 60 min (Fig. 3). The findings, therefore, support that these peptides offer gastrointestinal stability, and might also, *in vivo*, serve to generate antihypertensive effects.

3.7 Kinetics of enzyme inhibition

The ACEI kinetic properties must be carefully examined in order to discover the underlying mechanisms that allow peptides to serve as potential antihypertensive agents. From the Lineweaver–Burk plots (Fig. 4a and b), it is apparent that ETSGMKPTEL and ISSMGILVCL can both act as non-competitive inhibitors of ACE. The kinetic parameters of the ACEI by these two peptides are presented in Table 4. From these data, a constant value for K_m was observed ($0.14 \pm 0.06 \text{ mM}$), indicating the existence of non-competitive inhibition. In non-competitive inhibition, the binding of the substrate and the inhibitor occurs at different areas of the enzyme,³⁹ and so there is a constant affinity between the enzyme and the substrate. The V_{\max} ($10.94 \pm 0.03 \text{ mM min}^{-1}$) value decreased as the inhibitory peptide concentration increased because of a lowering of the ACE catalytic efficiency, which in turn reduces the efficiency of the enzymatic reaction. At identical concentrations, the V_{\max} for ETSGMKPTEL was lower than that of ISSMGILVCL, suggesting

a superior ACEI activity for ETSGMKPTEL compared to ISSMGILVCL.

From Fig. 4c and d, the K_i values were constant (14.02 ± 0.11 and $10.78 \pm 0.02 \text{ mM}$ for ETSGMKPTEL and ISSMGILVCL, respectively), thereby supporting non-competitive inhibition, which is an important trait. The majority of peptide ACEIs are competitive, while only very few are non-competitive, including those from sunflowers³⁰ and chick peas.³⁶ Accordingly, there is an advantage to be obtained from finding non-competitive inhibitors, such as ETSGMKPTEL and ISSMGILVCL, especially when compared to a competitive inhibitor since the concentration of the cellular substrate, such as angiotensin I, is quite high in relation to the K_m value. In that scenario, ETSGMKPTEL and ISSMGILVCL would not be competing with the substrate to bind with the free enzyme, and would, therefore, retain their effectiveness.

3.8 Molecular docking of ETSGMKPTEL and ISSMGILVCL at the ACE binding site

The molecular docking between ACE and the two small peptides was simulated using a computational approach that presents the ligand–receptor complex structures through the use of a scoring function.⁴⁰ The Hermes 1.10.1 software was used to performed the calculations involved in docking between ETSGMKPTEL or ISSMGILVCL and ACE, which was established to be non-competitive. The molecular docking supported that the effectiveness of the peptides' ACEI activity was due to the creation of H-bonds with a non-active site of ACE, leading to a distortion of the catalysis configuration. Fig. 5a and b present the ideal docking position in 3D structures, while Fig. 5c and d show the bonds between ACE and the peptides. It is noteworthy that the greatest potential from ligands and peptides comes from position ligand A6, which offers a ChemPLP fitness score of 53.8349 for ETSGMKPTEL and 70.8909 for ISSMGILVCL. These ligand–receptor combination scores serve to show the potential stability involved.

The ETSGMKPTEL peptide connected to ACE through six H-bonds linking the residues Gln541, Asn543, Gln489, Asn543, along with Ser189 with 2 H-bonds following docking. Moreover, ETSGMKPTEL exhibited five van der Waals interactions with ACE at Gln541, Asn543, Ser189, Gln192, and Glu200, creating the docked configuration for ACE with the ligand ISSMGILVCL. The most important interacting sites for ACE are those of the five H-bonds that involve residues Asn543, Ser189, Asp192, Gln192, and Arg196. Meanwhile, the van der Waals interactions

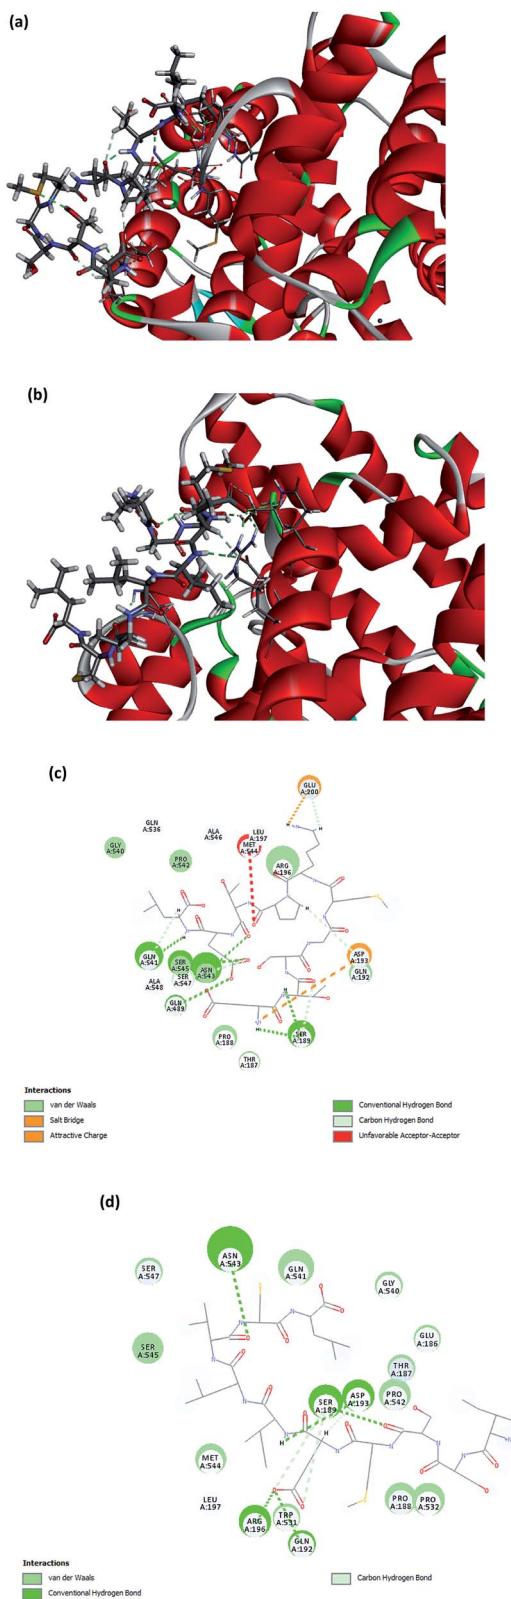

Fig. 5 A 3D illustration of the expected interactions between the synthesized peptides ((a) ETSGMKPTEL and (b) ISSMGILVCL) and the ACE complex. The 2D illustration then shows the expected interactions between the synthesized peptides ((c) ETSGMKPTEL and (d) ISSMGILVCL) and the ACE molecule. These pictures were created through the use of Discovery Studio 2019 software.

in the bonding between ACE and ISSMGILVCL further served to stabilize residues Ser189 and Asp193. The docking results suggest multiple H-bonds linking ACE and the peptides, indicating that when peptides inhibit ACE activity they do so by stabilizing the enzyme-peptide complex through H-bonding.^{41,42}

For ACE, the active site includes the residues Ala354, Glu384, Tyr523, Gln281, His353, Lys511, His513, Tyr520, and Glu162, which are the likely contact sites for competitive inhibitors. It is, therefore, the case that when binding arises between ETSGMKPTEL or ISSMGILVCL and ACE this does not use an active ACE site pocket. The findings support the potential use of ETSGMKPTEL and ISSMGILVCL as ACEIs and indicate that their development into functional foods to treat hypertension may be feasible.

4. Conclusions

The researchers believe that this study represents the first demonstration that stable ACEI activity from the enzymatic hydrolysate fractions of longan seeds by pepsin and pancreatin. Following fractionation *via* ultrafiltration and RP-HPLC, the peptides ETSGMKPTEL and ISSMGILVCL were shown to exhibit ACEI activity, which occurred non-competitively according to the Lineweaver-Burk plot. The results from molecular docking indicated that the links between ACE and the peptides were predominantly in the form of H-bonds, which were able to generate the inhibitory activity. It is broadly possible that such peptides produced from the pepsin-pancreatin hydrolysates of longan seeds might find applications in functional foods produced on an industrial scale. In the case of the antihypertensive properties, it will be necessary, however, to perform further studies, in particular assessing the effects observed during experiments involving mice.

Funding

Sincere thanks are expressed to the Annual Government Statement of Expenditure (GRB_BSS_79_57_61_11), the Ratchadapisek Sompoch Endowment Fund, Chulalongkorn University (R_016_2556), and the Ratchadapisek Sompoch Endowment Fund (2019), Chulalongkorn University (762008) in recognition of the financial assistance offered which enabled this research study to be completed.

Conflicts of interest

The authors have no conflict of interest. This publication has not been submitted earlier to any journal and is not being considered for publication elsewhere. All of the authors, including the corresponding authors, have read and approved the final submitted manuscript.

Acknowledgements

The researchers are grateful to the Institute of Biotechnology and Genetic Engineering at Chulalongkorn University for the

facilities they made available during the course of the study. We also thank Dr Robert Butcher (Publication Counseling Unit, Chulalongkorn University) for his constructive comments in preparing this manuscript.
