Investigation of K-ion storage performances in a bismuth sulfide-carbon nanotube composite anode†

Jang-Yeon Hwang, a Rudra Kumar,b Hee Min Kim,b Muhammad Hilmy Alfaruqi,a and Yang-Kook Sun a,b*†

Herein, we synthesize a nanostructured bismuth sulfide/carbon nanotube composite and demonstrate its potential use as a high-capacity anode for K-ion batteries, for the first time. The composite anode shows reversible K-ion storage capabilities that are supported by density functional theory calculations.
poly(vinylidene fluoride) were mixed with N-methyl pyrrolidone at a ratio of 8:1:1 by weight. The obtained slurry was pasted on the copper foil as a current collector and dried without air exposure at 80 °C.

To confirm the morphological properties and elemental distributions in the composite material, scanning electron microscopy (SEM) and transmission electron microscopy (TEM) with energy dispersive X-ray (EDX) mapping were conducted, respectively. The electrochemical behavior was examined in R2032-type coin cells with K metal as the counter electrode (CE) filled with 1 M mol dm⁻³ KFSI ethylene carbonate:diethyl carbonate (1:1 v/v) solution at room temperature. For comparison, bare Bi₂S₃ sample was also synthesized and characterized via same procedures.

Fig. 2a shows the typical orthorhombic structure of Bi₂S₃ with Pbnm symmetry. Fig. 2b reveals the Rietveld refinement of the high-resolution XRD pattern of the Bi₂S₃-CNT composite (JCPDS no. 00-017-0320). The Rietveld refinement of the XRD pattern of Bi₂S₃-CNTs yielded lattice parameters a, b, and c of 11.45592, 11.24392, and 4.01072 Å, respectively. The accuracy of the structural model obtained by Rietveld refinement was confirmed by the small reliability factors (Rwp: 16.6%). In addition to Bi₂S₃, the Bi₂S₃-CNT composite showed a pure orthorhombic structure belonging to the Pbnm space group without any impurities and secondary phase (Fig. S1†). The weight content of CNTs in the composite was determined to be ~10.2 wt% according to thermogravimetric analysis, as shown in Fig. S2.† We characterized the Bi₂S₃-CNT composite by SEM and TEM. As seen in Fig. 2c (SEM image), spherical Bi₂S₃ nanoparticles in the range 70–100 nm are highly interconnected through a web of CNTs that ensure the flow of electrons. TEM and EDX mapping of the Bi₂S₃-CNT composite clearly reveal the existence of carbon, bismuth, and sulfur element in the composite.

Fig. 3a shows that the predicted voltage curves using first-principles calculation overlap with the first charge–discharge voltage profile of the Bi₂S₃ electrode in the voltage range 0.01–3.0 V.

In previous reports on LIB and SIBs, Bi₂S₃ typically undergoes subsequent conversion and alloying reactions during the charge–discharge process. On the basis of those reaction mechanisms, we first predicted that the electrochemical reaction of Bi₂S₃ in KIB is likely proceeds as follows:

\[
\begin{align*}
\text{Bi}_2\text{S}_3 + 6\text{K} &\rightarrow 2\text{Bi} + 3\text{K}_2\text{S} \\
\text{Bi} + 3\text{K} &\rightarrow \text{K}_3\text{Bi} \\
\text{Bi} + \text{K} &\rightarrow \text{KBi}
\end{align*}
\]

In the first reaction step, Bi₂S₃ reacts with K to form metallic Bi and potassium sulfide. Then, metallic Bi and K react to form the K–Bi alloy compounds K₃Bi and KBi. Note that the discharge products of Bi, K₂S, K₃Bi, and KBi were selected based on stable species presence in the calculated phase diagrams of K–Bi–S ternary and K–Bi binary systems, which were obtained from Materials Projects. Through the conversion and alloying reaction, the theoretical capacity of eqn (1), (2), and (3) were calculated as 312, 384, and 145 mA h g⁻¹, respectively. To validate our proposed mechanism, we performed voltage calculations using the two-phase coexistence method. Our predicted theoretical voltages for the reactions Bi₂S₃ + 6K → 2Bi + 3K₂S, Bi + 3K → K₃Bi, and Bi + K → KBi were 1.28, 0.51, and 0.25 V, respectively.
respectively. As seen in Fig. 3, the Bi$_2$S$_3$ electrode delivered a high discharge–charge (potassiation–depotassiation) capacity of 820 and 650 mA h g$^{-1}$, respectively. The calculated voltages are in good agreement with experimental voltage profiles of Bi$_2$S$_3$ anode. The calculated capacity values in each potassiation step were nearly identical to those obtained from density functional theory (DFT) calculations. The calculation methods are provided in the ESI.$^{12}$ The Bi$_2$S$_3$-CNT composite electrode delivered much higher discharge–charge capacity of 900 mA h g$^{-1}$ and 750 mA h g$^{-1}$, respectively (see Fig. 3b). It should be noted that the irreversible capacity over the theoretical value during the potassiation step was mainly attributed to the formation of a solid-electrolyte interphase layer induced by CNTs.$^{24}$ As observed in SEM and TEM images, the interconnected CNT network in the composite provides effective conductive pathways for rapid electron transport, which are likely to assist K$^+$ ion storage in Bi$_2$S$_3$. In general, conversion-alloying-based electrodes are known to deliver high capacities but experience severe volume changes owing to the continuous self-pulverization of electrode materials during the electrochemical charge–discharge reaction. This phenomenon was observed in the Bi$_2$S$_3$ electrode upon cycling in LIBs,$^{13}$ which resulted in capacity degradation with prolonged cycles. In the case of KIB, our DFT calculations (Fig. 4) suggest that in the first stage, Bi$_2$S$_3$ formed the K$_2$S phase with unit cell volume of 403.74 Å$^3$. Further potassiation led to the formation of K$_3$Bi from metallic Bi with unit cell volume of 361.38 Å$^3$, followed by the formation of KBi phase in the final stage. This calculation revealed the high volume expansion of the Bi$_2$S$_3$ electrode in the KIB system. Such large volume changes often accelerate electrode damage, which leads to the loss of electrical contact, and subsequently rapid capacity fading.

Fig. 5a shows the cycle life test of Bi$_2$S$_3$ and Bi$_2$S$_3$-CNT electrodes in the voltage range 0.01–3.0 V at 200 mA g$^{-1}$. While Bi$_2$S$_3$ only delivered a charge capacity of 250 mA h g$^{-1}$ because of the sluggish kinetics of K-ions with Bi$_2$S$_3$, the capacity reached 450 mA h g$^{-1}$ for the Bi$_2$S$_3$-CNT composite electrode. After 10 cycles, the Bi$_2$S$_3$ electrode showed a drastic capacity loss; after 20 cycles, it had very limited capacity. Moreover, after the first few cycles, the CE of above 98% was stabilized for the Bi$_2$S$_3$-CNT composite electrode, while the CE for the Bi$_2$S$_3$ electrode was much worse; this corresponds to the typical trend of capacity decay in the cycling stability test for the two electrodes. The sudden capacity decay of the Bi$_2$S$_3$ electrode is mainly attributed to the huge volume changes during repeated charge–discharge process observed in the DFT calculation results in Fig. 4. In contrast, the CNT encapsulants provided a strong buffer effect that mitigated the large volume changes and pulverizations of Bi$_2$S$_3$ particles upon cycling, and enabled more efficient electronic conduction of the whole electrode during cycling. As a result, the Bi$_2$S$_3$-CNT electrode demonstrated much better cycling stability over 50 cycles. The electro-conducting CNT matrix enhances the electric conductivity of Bi$_2$S$_3$ and thus has been effective in overcoming the poor potassium intercalation ability in Bi$_2$S$_3$. To determine the correlation between the electrochemical performance and structural durability of these electrode materials, XRD, SEM, and TEM analyses were carried out with cycled (after 20 cycles) Bi$_2$S$_3$ and Bi$_2$S$_3$-CNT composite electrodes. As expected from the different cycling stability between the two electrodes, the Bi$_2$S$_3$ electrode experienced severe structural damage after cycling. A noticeable broadening
of the XRD peaks for the Bi₂S₃ electrode relative to the Bi₂S₃-CNT composite electrode was observed (Fig. 5b). The Bi₂S₃-CNT composite electrode retained its original crystal structure after cycling, while an amorphous phase was found in the cycled Bi₂S₃ electrode. As seen in SEM images (Fig. 5c), the cycled Bi₂S₃ electrode had extensive cracking on the surface, whereas the cycled Bi₂S₃-CNT electrode exhibited no signs of cracking. TEM examination of the Bi₂S₃-CNT electrode before and after cycling further revealed that CNTs play an important role in suppressing the periodic volume expansion of Bi₂S₃ during cycling (Fig. 5d). Although the Bi₂S₃ particles in the composite experienced large volume changes between before and after 20 cycles, Bi₂S₃ nanoparticles were well encapsulated within the CNT matrix. The CNT encapsulants provided a strong buffer effect that mitigated the large volume changes and pulverization of Bi₂S₃ particles upon cycling, and enabled more efficient electronic conduction of the whole electrode during cycling. Compare to the Bi₂S₃ electrode, the Bi₂S₃-CNT electrode showed much lower resistances and that CNT plays an important role to improve electronic conductivity and fast K⁺ ion diffusion kinetics (Fig. S3†). The XRD, SEM, TEM and EIS results clearly demonstrate the superior structural stability of the Bi₂S₃-CNT composite and its enhanced electrochemical K-storage performance.

In summary, we demonstrated the potential use of Bi₂S₃-CNT as an anode material for KIBs. A combination of experimental and first-principles calculations was used to investigate the overall K-storage mechanism of Bi₂S₃. The CNT matrix in this composite anode not only provides electronic conductivity but also decreases the absolute stress/strain, and accommodates a period of large volume changes during the potassiation-depotassiation process. As a result, the Bi₂S₃-CNT delivered high capacity and good cycling stability. We hope that this study provides insight on the design of new electrode materials and contributes toward the realization of KIBs as a sustainable next-generation battery.
