Effect of ultrasonic application during KOH pretreatment and anaerobic process on digestion performance of wheat straw†

 Rashid Mustafa Korai,^{ab} Akiber Chufo Wachemo,^{ac} Liu Yue,^a Muhammad Jaffar,^d Zhengwei Li,^a Muhammad Shahbaz,^a Hairong Yuan^a and Xiujin Li *^a

The digester performance was enhanced by ultrasonic application during pretreatment and the anaerobic digestion (AD) process. Two setups (with and without ultrasonic application) were applied during pretreatment and AD, to untreated and potassium hydroxide (KOH) pretreated wheat straw. The results confirmed that the ultrasonic application enhanced the hydrolysis process during pretreatment. The highest total volatile fatty acid (TVFA) ($3012 \pm 18 \text{ mg L}^{-1}$) production and overall lignin, hemicellulose, and cellulose (LHC) reductions ($22.4 \pm 0.5\%$) were obtained from ultrasonic assisted KOH pretreated (KOH_U) samples, after 36 hours of pretreatment. Similarly, the SEM analysis showed obvious disruption in the outer structure of KOH_U samples. However, the ultrasonic application during AD showed significant improvement in biodegradation rate, biogas and biomethane production. Obvious reduction in sonication time (76%) along with enhanced biogas ($570 \pm 9 \text{ mL gm}^{-1} \text{ VS}$) and biomethane ($306 \pm 12 \text{ mL gm}^{-1} \text{ VS}$) production were observed from KOH pretreated digesters, when ultrasonication was applied during AD. Moreover, the biodegradation rate reached up to 76% along with highest total solid (TS) and volatile solid (VS) reductions from digesters with single KOH pretreatment and ultrasonic influence during AD. Finally, the digester effluent ranged in between the stable values, confirming the completion of the AD process. These results suggested that ultrasonic application was more effective when applied during AD due to the higher liquid to solid ratio. The reduction in energy input can be beneficial for commercial applications and to recognize the better stage for ultrasonic application for enhanced biomethane yield.

Introduction

The dependence on alternative energy resources has increased due to limited availability of fossil fuels and their adverse environmental impact.¹ Therefore, anaerobic digestion (AD) is considered as a sustainable alternative green energy resource compared to other chemical processes.² Generally, the performance and stability of the AD process largely depends upon the characteristics of the biomass, as well as on the operational parameters such as pH, temperature, loading rate, and so on.^{3–5} By means of temperature conditions, two types of AD process,

namely thermophilic and mesophilic conditions, are used on commercial scales. Thermophilic digesters have faster degradation, but are considered sensitive and require higher energy inputs compared to mesophilic AD processes.⁶ Therefore, mesophilic AD systems are more economical for biofuel production. However, lower biodegradation rates may affect the AD efficiency resulting in severe inhibition along with availability of undigested biomass in the digestate.⁷ This biodegradation rate is further affected, when dealing with agriculture wastes such as wheat, rice, and corn straws. The hydrophobic linkages between lignin and hemicellulose limits the access of anaerobic microbes to organic portion of the biomass resulting in reduced digestion rate.⁸

Various pretreatment techniques such as acid and alkali treatments, are reported to increase the biodegradation of agriculture waste by reducing the influence of lignin on effective bioconversion during AD.^{9,10} The alkali pretreatment shows more affinity to break the linkage between polysaccharides and lignin monomers, resulting in more release of hemicellulose structure due to saponification effects on biomass during pretreatment.¹⁰ Alkali pretreatment such as sodium hydroxide (NaOH), potassium hydroxide (KOH), are suggested more effective compared to acid pretreatment in commercial applications.¹¹ However, high alkali concentrations may affect the digester stability and results in

formation of inhabitant acids such as furfural and reducing biodegradation efficiency.¹² Addition of co-pretreatment with alkali such as steam explosion, microwave, irradiation, adsorption and ultrasonication are reported for improving the disruption of lignin content.^{13–15} Yang *et al.*¹⁶ applied irradiation pretreatment on wheat straw using γ radiation to determine the effects and after effects of pretreatment and suggested effective breakdown of wheat straw structure. Similarly, Wu *et al.*¹⁷ reported that combination of alkalization and adsorption technique, in two step pretreatment of wheat straw was effective for enhanced hydrolysis during pretreatment.

Ultrasonic application can be helpful to get better result with lower alkali concentrations.¹⁸ The ultrasonic application during pretreatment are reported to increase structural disruption and process effectiveness for lignocellulosic biomasses, waste sludge, and many environmental processes.^{19–21} Specifically, combination of ultrasonic-assisted alkali pretreatment has shown significant improvements in biodegradation efficiency of digesters dealing with agricultural waste. Preeti *et al.*¹⁸ achieved 80% of delignification by applying ultrasonic assisted pretreatment to waste newspaper. Similarly, ultrasonication applications, during AD also revealed methane enhancement.²² Zou *et al.*²³ suggested that application of ultrasonic pretreatment on wheat straw can increase the accessible surface during AD for enhanced methane yield. The application of low strength ultrasonication during AD can improve 40% of methane production during AD.²⁴ However, there is limited work showing comparison of ultrasonic application during pretreatment and AD process.

Therefore, this study refers to the effectiveness of ultrasonic application by investigating its efficiency during KOH pretreatment and comparing with its application during AD. Though NaOH is considered cheaper than the KOH for pretreatment of wheat straw, but adding KOH during pretreatment will increase the value of the digestate in its application as bio-fertilizer.²⁵ Therefore, KOH was given preference over NaOH. Parameters like pH variation, total volatile fatty acid (TVFA) production, surface morphology, and LHC reduction were determined to compare and evaluate the effects of single and ultrasonic assisted KOH pretreatment on wheat straw. However, ultrasonic addition during pretreatment may increase the energy input, resulting in increased operational cost. Therefore, digester performance was compared by applying two setups, with and without ultrasonic assisted treatment during pretreatment and AD of untreated, single KOH pretreated KOH, and ultrasonic assisted KOH pretreatment (KOH_U) wheat straw. The object of this study was to minimize the ultrasonic energy input by reducing its time and increasing digester performance during AD. Moreover, system stability was also observed to confirm the benefits of enhanced biodegradation of wheat straw for digestate utilization. An appropriate stage with optimum energy can increase the potential of ultrasonic application for faster biodegradation and enhanced methane yields.

Materials and methods

Feedstock and inoculum

The wheat straw (WS) was obtained from agricultural farmland located at district Shunyi, Beijing. The WS was initially air-dried

Table 1 Initial characteristics of wheat straw and inoculum

Parameter (%)	Wheat straw	Inoculum
Total solid ^a	94.31 ± 0.05	7.38 ± 0.09
Volatile solid ^a	89.40 ± 0.12	4.07 ± 0.04
Total carbon ^b	43.55 ± 0.16	27.67 ± 1.65
Total nitrogen ^b	1.43 ± 0.01	2.45 ± 0.03
Total hydrogen ^b	5.46 ± 0.11	3.71 ± 0.28
Total LHC ^b	80.00 ± 0.38	—
Lignin content ^b	11.34 ± 0.53	—
Hemicellulose content ^b	22.32 ± 0.27	—
Cellulose content ^b	46.34 ± 0.21	—

^a As received. ^b On dry basis; all the values are mean ± SD ($n = 3$).

and then cut into small size (5–10 cm), with the help of paper cutter (PC500, Staida Co., Tianjin) and was further grounded to obtain a mesh size of 5–10 mm, through hammer mill (Fe130, Staida Co., Tianjin). The inoculum was an activated sludge obtained from an effluent of anaerobic digester plant of dairy manure (Nanwu biogas plant in Shunyi District, Beijing, China) operating under mesophilic conditions. The composition and properties of raw feedstock and inoculum, are shown in Table 1.

KOH pretreatment with and without ultrasonic application

The pretreatment was performed in 1.0 L bottles. The ratio of 1 : 0.04 : 6 (w/w) for WS : KOH : H₂O was used to prepare all pretreatment bottles.²⁶ Initially KOH solutions were prepared and left for a little time to remove any exothermic temperature increase. A 50 g TSL⁻¹ of WS was added in each bottle containing KOH solution. 4% KOH concentrations were optimized in our preliminary experiments for effective disruption during ultrasonic assisted pretreatment technique. The WS was then mixed with KOH solution and placed under two separate conditions at ambient temperature (22 ± 1 °C); (i) with normal condition (without ultrasonic application) in sealed plastic bags, and (ii) with ultrasonic application during pretreatment. The ultrasonication treatment was applied through an ultrasonic bath (KH5200DE, Nanjing Xiao equipment company limited, China), operating at 20 kHz frequency and ambient temperature. The experimental device and operating conditions during ultrasonic pretreatment are shown in ESI (Fig. S1†). The temperature increase due to the cavitation in the bath was controlled to set point values by replacing the bath water with fresh water. The pH was used as prediction parameter for completion of the pretreatment process. After completion of pretreatment process, the portions of sample were taken and separated as solid and liquid for further analysis.

Anaerobic digestion process with and without ultrasonic application

The experimental setup and ultrasonic conditions during AD are shown in (Fig. 1). Equal amount of untreated WS (50 g TSL⁻¹) was prepared in separate 1.0 L bottles and placed at ambient condition parallel to the pretreated bottles. Batch anaerobic digestion was applied in a bath with mesophilic

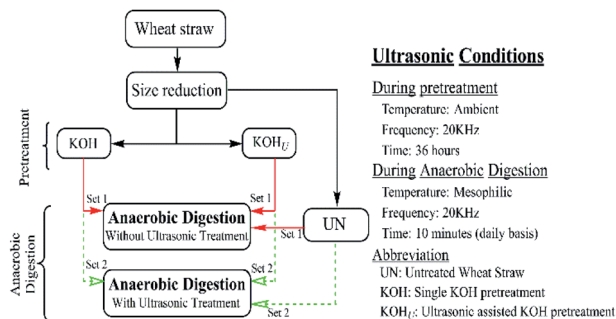

Fig. 1 Experimental setup and ultrasonic conditions during pretreatment and anaerobic digestion process.

temperature condition 37 ± 1 °C. A 15.0 g TSL^{-1} of inoculum was added in each bottle, which was based on study by Zhang and Zhang.²⁷ The remaining working volume (80%) was obtained by adding distilled water in each digester. All the digesters were placed in the AD bath operating at mesophilic temperature (37 ± 1 °C). Two sets of each condition *i.e.* untreated, single KOH pretreated, and KOH_U pretreated samples were prepared in triplicate. The first set remained in the AD bath throughout the digestion time, whereas second set was given ultrasonic treatment for 10 minutes on daily basis and without disturbing the mesophilic temperature (Fig. S1†). This was done by placing triplicate bottles for each condition in the ultrasonic bath (already maintained at mesophilic temperature) after measuring the daily biogas volume and removing the daily biogas produced. After ultrasonic treatment the bottles were placed back to anaerobic digestion bath. Two bottles containing only inoculum were also prepared as control for each set in triplicate.

Kinetic model

Modified Gompertz model was applied in order to compare the experimental data with model predictions as per eqn (1).²⁸

$$B = B_0 \exp \left\{ -\exp \left[\frac{\mu_m e}{B_0} (\lambda - 1) + 1 \right] \right\} \quad (1)$$

where B is the cumulative methane yield (CMY), B_0 is the ultimate methane produced, μ_m is the specific methane yield rate, t is the time for AD process, λ is the phase time lag, and e is the constant value (2.72).

Biodegradability

The biodegradability was determined by using eqn (2).²⁹

$$B_d\% = \frac{\text{EMY}}{\text{TMY}} \times 100 \quad (2)$$

where TMY is the theoretical methane yield and EMY is experimental methane yield.

Analytical methods

The analysis for parameters like, total solid (TS), volatile solid (VS), alkalinity, total ammonia nitrogen (TAN) were performed as

per APHA guidelines.³⁰ Elemental composition such as total carbon and nitrogen were obtained using TC analyzer (Vario EL/micro analyzer, Germany) and the total Kjeldahl nitrogen analyzer (model KDN-2C, Shanghai), respectively. Fiber analyzer (ANKOM A2000i, country) was used to evaluate the lignin (L), hemicellulose (H), and cellulose (C) contents as per the procedure suggested by (Van Soest *et al.*, 1991).³¹ Daily biogas yield were measured by water displacement method and the total sum of the daily volume was termed as cumulative yield. This volume was then calibrated to standard temperature and pressure volume by applying the ideal gas law. The gas samples were collected through rubber connections of each digester bottle (on daily basis) and the corresponding methane concentrations were determined through a gas chromatograph (GC) (HJAT, SP2100, China) equipped with detector molecular sieve packed stainless-steel column with the length and diameter of $2.0 \text{ mm} \times 3.0 \text{ mm}$ (TCD) and (TDX-01) and connected to a thermal conductivity detector (TCD), and argon was used as the carrier gas. The temperature values for the injector, column, and detector were maintained at 140 °C, 150 °C, and 150 °C, respectively. For volatile fatty acid (VFA) analysis samples were first centrifuged to obtain liquid supernatants and were then filtered through $0.22 \mu\text{m}$ membrane. The concentration of VFAs in the pretreated samples and AD refuse, such as ethanol, acetic acid, propionic acid, valeric acid and butyric acid, were determined by a gas chromatograph (SHIMADZU, GC2014) equipped with a flame ionization detector (FID) and a $30 \text{ m} \times 0.25 \text{ mm} \times 0.25 \mu\text{m}$ column (Agilent, DB-WAX). Elemental analysis data was used to calculate the theoretical methane yield (TMY) of the raw wheat straw using Buswell's equation.³²

Results & discussion

Effect of ultrasonic application on hydrolysis of wheat straw

The ultrasonic application during KOH pretreatment had significant effect on hydrolysis of wheat straw (Fig. 2). The pH values were determined every four hours during pretreatment, to identify the kinetics of hydrolysis process. It was observed that the pH of ultrasonic assisted KOH pretreated (KOH_U) samples declined faster as compared to single KOH samples, Fig. 2(a). This was due to faster interaction of hydroxyl ions of KOH, caused by simultaneous and effective vibrations from ultrasonication process. Zhao *et al.*³³ reported increased surface disruption and cellulose activity by cavitation from ultrasonic pretreatment on WS. The pH values of KOH_U samples reached to equilibrium in 36 hours compared to the single KOH samples, which attained the similar equilibrium after 68 hours of the pretreatment process. According to previous studies, Yao *et al.*¹ suggested 5 days of pretreatment time for wheat straw by single pretreatment with 1% urea concentration. Similarly, Zheng *et al.*³⁴ suggested 3 days of pretreatment time for effective degradation of corn straw with 2% NaOH concentrations, at ambient temperature conditions and 90% moisture content. In this study, the cavitation effect caused by the ultrasonic vibrations allowed loosening of outer fiber bonding within the lignocellulosic structure of wheat straw and showed higher hydrolysis rate.³³ Therefore, less pretreatment time was

Fig. 2 Effect of ultrasonic application during pretreatment of wheat straw (a) pH variation, and (b) VFA concentration.

observed in ultrasonic influenced samples. Similar trend was observed by Xu *et al.*¹⁹ for ultrasonic addition during corn straw pretreatment.

Similarly, Fig. 2(b) shows the VFA concentration of untreated and KOH pretreated samples with and without ultrasonic application. Significant increase in TVFA production was observed in all samples under ultrasonic influence during pretreatment as compared to the samples without ultrasonic application. The untreated_U samples produced $903.47 \pm 5.22 \text{ mg L}^{-1}$ of TVFA, which was 100% more than the TVFA values of untreated WS samples without ultrasonic influence. The KOH_U produced the highest TVFA ($3012 \pm 18 \text{ mg L}^{-1}$) among all samples, with 6.6 times higher TVFAs than the untreated WS sample. However, there was very little variation in TVFA values of single KOH pretreated samples

compared to KOH_U. This can be explained as the ultrasonic collisions responded in structural vibrations which increased the outer surface gaps during pretreatment and the disruption was in actual due to alkali contact absorbing the organic matter from wheat straw.³⁵ Therefore, the addition of ultrasonic treatment influenced the reaction time during hydrolysis of wheat straw and more TVFA were released in less time compared to the samples without ultrasonic contact during pretreatment process. Likewise, Zhong *et al.*³⁵ also achieved enhanced saccharification (92.4%), by combining ultrasonic application with quaternary ammonium hydroxide (15% aqueous solution) pretreatment on wheat straw. The results in this study confirms the positive influence of ultrasonic application for increasing the kinetic rate of wheat straw hydrolysis, which can be helpful to treat more amount of biomass in less time.

Effect on main composition after pretreatment

Table 2 shows the individual and overall LHC reductions of untreated and KOH pretreated WS samples, after normal and ultrasonic assisted KOH pretreatment. It was observed that single ultrasonication application had no significant effect on WS for LHC reductions. This can be explained as the ultrasonication effects on the outer layer of the WS and requires organic content from WS. The lignin are phenolic compounds and has more affinity with hydroxyl ions, therefore the lignin disruption was more obvious in KOH pretreated samples with or without ultrasonic application.³⁶ Moreover, the KOH pretreated sample with and without ultrasonic treatment showed a larger difference in the respective reduction of lignin and hemicellulose content. These results confirmed that the ultrasonic application considerably affected the outer layer of WS, which allowed deeper penetration of KOH ions. The pretreatment time for KOH and KOH_U samples were also essential for demonstrating the ultrasonic influence on WS. As the time taken by KOH_U samples was 52.92% less as compared to single KOH pretreated samples. These results suggested that the ultrasonic vibration successfully influenced the outer rigid surface of WS, resulting in maximum lignin removal, in less pretreatment time. Therefore, the highest LHC reductions were achieved by KOH_U samples ($22.38 \pm 0.51\%$), which were 7.42 and 1.19 folds higher than the untreated and KOH sample, respectively. Similar difference in the individual LHC content reductions were also observed from KOH_U samples compared to untreated and single KOH pretreatment. The hemicellulose content was most effected KOH_U samples and reached to highest reduction at $29.60 \pm 1.03\%$.

Table 2 LHC reductions of untreated and KOH pretreated wheat straw, with and without ultrasonic application^a

Content	LHC ^b (%)	Cellulose ^b (%)	Hemicellulose (%)	Lignin ^b (%)
Untreated _U	2.53 ± 0.46	1.67 ± 1.08	2.83 ± 0.66	5.57 ± 0.96
KOH	18.79 ± 0.39	16.99 ± 0.45	21.31 ± 1.33	19.58 ± 2.04
KOH _U	22.38 ± 0.51	16.71 ± 1.74	29.60 ± 1.03	26.96 ± 0.85

^a All value are mean \pm SD ($n = 3$). ^b On a dry basis.

Fig. 3 SEM images for untreated (a); single KOH pretreatment (b); and ultrasonic assisted KOH pretreatment (c) of wheat straw.

Effect on physical morphology

The SEM analysis results are shown in Fig. 3. The ultrasonic application during KOH pretreatment had great influence on the physical disruption of wheat straw. The untreated WS sample (Fig. 3(a)) showed longer, straight, and attached fibers, whereas the single KOH pretreated samples (Fig. 3(b)) were completely destroyed with clear appearance of broken backbone of the fiber. On the other hand, numerous small holes were observed throughout the surface of KOH_U samples (Fig. 3(c)), indicating severe disruption. These results confirmed that the ultrasonic application totally destroyed the outer layer which is supposed to give maximum resistance to release organic content during pretreatment. However, the increased effectiveness of ultrasonic application during AD can be explained as there was more liquid to solid ratio available for ultrasonication

process during AD, thereby, more effect of ultrasonic process was observed.³⁷

Effect on biogas and methane yield

In this work, an obvious difference in daily as well as cumulative yields of biogas and methane were observed from anaerobic digesters with ultrasonic influence (AD_U), as shown in Fig. 4(a–d). There was negligible variation in biogas production during first week from all KOH pretreated digesters, with or without ultrasonic treatment during AD (Fig. 4(a and b)). This could be attributed to sufficient availability of organic content in all the KOH digesters at early stage of digestion process. The biogas and methane production was increased from second week in all AD_U , indicating further release of VFAs due to ultrasonication effect.¹³ Additionally, a clear boost in KOH-AD_U was observed from second week, which continued till the end of digestion time. The KOH-AD_U reached to

Fig. 4 (a–d) Daily and cumulative biogas and biomethane productions.

the highest cumulative biogas yield (CBY) with $569.89 \pm 9.09 \text{ mL g}^{-1} \text{ VS}_{\text{loaded}}$ in 50 days of digestion time. Similarly, the CBY from $\text{KOH}_{\text{U}}\text{-AD}_{\text{U}}$ and untreated AD_{U} digesters reached to 475.77 ± 12.44 and $414.76 \pm 12.58 \text{ mL g}^{-1} \text{ VS}_{\text{loaded}}$, respectively. The untreated, KOH, KOH_{U} digesters without ultrasonic influence could reach only 354.44 ± 13.61 , 428.92 ± 13.46 and $482.42 \pm 17.12 \text{ mL g}^{-1} \text{ VS}_{\text{loaded}}$, respectively. These results indicated that addition of ultrasonication during AD was more effective as compared to the pretreatment stage. Tao Yu *et al.*¹⁵ also reported similar increments in the biogas production when applied microwave pretreatment on swine manure. Moreover, comparison between ultrasonic treatment during both stages ($\text{KOH}_{\text{U}}\text{-AD}_{\text{U}}$) with KOH_{U} showed no significant difference in biogas yield.

Similarly, the daily and cumulative biomethane productions (Fig. 3(b and d)), for the digesters under ultrasonic influence AD_{U} , remained higher throughout the digestion time. However, the relative boost in daily methane production was more obvious in AD_{U} digesters compared to normal AD digesters. Among all digesters, $\text{KOH}\text{-AD}_{\text{U}}$ reached to highest values with $305.57 \pm 11.71 \text{ mL g}^{-1} \text{ VS}_{\text{loaded}}$ cumulative methane yield (CMY). Similarly, the CMY for untreated, untreated_U, KOH, KOH_{U} , $\text{KOH}_{\text{U}}\text{-AD}_{\text{U}}$ were at 188 ± 11 , 217 ± 10 , 234 ± 14 , 259 ± 13 and $268 \pm 12 \text{ mL g}^{-1} \text{ VS}_{\text{loaded}}$, respectively. The reason for this increased digester performance can be postulated as; (i) the simultaneous utilization of VFA produced during pretreatment of WS and production of more VFA due to ultrasonic vibrations during AD and, (ii) the ultrasonic application during AD allowed more free movement of the anaerobic microbes within the biomass, resulting in more biodegradation. These results suggest that ultrasonic addition during AD increases the digester performance along with effective increase in methane production.

However, an obvious difference in the B_{d} values were observed in all digesters under ultrasonic influence during AD process compared to the one with no ultrasonication. This increase in B_{d} values in AD_{U} can be attributed to the high liquid to solid ratio during anaerobic digestion process which helped in increasing the effects of ultrasonication throughout the substrate.³⁷ The another reason for this increased biodegradation can be possible VFA utilization during AD, which did not caused inhibition due to higher acidification.^{38,39} Thus, increased digester performance was observed in ultrasonic assisted anaerobic digester for all substrate types.

Effect on biodegradability and biodegradation rate

The biodegradability (B_{d}) of both untreated, KOH digesters with and without ultrasonic treatment, were calculated using eqn (2). The biodegradability results suggested that application of ultrasonic technique during AD had significantly increased in the digester performance compared to its application during pretreatment stage. The biodegradability of untreated wheat straw digester, untreated- AD_{U} , KOH, $\text{KOH}\text{-AD}_{\text{U}}$, KOH_{U} , and $\text{KOH}_{\text{U}}\text{-AD}_{\text{U}}$ digesters reached to 46.72, 53.99, 58.23, 76.15, 66.85, and 64.37%, respectively. There was no significant difference in B_{d} of digesters with ultrasonic application during both stages (KOH_{U} and $\text{KOH}_{\text{U}}\text{-AD}_{\text{U}}$). This could be attributed to the fact that most of TVFAs were released during pretreatment and had no further effect on ultrasonication during AD. Similarly, T_{80} values were also calculated to evaluate the biodegradation rate. Lower T_{80} values in ultrasonic assisted anaerobic digesters, suggested faster biodegradation rates, compared to the digester without ultrasonic application during AD. The $\text{KOH}\text{-AD}_{\text{U}}$ reached the fastest T_{80} value, on 20th day of anaerobic digestion process compared to 25th day of T_{80} from single KOH digestion, when no ultrasonication was applied.

Similarly, the corresponding T_{80} values for untreated, untreated- AD_{U} , KOH_{U} , and $\text{KOH}_{\text{U}}\text{-AD}_{\text{U}}$, were achieved on 32nd, 27th, 24th, and 22nd day, respectively. These results suggested that the specific CMP values on the T_{80} were higher in AD_{U} than the normal AD, indicating higher biodegradation rates. Moreover, the optimized time duration for ultrasonic application during pretreatment was 36 h, and the total time for ultrasonic application during AD (10 minutes on daily basis for each group) accounted 8.33 hours, only. These results confirmed that ultrasonic application was more feasible during the AD stage, due to less energy input requirement (76.9%) compared to pretreatment stage.

Kinetic model

Modified Gompertz law was applied to fit the biomethane production data, using eqn (1). Table 3 shows different parameters of modified Gompertz model for both types of anaerobic digesters of untreated, KOH, and KOH_{U} wheat straw. The R^2 values ranged in between 0.995–0.999, which reflects successful simulation of the model for this study. The B_0 values predicted by model were also in agreement to the EMY. The highest EMY from $\text{KOH}\text{-AD}_{\text{U}}$ digesters suggested to be best combination with

^a All the values are mean ± SD (*n* = 3).

ultrasonic application for effective digester performance. The λ values showed no difference for both sets of digester with or without ultrasonic application. This was also in agreement to the experimental results as the difference in the ultrasonic assisted anaerobic digester was observed after first week, and all the digester had sufficient organic content at initial stage of digestion process. However, μ_m values observed from all AD_U digesters were slight higher compared to corresponding set of digester without ultrasonic influence. This increase confirmed the hypothesis of late but higher biodegradation rate in ultrasonic assisted AD processes. However, the experimental values of μ_m were little higher as compared to the model prediction. The experimental μ_m achieved by untreated, untreated_U, KOH, KOH-AD_U, KOH_U, and KOH_U-AD_U, were 9.48 ± 0.55, 10.50 ± 0.09, 15.25 ± 0.13, 17.08 ± 0.06, 16.19 ± 0.29, and 16.78 ± 0.32 at 24th, 16th, 6th, 13th, 6th, and 6th day, respectively.

TS and VS reductions

Table 4 shows the TS and VS reduction after anaerobic digestion process. In consistent to biogas and biomethane results, the TS and VS reduction for ultrasonic assisted anaerobic digesters were higher compared to the conventional digesters. The change between AD_U and AD digesters were also statistically significant at ($\infty < 0.05$). The highest TS and VS

reductions were observed in KOH-AD_U digester, reflecting conversion of more organic content from anaerobic microbes. This could be explained as KOH pretreatment of wheat straw partially disrupted the lignin cross linkage and ultrasonic vibrations during AD further loosen the linkage allowing microbes deeper access to more dry matter. Thus more biodegradation was observed from KOH-AD_U digesters, with higher TS and VS reductions.

Digestate characteristics

Table 5 shows the characteristics of digester refuse after anaerobic digestion process. The pH value for all digesters refuse were within the stable digester effluent range and did not required any adjustment after anaerobic digestion process.⁴⁰ Similarly, the total ammonia nitrogen (TAN), value ranged between 303 to 355 mg N-NH₄ L⁻¹. These values were also in agreement with the stable ranges of digester effluents.⁴¹ TA values were high indicating sufficient buffering potential for any acidification. However, the untreated wheat straw digesters with normal AD showed, comparatively lower alkalinity values. All the values TVFA were higher than the minimum limit required for buffering the nitrification effect.⁴² Finally the values like TA/TVFA were also measured to identify the digester stability. The lower TVFA/TA ratio showed negative possibility

for acidification and revealed that no further treatment was required to digestate.⁴³

Conclusions

The ultrasonic application is one of the effective and promising method to overcome slower biodegradation rates for lignocellulosic based substrates. The increase in hydrolysis rate during pretreatment confirmed that addition of ultrasonic application disrupted more organic content from wheat straw. As a result, pH declined faster with more TVFA release in less pretreatment time compared to normal pretreatment without ultrasonication. Similarly, highest LHC reduction was observed from KOH_U samples (22.38%) compared to untreated and single KOH pretreated wheat straw. However, the ultrasonic effects were more obvious when applied during AD. The highest biogas and methane yield was achieved by KOH-AD_U (569.89 ± 0.79 and 305.58 ± 0.85 mL g⁻¹ VS_{loaded} respectively), which were 32.86 and 63.0% higher than the untreated digester, without ultrasonication during AD. Moreover, significant difference in energy input were also observed from ultrasonic application during pretreatment (36 h) and AD (8.33 h) reflecting 76.9% reduction in ultrasonic time. These results suggested the ultrasonic application was more beneficial during AD stage compared to pretreatment, for increasing biodegradation rate as well as biomethane yield.

Conflicts of interest

There are no conflicts to declare.
