An efficient and robust exfoliated bentonite/ $\text{Ag}_3\text{PO}_4/\text{AgBr}$ plasmonic photocatalyst for degradation of parabens[†]

 Jianchao Ma,^a Shurong Yang,^a Huixian Shi,^{*b} Jin Pang,^a Xiaopeng Zhang,^a Yuxing Wang^a and Hongqi Sun^{ID, *c}

Efficient visible-light-driven heterojunction photocatalysts have attracted broad interest owing to their promising adsorption and degradation performances in the removal of organic pollutants. In this study, a mesoporous exfoliated bentonite (EB)/ $\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) photocatalyst was obtained by stripping and exfoliating bentonite as the support for loading Ag_3PO_4 and AgBr . The particle size ranges of Ag_3PO_4 and AgBr were about 10–30 nm and 5–10 nm, respectively. The exfoliated bentonite could greatly improve the dispersion and adsorption of Ag_3PO_4 and AgBr , and significantly enhance the stability of the material during paraben photodegradation. 0.2 g L⁻¹ methylparaben (MPB) was completely decomposed over the EB/ $\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) in 40 min under visible light irradiation. In addition, the photocatalytic activity of EB/ $\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) remained at about 91% after five recycling runs manifesting that EB/ $\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) possessed excellent stability. Radical quenching tests revealed that holes (h⁺) and hydroxyl radicals (·OH) were the major radicals. They attacked the side chain on the benzene ring of parabens, which were gradually oxidized to the intermediates, such as benzoic acid, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, azelaic acid, and eventually became CO₂ and H₂O. The enhancement of photocatalytic activity and photo-stability could be ascribed to the stable structural characteristics, enlarged surface area, high absorption ability, and improved light absorption ability from loading Ag_3PO_4 onto EB. Meanwhile, the matched energy levels of Ag_3PO_4 and AgBr made the photoelectron–hole pairs separate and transfer effectively at the interfaces. As a result, the photocatalytic properties of EB/ $\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) composites were enhanced.

1. Introduction

Parabens, such as methylparaben (MPB) and ethylparaben (EPB),¹ are widely used in food, cosmetics and pharmaceuticals. The effluent from wastewater containing parabens has caused serious environmental problems.² Paraben exposure to the community could induce adverse health issues, such as carcinogenic potential,³ endocrine dyscrasia, immune dysfunction and developmental and behavioral disorders.⁴ Thus, the development of efficient treatment technologies has become an urgent need. Many technologies, for example, adsorption,⁵ biodegradation,⁶ and advanced oxidation processes,⁷ have been applied to remove parabens from wastewater. Among advanced

oxidation technologies, photocatalysis has been paid much attention because of its energy saving and high efficiency. TiO₂ is the most commonly used photocatalyst. But it has a large band gap energy (3.2 eV) and cannot respond visible light, which presents 42% solar energy. The limited light absorption of ultraviolet region (5% of solar energy) results in a low removal efficiency in response to sunlight. Coupling TiO₂ photocatalysis with H₂O₂ could result in a higher removal efficiency,⁸ or applying as a self-organized electrode to improve the defects of TiO₂.³ However, the addition of extra oxidants and the design of oxidation electrodes still not extend the light absorption range. The development and exploration of photocatalytic materials with a low band energy is of critical importance. So far, Ag-based catalysts have been widely reported due to their low band gap energies overlying all wavelengths within the near infrared region, showing high photoluminescence quantum yields.

Silver orthophosphate (Ag_3PO_4) with an indirect band gap of 2.36 eV has been extensively investigated since it was reported by Ye *et al.*⁹ Although Ag_3PO_4 is a prospective photocatalyst for environment remediation,¹⁰ it has very low solubility in aqueous solution and very easy to occur agglomeration.¹¹ These greatly destroy its stability and make it difficult for being recovered

after reaction.¹² It is also prone to photo-corrosion.¹³ Therefore, a cost-effective and efficient material to further improve the stability and reduce the photo-corrosion of Ag_3PO_4 can play a critical role for the feasibility.

Recently, many researches aim to search suitable propping materials for increasing dispersion of photocatalyst for enhancing its stability.¹⁴ Common supports used for photocatalysts are metallic oxide,¹⁵ ordered mesoporous silica materials,¹⁶ layered graphite,¹⁷ hollow glass bead, quartz glass tube (sheet), ordinary (conductive) glass sheet, organic glass,¹⁸ optical fiber,¹ natural clay,¹⁴ activated carbon,¹⁸ hydrotalcite-like compounds,¹⁹ and CNTs,²⁰ etc. Clay materials are widely recognized as the good substrates because of their large reserve, low cost, cohesiveness and large specific surface area. Bentonite is abundant on the Earth. It has been extensively served as a native, financial sorbent and upholder for catalysis in sewage disposal.²¹ It possesses remarkable adsorption capacities and owns cation exchange sites at both the interlamination and the outside edges. Thus, bentonite is used to synthesize composite photocatalysts with high activity, such as, $\text{ZnFe}_2\text{O}_4/\text{Na-Ben}$,²¹ HO-Ca-Ben ,²² $\text{BiVO}_4/\text{bentonite}$,²³ $\text{MoS}_2/\text{bentonite}$,²⁴ $\text{ZnS}/\text{bentonite}$.²⁵ These composite photocatalysts were effectively used to degrade organic pollutants, because active component of photocatalyst was evenly dispersed on clay matrix producing different reaction sites. Bentonite improved the stability of these catalyst due to a great specific surface area. But it has been widely accepted that the method of interlayer loading is disadvantageous to the photon absorption. So degradation performances of photocatalyst nanoparticles supported on bentonite layers outside are better than that of in the interlayers.²⁶ Bentonite was delaminated to form the exfoliation material with the huge external surface area, which overcame the aggregation and instability issues of Ag_3PO_4 .²⁷

The photo-corrosion of Ag_3PO_4 still existed after Ag_3PO_4 loading on the exfoliated bentonite due to lack of electron receiver.²⁸ The exterior was formed by shiny black Ag granules, which would inescapably hinder the sorption of visible light by Ag_3PO_4 . In recent years, a remarkable way to ameliorate the photocatalytic activity of Ag_3PO_4 is to compound it with another semiconductor possessing different band structures, for instance, AgCl ,²⁹ glass,¹⁰ WO_3 ,³⁰ sulfate-doped,³¹ and Fe_2O_3 ,³² etc. The proper alignment of conduction band and valence band position between two outstanding catalysts provides driving force for the separation and transfer of photoinduced electrons and electronic-hole.³³ AgBr was among the best candidate material for the synthesis of semiconductor heterojunctions because the insoluble AgBr nanoparticles could effectively inhibit the dissolution of Ag_3PO_4 in aqueous solutions.³⁴ The formation of $\text{Ag}_3\text{PO}_4/\text{AgBr}$ heterojunction increased the charge transfer because the excited-electrons by plasma in Ag NPs tend to transfer to AgBr , effectively resisting to the photo-corrosion phenomenon of Ag_3PO_4 .

Herein, an efficient $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) hybrid was synthesized by a nucleation reaction and anion-exchange method. The effect of the complex of AgBr and Ag_3PO_4 with different mass fraction on the degradation of MPB was investigated. The structure, morphology, light absorption and

photocatalytic activity were studied through a number of characteristic methods. The photochemical degradation ability and stability of $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) were investigated using parabens as the degradation substrate. The reactive species trapping experiments and high performance liquid chromatography-mass spectrometry (LC-MS) tests were conducted to propose a possible mechanism. In addition, kinetic studies were conducted.

2. Experimental

2.1. Materials

Inartificial bentonite was bought from Liaoning, Heishan, China. Sodium bromide (NaBr, 99%), silver nitrate (AgNO_3 , 99%), sodium dihydrogen phosphate ($\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$, 99%), methylparaben ($\text{C}_8\text{H}_8\text{O}_3$, 99%), ethylparaben ($\text{C}_9\text{H}_{10}\text{O}_3$, 99%), propylparaben ($\text{C}_{10}\text{H}_{12}\text{O}_3$, 99%), and butylparaben ($\text{C}_{11}\text{H}_{14}\text{O}_3$, 99%) were bought from Guoyao agentia Co., Ltd. All chemicals were of the analytical grade and used without purification.

2.2. Exfoliation of bentonite

The double layered of bentonite was peeled adopting a liquid-phase peeling method.²⁷ The typical process was as follows: 10 g bentonite was mixed with 200 mL H_2O dissolved with 0.4 g NaF, then stirred at 80 °C for 90 min. Then, 0.05 g (NaPO_3)₆ was added to the suspension which was then transferred into a 250 mL round-bottomed flask to carry out high-speed mechanical agitation and treatment with ultrasound for 60 min, respectively. After ultrasonic oscillation, the mixture was aged for 24 h and afterwards centrifuged with 10 000 rpm for 30 min to segregate colloidal part from the supernatant. The colloidal portion of the supernatant was regarded as the Exfoliated Bentonite (EB).

2.3. Preparation of $\text{EB}/\text{Ag}_3\text{PO}_4$ and $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$

The preparation processes of $\text{EB}/\text{Ag}_3\text{PO}_4$ and $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ are shown in Fig. 1. $\text{EB}/\text{Ag}_3\text{PO}_4$ was prepared by electrostatic attraction and the nuclear reaction. First, 40 mL aqueous suspension containing 50 g L⁻¹ exfoliated bentonite, 0.4 g PVP and 15 mmol AgNO_3 were mixed, and then 5 mmol $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$ was added drop by drop. Ag_3PO_4 was precipitated after stirring in darkness for 5 h, and then the olive yellow $\text{EB}/\text{Ag}_3\text{PO}_4$ was gathered by filtration. After rinsing several times with deionized water, $\text{EB}/\text{Ag}_3\text{PO}_4$ nanoparticles were obtained after vacuum drying at 60 °C for 12 h. Meanwhile, 0.84 g $\text{EB}/\text{Ag}_3\text{PO}_4$ nanoparticles and 0.1 g PVP were dispersed in 50 mL of water by ultrasound. After that 0.025 mol L⁻¹ NaBr solution was rapidly dropped into the mixture under the magnetic stirring at dark for 120 min at room temperature. And then the $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ photocatalysts were prepared after they were collected by vacuum drying at 60 °C for 12 h. The series of photocatalysts prepared were labeled as $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (X) (X represents the mass fraction of AgBr in the composite system. X = 10%, 20%, 30%, 40%, and 50%), and the composite (Fig. S1†) with 30% AgBr was evaluated to be the best catalyst for the subsequent experiments.

Fig. 1 Synthesis procedure for EB/Ag₃PO₄/AgBr.

2.4. Characterization

The photocatalysts were characterized with XRD patterns obtained with a DX-2700 diffraction instrument. The appearance images were taken on an emission scanning electron microscope (JSM-7800F). TEM was conducted using a JEOL JEM-2010 equipment. UV-Vis spectra were obtained from the Lambda 950 equipment. X-ray photoelectron spectroscopy (XPS) spectra were acquired using monochromatic Al-K α radiation on a Thermo K-Alpha device. Specific surface areas, and aperture of the compounds were analyzed using the Micromeritics Instruments (ASAP 2010). MPB and the degradation pathway was also explored using LC-MS, on a PerkinElmer Clarus 500 system gas chromatography equipped with a quadrupole spectrometer.

2.5. Photocatalytic MPB degradation

The degradation performances of the materials were evaluated by the photocatalytic oxidation of parabens. MPB was the target pollutant, and degradation performance of other parabens was also discussed. 100 mL MPB solutions (20 mg L⁻¹) and 0.1 g catalyst were stirred in dark for 1 h to guarantee adsorption-desorption equilibrium. The reaction system was then put under a 300 W Xe arc lamp. At given interval of time, collecting and centrifuging of 4 mL suspension. The centrifugal fluid was injected into a colorimetric dish by a 0.22 μ m filter a syringe. The degradation performance of parabens was measured in UV-vis spectra at 308 nm (256 nm). The percentage removal could be calculated by eqn (1):

$$C/C_0 = (C_0 - C)/C_0 \times 100\% \quad (1)$$

C_0 is the primeval consistence of paraben (mg L⁻¹) and C is the consistence of MPB after a certain amount of illumination time t (min).

The stability of composites was evaluated as below: at every run of cyclic experiment, the suspension was extracted and abandoned. The amount of reaction substrates was measured by 20% loss of catalyst per time.

3. Results and discussion

3.1. Characterization results

Fig. 2(a) displays the XRD patterns. The peaks at $2\theta = 6.84^\circ$, 20.12° , and 28.7° are from natural bentonite (JCPDS no. 79-1910). The exfoliation bentonite was obtained and confirmed by the broad and weak peak at a low angle ($2\theta < 10^\circ$), as shown in Fig. 2(b). Ag₃PO₄ (JCPDS no. 06-0505)³⁵ and AgBr (JCPDS no. 06-0438)³⁶ with high crystallinity can be observed in Fig. 2(c) and (d), respectively. They played the main photocatalytic roles in the composite photocatalyst. Fig. 2(e) shows the characteristic peak of EB and Ag₃PO₄, revealing the synthesis of EB/Ag₃PO₄

Fig. 2 XRD patterns of (a) natural bentonite, (b) EB, (c) AgBr, (d) Ag₃PO₄, (e) EB/Ag₃PO₄, (f) EB/Ag₃PO₄/AgBr (30%).

composites. The peak reduction of the exfoliated bentonite may be as a result of the damage of bentonite gel when it was washed. From Fig. 2(f), AgBr, EB and Ag_3PO_4 are found, indicating that EB/ Ag_3PO_4 /AgBr (30%) composites were successful synthesized. In addition, from the XRD picture, AgBr did not alter the peak locations of Ag_3PO_4 , showing that AgBr was loaded on the surface of Ag_3PO_4 .

The SEM (Fig. 3(a)) and HRTEM (Fig. 3(b)) images of exfoliated bentonite are exhibited in Fig. 3. The exfoliated bentonite was like a "cicada's" wing and possesses smooth, thin-layered structures with curly edges, indicating that the bilayer bentonite has been stratified.

Fig. 3(c) presents that Ag_3PO_4 is of an irregular rugby ball morphology while AgBr is of a regular spherical shape, as shown in Fig. 3(d). HRTEM image in Fig. 3(e) shows that the granule size range of Ag_3PO_4 and AgBr is about 10–30 and 5–10 nm, respectively. And there was direct alignment between the EB/ Ag_3PO_4 and AgBr in this heterojunction. Thus, EB/ Ag_3PO_4 /AgBr (30%) was favorable for surface charge transfer. In the HRTEM images, two different kinds of lattice fringes can be observed. One of the fringe intervals is 0.24 nm, which may match the interplanar spacing of plane for AgBr. The other one is 0.27 nm, which could be assigned to the (210) crystallographic plane of Ag_3PO_4 .³⁷ It can then be deduced that the heterojunction structure was formed between the two phases. Based on the above results, the hybrid of EB/ Ag_3PO_4 /AgBr (30%) with a stable structure was confirmed. This revealed that the formation of

hybrid of EB/ Ag_3PO_4 /AgBr (30%) could be conducive to the transfer of photoinduced electron–hole pairs and enhance the photoactivity, which is beneficial to the degradation of organic pollutants.

In addition, Fig. 3(f) shows the EDS mapping of the EB/ Ag_3PO_4 /AgBr (30%). O, P and Ag peaks were observed, where the content of Ag reaches 43%. Br signals corresponding to AgBr were also observed, further confirming that AgBr was produced on the outside surface of Ag_3PO_4 by ion-exchange reaction. Besides, Na, Si, Al, Mg were homogeneously distributed in the EB/ Ag_3PO_4 /AgBr (30%) particles, attributing to the exfoliated bentonite. These further proved that EB/ Ag_3PO_4 /AgBr (30%) was successfully prepared.

The compositions and element valence states of the EB/ Ag_3PO_4 /AgBr (30%) were detected through XPS, the results are shown in Fig. 4. The XPS spectrum (Fig. 4(a)) displays C 1s, O 1s, Ag 3d, Br 3d and P 2p, Si 2p, Al 2p, Na 1s peaks for EB/ Ag_3PO_4 /AgBr (30%), which are consistent with the chemical compositions of the photocatalyst. The peak at 531.58 eV in Fig. 4(b) originating from the lattice oxygen of Ag_3PO_4 .²⁹ Two individual peaks of the Ag 3d spectra in Fig. 4(c) are at about 367.8 and 373.8 eV, corresponding to $\text{Ag} 3d_{5/2}$ and $\text{Ag} 3d_{3/2}$, separately, they were ascribed to Ag^+ from Ag_3PO_4 and AgBr.¹⁷ No XPS peaks of Ag nanocrystals were found, indicating that Ag^0 could not be formed during the preparation procedure. Two peaks of P 2p at 133.2 and 132.52 eV were fully justified of P 2p_{1/2} and P 2p_{3/2}, separately,²⁹ as appeared in Fig. 4(d). In addition, The Si 2p peak

Fig. 3 SEM images of (a) EB and HRTEM images of (b) EB, SEM images of (c) Ag_3PO_4 , (d) AgBr, (e) HRTEM images of EB/ Ag_3PO_4 /AgBr (30%), and (f) the corresponding EDS pattern for EB/ Ag_3PO_4 /AgBr (30%) composite.

Fig. 4 XPS spectra of EB/Ag₃PO₄/AgBr (30%) compound: (a) full-spectrum, (b) O 1s and (c) Ag 3d, (d) P 2p, (e) Si 2p, and (f) Br 3d.

at 103.85 eV is corresponding to SiO₂ (Fig. 4(e)), which is the main component of exfoliated bentonite.²¹ The exfoliated bentonite would provide a larger contact area for photocatalytic reaction. It could also promote photo-induced carriers' separation between Ag₃PO₄ and AgBr on the EB/Ag₃PO₄/AgBr (30%), and greatly enhance the stability of the photocatalyst. The binding energy of Br 3d was 68.38 eV in Fig. 4(f), which could be ascribed to the lattice of Br⁻ in AgBr.³⁸

Fig. 5 presents the adsorption isotherm of stripped-bentonite belongs to type II isotherms, suggesting non-porous or macroporous solid materials. Fig. 5(b) and (c) show that EB/Ag₃PO₄ and EB/Ag₃PO₄/AgBr (30%) are mesoporous materials. The inset of Fig. 5 shows that EB/Ag₃PO₄ and EB/Ag₃PO₄/AgBr (30%) had average pore sizes of 13.53 and 33.3 nm, respectively. The pore size distributions of both catalysts

exhibited the narrow mesoporous range, showing that they had the regular mesoporous framework. Table S1[†] suggests that the pore capacity and aperture of EB/Ag₃PO₄/AgBr (30%) were significantly larger than EB/Ag₃PO₄ and stripped-bentonite. The larger pore size for EB/Ag₃PO₄/AgBr (30%) than ones for exfoliated-bentonite and EB/Ag₃PO₄ may be attributed to the AgBr solidifying on the pore walls and suppressing the structure collapse of the microporous stripped-bentonite and the mesoporous EB/Ag₃PO₄. Compared with the exfoliated bentonite, the reasons for the fractionally diminish in the specific surface area of EB/Ag₃PO₄ and EB/Ag₃PO₄/AgBr (30%) are Ag₃PO₄ or both Ag₃PO₄ and AgBr support on the exfoliated bentonite. It could be explained that EB containing Ag₃PO₄ and AgBr formed three-dimensional mesoporous EB/Ag₃PO₄/AgBr (30%) which can greatly improve the stability of EB/Ag₃PO₄/AgBr (30%).

Fig. 5 N₂ adsorption–desorption isothermal curve and pore size distribution of (a) EB, (b) EB/Ag₃PO₄, and (c) EB/Ag₃PO₄/AgBr (30%).

Moreover, a large specific surface area of exfoliated bentonite could solve agglomeration of Ag₃PO₄ and poor dispersion of heterojunction formed of Ag₃PO₄ and AgBr.

The UV-vis spectra of the designed catalysts are shown in Fig. 6. AgBr has a photoabsorption edge is about 481 nm.³³ Ag₃PO₄ has a wide photoabsorption region, and the light absorption distribution from UV light region to 530 nm,⁹ echoing the band gap (E_g) of 2.36 ev. The exfoliated bentonite hardly absorbs the visible light. But the EB/Ag₃PO₄ emerged a mixed absorbance of EB and Ag₃PO₄ in comparison with the bare Ag₃PO₄, existing a slight band redshift. When AgBr was introduced into EB/Ag₃PO₄ to form the heterojunction structure EB/Ag₃PO₄/AgBr (30%), the absorption band of 400–800 nm and stronger light response were observed in the entire visible light

region. This could reveal that the strong interaction between the monomers of the composite allowed the solar spectrum to be used more effectively. Moreover, the local surface plasmon response of Ag and the double heterojunctions of Ag₃PO₄ and AgBr could improve the efficiency of photocharge transfer and inhibit the charge recombination, which enhanced the photocatalytic property of EB/Ag₃PO₄/AgBr (30%).

To investigate the separation of photogenerated electron–hole pairs more deeply, photocurrent responses of the Ag₃PO₄, and EB/Ag₃PO₄/AgBr (30%) composites samples were recorded and the results are shown in Fig. S2.^{†2} The photocurrent response of EB/Ag₃PO₄/AgBr (30%) electrodes under visible light irradiations was observed. However, the photocurrent of Ag₃PO₄ was not detected under the same test conditions. It can be found that EB/Ag₃PO₄/AgBr (30%) exhibited a constant photocurrent density during 20 min light irradiation, indicating a higher photoelectric conversion efficiency and higher stability of EB/Ag₃PO₄/AgBr (30%) than pristine Ag₃PO₄. It can be inferred that the heterojunction structure formed in the composite is conducive to the separation of electrons and holes due to the matched energy level structure and the interface interaction between Ag₃PO₄ and AgBr loaded on the exfoliated bentonite. Therefore, a stronger photocurrent than the active component Ag₃PO₄ is produced.³⁹ This will make the composite have a stronger degradation effect on pollutants.

Fig. 6 UV-vis diffuses reflectance absorption spectra of AgBr, EB, pure Ag₃PO₄, EB/Ag₃PO₄ and EB/Ag₃PO₄/AgBr (30%).

The line of a blank experiment (under visible light without a catalyst) in Fig. 7(a) was stable, showing the negligible self-photolysis of MPB without photocatalysis under visible light irradiations.⁴⁰ Addition of EB has only adsorption effect on MPB. Moreover, the MPB degradation reached 64.97% and 92.79% with the addition of AgBr and Ag₃PO₄, respectively. But only 62.47% of MPB was degraded with BT/Ag₃PO₄. It seemed that Ag₃PO₄ was inserted into interlayer and decreased its activity. In comparison, EB/Ag₃PO₄ possessed a good activity (94.99%). The introduction of AgBr into EB/Ag₃PO₄ enhanced the photocatalytic activity, whereas MPB completely reached degradation in 40 min. Compared with AgBr, Ag₃PO₄, EB and BT/Ag₃PO₄, EB/Ag₃PO₄, respectively, EB/Ag₃PO₄/AgBr (30%) unfolded the supreme catalytic function. This can be credited to loading Ag₃PO₄ on the exfoliated bentonite, which improved the dispersion of Ag₃PO₄ and enhanced the stability of EB/Ag₃PO₄/AgBr (30%). Introduction of AgBr into EB/Ag₃PO₄ could greatly enhance the catalytic function owing to the retardation of the light corrosion about Ag₃PO₄. Fig. S3 and S4[†] show that the degradation rate of EPB, PPB, and BuPB is 99.4%, 95.6%, and 93.93%, respectively. The results confirmed that EB/Ag₃PO₄/AgBr (30%) has strong visible light catalytic properties for the decomposition of paraben. The reaction rate constant of EB/Ag₃PO₄/AgBr (30%) ($K_3 = 0.0358 \text{ min}^{-1}$) for MPB degradation was more than 4 times of that on Ag₃PO₄ ($K_1 = 0.011 \text{ min}^{-1}$), and more than 2.75 times of that on EB/Ag₃PO₄ ($K_2 = 0.013 \text{ min}^{-1}$). It suggests that the modification of Ag₃PO₄ with

EB and AgBr can significantly improve the photocatalytic properties of materials under the irradiations.

Fig. 7(c) reveals that the adsorption capacity before sunlight irradiations for AgBr, EB, Ag₃PO₄, BT/Ag₃PO₄, EB/Ag₃PO₄ and EB/Ag₃PO₄/AgBr (30%) are 1.092%, 33.97%, 1.88%, 23.4%, 33.57% and 29.45%, respectively. EB displays a distinctly higher absorptivity for Ag₃PO₄, which was beneficial for strengthening the photochemical catalysis function and stability. Adsorption capacity of EB/Ag₃PO₄/AgBr (30%) is lower than EB/Ag₃PO₄ although the reaction rate was much faster. Noteworthy, EB/Ag₃PO₄/AgBr (30%) presented the maximum reaction rate constant, which was approximately 13 times and 1.1 times more than that of the Ag₃PO₄ and EB/Ag₃PO₄, respectively. This could effectively reduce the overall degradation time of MPB to achieve rapid degradation of MPB in industrial wastewater treatment. This also indicated that the adsorption capability was the one of reasons for the high degradation activity of EB/Ag₃PO₄/AgBr (30%).

3.3. Reusability and stability of the photocatalysts

Recycling experiments of MPB degradation over EB/Ag₃PO₄/AgBr (30%) were implemented to assess the stability of materials. From Fig. 8(a), the MPB decomposition on Ag₃PO₄ and EB/Ag₃PO₄ decreased to 14% and 57% after 5 consecutive cycles, respectively. By contrary, the degradation rate of EB/Ag₃PO₄/AgBr (30%) to MPB was still 91% after five recycling runs, revealing that it had excellent stability under the illumination. To further unveil the stability of catalyst, XRD was tested to compare the crystal structure changes of the EB/Ag₃PO₄/AgBr (30%) before and after the reaction. Fig. 8(b) shows that the

Fig. 7 (a) Photocatalytic degradation of MPB by composites; (b) kinetics fitting for the degradation of MPB; (c) adsorption properties and rate coefficients of (A) AgBr, (B) exfoliated bentonite, (C) Ag₃PO₄, (D) bentonite/Ag₃PO₄ composites, (E) EB/Ag₃PO₄, (F) EB/Ag₃PO₄/AgBr (30%), (G) visible without catalytic, (H) dark + EB/Ag₃PO₄/AgBr (30%).

utilized EB/Ag₃PO₄/AgBr (30%) had a similar crystal structure with the fresh one. No additional characteristic peaks were observed in the used EB/Ag₃PO₄/AgBr (30%), implying that no crystalline structure was evidently changed after the photocatalytic reactions.

The used EB/Ag₃PO₄/AgBr (30%) was also characterized by XPS, and giving the outcomes as follows in Fig. 8(c). After 5 cycle experiments, the binding energies of Ag 3d_{5/2} and Ag 3d_{3/2} are 367.89 and 373.99 eV about the used EB/Ag₃PO₄/AgBr (30%), respectively. The Ag 3d_{3/2} was fitted into two distinct peaks (373.8 and 374.15 eV).⁴¹ The values of Ag 3d at 373.8 and 367.89 eV echoed Ag⁺.⁴² The peak at 374.15 eV was due to metallic silver, which was much smaller than ones of Ag⁺.⁴³ The formation of a small amount of Ag⁰ would not wrap Ag₃PO₄ to affect the activity of the active component but form a plasma effect to boost the photocatalytic oxidation of the samples. The intensity of Ag⁺ decreases and Ag⁰ increases suggested that EB/Ag₃PO₄/AgBr (30%) was turned into EB/Ag₃PO₄/AgBr (30%)@Ag in the procedure of photochemical catalysis. It could form a stable plasma heterojunction photocatalyst because of the formation of Ag⁰ with plasma resonance effect between Ag₃PO₄ and AgBr. The results further demonstrated that AgBr and Ag₃PO₄ supported by exfoliated bentonite could significantly increase the photocatalytic degradation stability and activity.

3.4. Mechanistic studies

It has been widely accepted that the photoinduced holes (h⁺), ·O₂⁻, and ·OH radicals⁴⁴ are the several reactive substances in

the photocatalytic process.⁴⁵ Thus, catalase, Cr(vi), Na₂C₂O₄, isopropanol⁴⁶ and vitamin C (VC) were used to investigate the contribution rate of H₂O₂,⁴⁷ e⁻, h⁺, ·OH, and ·O₂⁻ (ref. 20) for MPB degradation. The results are exhibited in Fig. 9. The removal of MPB decreased to 70.92% with the addition of catalase. The contribution of H₂O₂ was 29.08%, improving that H₂O₂ acted a certain part during the process of photochemical catalysis deactivation. Degradation rate of MPB dropped to 90.11% or 82.55% with the introduction of VC or Cr(vi), respectively. These implied that ·O₂⁻ and e⁻ contributed 9.89% and 17.45% to the reduction of MPB. Interestingly, degradation rate of MPB reached 25.59% and displayed a significant inhibitory effect with the addition of Na₂C₂O₄, demonstrating that

Fig. 9 Effect of different quenching agents on the decomposition of MPB over EB/Ag₃PO₄/AgBr (30%) under irradiations.

Fig. 8 (a) Recycling experiments for MPB photodegradation by Ag₃PO₄, EB/Ag₃PO₄ and EB/Ag₃PO₄/AgBr (30%) under the illumination, (b) the XRD patterns of EB/Ag₃PO₄/AgBr (30%) after 5 cycle experiments, and (c) the XPS patterns of EB/Ag₃PO₄/AgBr (30%) after 5 cycle experiments.

the contribution of h^+ to removal rate of MPB was 74.41%. The results indicated that the holes were the most important component in the photolysis of MPB. When isopropanol was added, $\cdot OH$ ⁴⁸ contributed 30.88% to the degradation efficiency of MPB, revealing that $\cdot OH$ played the second major role in the decomposition of MPB. Besides, to the photocatalytic process, the combination of $Na_2C_2O_4$ and isopropanol were employed to go a step further verify the dedications of h^+ and $\cdot OH$, and the degradation degree of MPB was 24%. Nevertheless, the addition of VC, Cr(vi) and catalase at the same time had a feeble inhibitory effect on the removal of MPB. Therefore, it concludes that all the h^+ and $\cdot OH$ contributed to the high photo-catalytic properties of EB/ $Ag_3PO_4/AgBr$ (30%) for the removal of MPB.

In order to further explore the possible degradation pathway, LC-MS analysis was carried out on the products of MPB photodegradation over EB/ $Ag_3PO_4/AgBr$ (30%), and the outcomes are presented in the Fig. S5.† The main photodegradation intermediates of MPB are hydroxylated substances including benzoic acid, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid and other benzene substances. These hydroxylated products can be further oxidized and discomposed by the attack of h^+ and $\cdot OH$. Benzoic acid was formed by the oxidation decomposition of the side chain of benzene ring. Along with the oxygenolysis further reacts, benzoic substances such as 3-hydroxybenzoic acid and 4-hydroxybenzoic acid were obtained by the further degradation of benzoic acid. With the reaction proceeding, the above products could be oxidized and generate some smaller molecule carboxylic acids before the formation of carbon dioxide and water.

Based on the above outcomes, the feasible mechanism of photodecomposition of parabens on EB/ $Ag_3PO_4/AgBr$ (30%) was proposed. The light adsorption capacity of EB/ $Ag_3PO_4/AgBr$ (30%) in the visible region was improved (Fig. 10). The work function about AgBr was higher than that of Ag ($\phi_{Ag} = 4.25$ eV, $\phi_{AgBr} = 5.3$ eV) while Fermi energy level was lower. Thus, electrons were shifted directly from the plasma metal Ag to the guide band of AgBr. The energy of incident photon was converted by Ag and entered the local surface plasmon resonance (SPR) vibration⁴⁹ and transfers its energy to Ag_3PO_4 by resonance energy transfer, generating electron–hole pairs in Ag_3PO_4 . Thus, SPR electrons generated by Ag and photo-generated electrons obtained by AgBr could be readily diverted to the interface of Ag_3PO_4 , which greatly enhances the photocatalyst property in the light.

It was well known that effective suppression of electron–hole pair recombination was essential to improve photocatalytic activity.⁴² Under the illumination, an animate photon rapidly excited the electron transition through the Ag_3PO_4 and AgBr valence band (VB) to the conduction band (CB) (eqn (2)).⁴⁰ The photosensitive electrons on the CB of AgBr could shift liberally to the CB of Ag_3PO_4 , while the h^+ on the VB of Ag_3PO_4 could freely move to the VB of AgBr. These lead to that the recombination of electron–hole pairs was effectively suppressed (eqn (3)). AgBr (CB = 0.07 eV, VB = 2.67 eV) had minus conduction and valence band potentials than Ag_3PO_4 (CB = 0.45 eV, VB = 2.90 eV).²⁷ Thus, SPR electrons generated by Ag and photo-induced electrons generated by AgBr could be readily diverted to

Fig. 10 The photodegradation mechanism of MPB on EB/ $Ag_3PO_4/AgBr$ (30%).

the interface of Ag_3PO_4 . The photogenerated holes of Ag_3PO_4 could be also migrated on the outer face of AgBr. This could powerfully restrain the charge re-merge, making more carriers ready for the decomposition of parabens.⁴³ Plasma electrons would be ejected into the conduction band of Ag_3PO_4 , which could be captured and reacted with O_2 to form $\cdot O_2^-$ (eqn (4)). Furthermore, $\cdot O_2^-$ and H_2O might be transformed into H_2O_2 and $\cdot OH$ to oxidize parabens (eqn (5)). The resulting active substances could be rapidly used to decompose organic matter, moreover, the holes produced by Ag^o would have a great synergistic effect for parabens oxidization.⁴⁴ Concurrently, the holes generated by Ag_3PO_4 move toward AgBr, and further participate in the degradation reaction of the organics (eqn (6)). In addition, the holes have the interaction with H_2O to produce $\cdot OH$ (eqn (7)) for parabens decomposition. Our work suggested that the mechanism for the photodegradation of MPB over EB/ $Ag_3PO_4/AgBr$ (30%) can be explained as follows: (a) the plasma metal Ag can efficiently shift the photogenerated electrons to Ag_3PO_4 and AgBr for reacting with O_2 to form $\cdot O_2^-$, H_2O_2 and $\cdot OH$ to oxidize parabens. (b) The holes produced by Ag^o would also act on the oxidation of parabens. (c) Photoinduced h^+ and $\cdot OH$ radicals directly produced by the h^+ can lead to the mineralization of organic pollutants into CO_2 and H_2O .

Therefore, high activity and stability of EB/ $Ag_3PO_4/AgBr$ (30%) can be explained as follows. Structural stability of EB/

$\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) composite can be greatly enhanced because of Ag_3PO_4 loaded on the surface of exfoliated bentonite. Besides, $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) exhibited a large BET external surface area and kept a good adsorption performance of organic pollutants molecules. Furthermore, bulk heterojunction of AgBr and Ag_3PO_4 realized *in situ* photo-reduced Ag nanoparticle, which prominently diminished the association rate of electron-hole pairs on $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) and improved photocatalytic activity.

4. Conclusions

$\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) hybrid was successfully synthesized using a deposition-precipitation and *in situ* anion-exchange methods. $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) exhibited superior photocatalytic performance to pure Ag_3PO_4 and $\text{EB}/\text{Ag}_3\text{PO}_4$ in the parabens photodegradation under visible light irradiations. Furthermore, degradation efficiency of MPB still remained 91% after 5 recycled tests. Degradation of MPB was mainly *via* $\cdot\text{OH}$ and h^+ oxidation decomposition over $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%). The high activity and stability of $\text{EB}/\text{Ag}_3\text{PO}_4/\text{AgBr}$ (30%) can be attributed to the strong structural stability of materials, which significantly reduced the recombination rate of the electron-hole pairs.
