MRI contrast enhancement of liver pre-neoplasia using iron–tannic nanoparticles†

 Thipjutha Phatruengdet,^a Jannarong Intakhad,^a Monreudee Tapunya,^a Arpamas Chariyakornkul,^{bc} Chi Be Hlaing,^b Rawiwan Wongpoomchai^{bc} and Chalermchai Pilapong *^{ad}

The most challenging part of liver cancer detection is finding it in the very early stages. It has been argued that liver preneoplasia is found at the very earliest stages of liver cancer. The presence of a lesion is closely related to the development of HCC. We report herein a new class of iron-based T₁ MRI contrast agents which are nanoparticles of iron–tannic complexes (so-called Fe–TA NPs) that can be used for detecting liver preneoplasia. Preliminary assessment of their toxicity in healthy rats provides suitable imaging dose ranges with acceptable toxicity. In diethylnitrosamine (DEN) induced rats, it is shown that Fe–TA NPs are capable of enhancing MRI signals in rat livers having pre-neoplastic lesions within 60 minutes post-injection. The enhancement efficacy is strongly dependent on the characteristics of pre-neoplastic foci (GST-P+ foci). The highest enhancement was in good correlation with the size of GST-P+ foci and amount of Fe–TA NPs accumulated in the liver, and might be caused by the dysfunction of liver sinusoids along with cellular uptake capability of pre-neoplastic hepatocytes. Our results show that Fe–TA NPs are of great interest to develop as an efficient MRI imaging agent for risk assessment of liver cancer.

Introduction

Liver cancer is one of the most important challenges of global health, especially in developing countries such as in Asia where most of the burden of this disease is borne.¹ Due to the fact that early stage liver cancer does not show any signs and symptoms, the majority of cases of liver cancer are diagnosed at advanced stages of the disease, making it too late for treatment.^{2,3} It is well known that early detection is the key to successful treatment of liver cancer and improves survival rates,³ therefore it is critically important to develop a diagnostic platform for detecting liver cancer as early as possible. Imaging diagnosis with magnetic resonance imaging (MRI), one of the current means of liver cancer diagnosis, provides high spatial resolution of soft tissue images in three-dimensions without using ionizing radiation.⁴ Although the current guidelines for diagnosing liver cancer are very advanced, the mortality rate of patients is still high.⁵

Currently, very early diagnosis of liver cancer with MRI cannot be easily performed due to the limitations of the measurement. Even though various imaging agents have been developed for imaging implication in different stages of liver cancer, there has been no clinically available MRI agent for very early stage liver cancer.^{6,7} It is accepted that the presence of preneoplastic lesions at early stage of hepatocarcinogenesis is closely related to the development of HCC later on.⁸ There should be great interest in improving imaging techniques to detect liver pre-neoplasia. Moreover, because there is a long period before the development of liver cancer, imaging liver preneoplasia provides increased opportunities for interventions that prevent the progression of the disease. Therefore, development of MRI agent for hepatic preneoplasia is a promising approach for early detection of liver cancer.

At present, Gadolinium (Gd³⁺) based contrast agents are mainly used in MRI scans performed in clinics.⁹ However, free Gd³⁺ ions are very toxic to both patient and the environment.^{10,11} Iron (Fe³⁺) complex can be also used as a contrast agent instead of Gd³⁺ because Fe³⁺ is also a paramagnetic material having less toxicity.^{12–14} The iron–tannic nanoparticles (Fe–TA NPs), which have been produced by the interaction of Fe³⁺ and tannic acid (TA), have shown beneficial properties. Examples of their beneficial properties are that they have small size, high MRI relaxivity, high stability, good water solubility, and demonstrate high uptake efficiency in tumor cells with capability of being responsive to abnormal microenvironments.^{15,16} Because of their good physico-chemical properties along with their ease of

scale-up reproducibility, Fe-TA NPs could offer great feasibility as a low-cost clinical MRI contrast agent with many advantageous characteristics for use in liver cancer diagnosis. In this research, we aimed to investigate the feasibility of using iron-tannic nanoparticles to enhance MRI contrast of rat liver with preneoplastic lesions. Hopefully, our findings provide approaches for non-invasive and early screening of liver cancer along with the development of a clinically or commercially translatable MRI agent in the near future.

Methods

Fe-TA NPs synthesis

Fe-TA NPs were synthesized according to our previous work with some modifications.¹⁶ In brief, 10 mmol of tannic acid and 30 of mmol of FeCl₃·6H₂O were added to 300 ml of phosphate-buffered saline (PBS). The Fe-TA NPs were suddenly obtained, appeared as red-wine color. The obtained Fe-TA NPs were heated at 90 °C in order to concentrate the Fe-TA NPs and further purified by dialysis method. Then, the Fe-TA NPs were filtered through cellulose acetate membrane filters (pore size = 0.22 μm) for sterilization. The Fe-TA NPs were subjected to quantification and characterization and stored at 4 °C for further experiments. Calculation of the concentration of the Fe-TA NPs is shown in ESI.†

Animal preparation

Male Wistar rats were purchased from Nomura Siam International Co., Ltd. Bangkok, Thailand. All rats were kept in stainless steel cages of the Animal House, Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand. They were housed and acclimated under a 12 hour light/dark cycle at 21–25 °C and relative humidity set at 50–60% throughout the study. All animals were free access to food and water. The animal used protocols were approved by the Animal Ethics Committee of Faculty of Medicine, Chiang Mai University, Thailand (Protocol Number: 09/2562).

Acute toxicity of Fe-TA NPs

To determine possible toxicity and optimal imaging dose of Fe-TA NPs in rats, 8 week-old female rats were intravenously injected with 17.5 mg kg⁻¹ b.w. (*n* = 3), 27.5 mg kg⁻¹ b.w. (*n* = 3), and 55 mg kg⁻¹ b.w. of Fe-TA NPs (*n* = 5). After injection, all rats were regularly monitored for 14 days in order to observe any symptoms and death for LD₅₀ estimation. In addition, their weights were recorded before and after injection of Fe-TA NPs. At the end of the study period, the rats were sacrificed, the blood was collected for complete blood count analysis, and vital organs including lung, heart, thymus, liver, pancreas, kidneys, spleen, adrenal glands, ovary, and brain were collected to find any organ abnormality.

DEN induced liver pre-neoplasia model and MRI examination

Six-week-old rats were divided into 2 groups. In the DEN-induced group (*n* = 3), DEN (Sigma) at 100 mg kg⁻¹ b.w. was intraperitoneally injected once a week for 3 weeks. In the

control group (*n* = 2), 5 ml kg⁻¹ b.w. of 0.9% NaCl was injected with instead of DEN. After 2 weeks of the last injection (week 5), rats were subjected to partial hepatectomy for removal of median and left lateral lobes of the liver. At week 16 of the experiment, all rats were anaesthetized using a 40 mg kg⁻¹ b.w. of thiopental *via* intraperitoneal injection and were whole body scanned by an MRI scan (Philips Ingenia 1.5 T MRI scanner) which was performed in both axial (ax) and coronal (cor) plane before and after intravenous injection of 11 mg kg⁻¹ b.w. Fe-TA NPs using T₁-weighted imaging. The MRI parameters were used as followed: repetition time, 400 ms; echo time, 8 ms; scan time, 14 minutes; field of view, 200 mm; and slice thickness and gap, 1.5/0.2 mm. At the end of the experiment, all rats were sacrificed by overdose of thiopental injection and their livers were cut and fixed in 10% formalin for further immunohistochemical examinations.

For MRI image analysis, signal intensity (SI) was measured by drawing a region of interest (ROI) on 80% area of liver in each slide of the image using Philips DICOM Viewer R3.0 software, these were then compared to those drawn on muscle of each plane. Percentage of MRI signal enhancement (% enhancement) was calculated by the following equation listed below:

$$\% \text{ enhancement} = \frac{SI_{\text{post}} - SI_{\text{pre}}}{SI_{\text{pre}}} \times 100$$

where, SI_{pre} is mean of corrected SI (SI_{liver}/SI_{muscle}) before injection of Fe-TA NPs, SI_{post} is mean of corrected SI (SI_{liver}/SI_{muscle}) after injection (45 min in axial plane and 60 min in coronal plane).

After MRI examination, all rats were sacrificed, the liver was collected, weighed, and was subjected to further analysis such as accumulation of Fe-TA NPs and histology analysis.

Fe-TA NPs content analysis in liver

For quantitative accumulation of Fe-TA NPs analysis, quantity of liver was homogenized in a mixture of pure nitric (≥69%) (RCI Labscan) and hydrochloric acid (≥37%) (RCI Labscan) for 24 hours at room temperature. The homogenate was centrifuged at 10000g for 10 minutes. The supernatant was collected and was further diluted in 2% mixed acid solution. The solution was subjected to ICP-OES analysis for iron content determination according to standard protocol.

Liver histology analysis

Formalin-fixed and paraffin-embedded (FFPE) tissues were used for our tissue analysis. Various experiments were carried out and described as follows:

Prussian blue staining. Liver sections (2 μm) were deparaffinized with xylene (RCI Labscan) and then were washed in absolute ethanol (Merck). Next, the sections were rehydrated in serial dilutions of alcohol until DI water was used. After that, the sections were immersed in a mixture of 5% HCl and 5% potassium ferrocyanide (Merck) for 30 minutes at room temperature. After washing with DI water, the sections were counterstained with 0.2% neural red (May & Baker) for 5 minutes at room temperature and then were washed with DI

water until they were clear. Finally, the sections were examined with an inverted microscope (Nikon, Eclipse Ts2).

H&E staining. Liver sections (5 μm) were first deparaffinized and rehydrated according to the procedure mentioned above. The sections were subjected to consecutive staining with hematoxylin and eosin, respectively. The sections were dehydrated in absolute ethanol and xylene, respectively, and were then mounted with Permount (Merck). Finally, the sections were observed with an inverted microscope.

Immunohistochemistry staining of GST-P positive foci. After deparaffinization and rehydration were performed on paraffin embedded slides according to a standard protocol, the immunohistochemical staining of GST-P positive foci was examined using the method according to Punvittayagul *et al.*¹⁷ Briefly, the liver sections were soaked in hydrogen peroxide and skim milk to block endogenous peroxidase activity and nonspecific protein binding, respectively. Then, the sections were incubated with rabbit polyclonal anti rat GST-P antibody (Medical and Biological Laboratories) for 2 hours and stained with anti-rabbit IgG biotinylated antibody (Vector Laboratories) as a secondary antibody for 30 minutes in a humidify box at room temperature. After washing free antibodies with PBS, the sections were labeled with avidin-biotin complex and further stained by diaminobenzidine. They were counterstained with hematoxylin and dehydrated in absolute ethanol and xylene. The GST-P positive foci were observed with an inverted microscope. Size and number of foci were analyzed using ImageJ software.

Scanning electron microscope (SEM) analysis of liver section. H&E stained liver sections were used for SEM analysis. In a typical procedure, the coverslip was carefully removed from the mounted H&E stained liver sections using xylene. The sections were dried overnight at 80 $^{\circ}\text{C}$. Next, the sections were cut and put on a copper stub. The sample stubs were subjected to gold sputtering. Finally, the liver sections were observed with SEM (JEOL JSM-5910LV).

Immunofluorescence staining of CD34. Immunofluorescence of CD34 is a method used to identify capillaries and sinusoids in liver using anti-CD34 monoclonal mouse antibody (CD34) (US Biological). In a typical procedure, the liver sections (5 μm) were deparaffinized and rehydrated according to standard protocol. Next, antigen retrieval was performed by boiling the sectioned slides in 10 mM sodium citrate buffer (pH 6.0). After cooling down to room temperature and washed with DI water, the sections were permeabilized with a permeabilization solution containing 1% BSA (Capricorn), 0.4% Triton X-100 (Bio Basic) in PBS for 10 minutes and were further incubated with a blocking solution (5% BSA) for 30 minutes. Afterward, the permeabilized sections were incubated with an anti-CD34 monoclonal mouse antibody (FITC labeling) for 24 hours at 4 $^{\circ}\text{C}$. After washing twice with 1% BSA in PBS, the stained sections were mounted with Permount. The CD34⁺ capillaries and sinusoids in liver were then observed under an inverted fluorescence microscope (Nikon, Eclipse Ts2).

Immunohistochemistry staining of OAT. After deparaffinization and rehydration were performed on paraffin embedded slides according to a standard protocol. After antigen retrieval, the liver sections were soaked in 3% hydrogen peroxide and

normal goat serum to block endogenous peroxidase activity and nonspecific protein binding, respectively. Then, the sections were incubated with rabbit polyclonal antibody of organic anion transporter (OAT) (Elabsience) for 2 hours and stained with poly-HRP anti mouse/rabbit IgG (Elabsience) as a secondary antibody for 20 minutes. After washing, the sections were stained by diaminobenzidine. The sections were counterstained with hematoxylin and then dehydrated, transparentized and sealed. Finally, the sections were observed under an inverted fluorescence microscope (Nikon, Eclipse Ts2).

Results and discussion

The Fe-TA NPs were easily obtained by simple mixing of PBS solution of tannic acid and ferric chloride. In such conditions, iron-mediated self-assembly of iron-tannic complexes occurs. It is important to note that pH of mixing solution is critical for the self-assembly process and the coordination state of the complexes. Reaction proceeded in solution without controlling pH, and different physico-chemical properties were then obtained. PBS buffer (pH 7.4) was chosen as the reaction medium because this condition is suitable to form nanosized Fe-TA complexes with predominantly Tris-coordinated structure that are more stable structures.¹⁶ Schematic illustration for Fe-TA NPs preparation and typical characteristics of Fe-TA NPs are shown in Fig. S1.† The obtained Fe-TA NPs exhibited very good physico-chemical properties such as small size with narrow size distribution, and good colloid stability. Indeed, they were highly stable for transchelation and transmetalization.¹⁶ Our method for preparing the Fe-TA NPs was simple and reproducible without having to use expensive equipment and reagents, which allows us to apply this method for an industrial application.

As far as toxicity is concerned, toxicology of Fe-TA NPs was carried out according to OECD guidelines with some modifications.¹⁸ Initially, rats were intravenously injected with 17.5 mg kg⁻¹ b.w. ($n = 3$) and 27.5 mg kg⁻¹ b.w. ($n = 3$) Fe-TA NPs. It was found that no clinical signs of mortality and morbidity were observed for 14 days. After that 55 mg kg⁻¹ b.w. Fe-TA NPs was injected into 5 rats. We found that a rat had died after a 24 hour of injection while the others had no any clinical signs for 14 days. Changes in body weights and organ weights were summarized in Table S1.† No change in body weights were observed in all treatment groups as compared to control animals. Treatment group with 17.5 mg kg⁻¹ b.w. Fe-TA NPs showed significantly greater kidney weight and relative liver and kidney weight than negative control, but those in treatment groups of 27.5 and 55 mg kg⁻¹ b.w. showed no significant difference in the relative liver, spleen, and kidney weight. In addition, blood tests showed that 27.5 and 55 mg kg⁻¹ b.w. Fe-TA NPs did not affect white blood cells (WBC), red blood cell (RBC) and platelet (PLT). According to data above mentioned, it can be inferred that Fe-TA NPs has low toxicity with LD₅₀ > 55 mg kg⁻¹ b.w. Before being subjected to *in vivo* MRI, a serial dilution of Fe-TA NPs was imaged to confirm their capability of enhancing MRI signals. Fig. S2† shows signal intensity with the corresponding MRI image of solutions of Fe-TA NPs. Clearly, increasing signal intensity in a concentration-dependent

manner, demonstrating their potential application as MRI agents.

In order to investigate capability of Fe-TA NPs in MRI contrast enhancement of liver pre-neoplasia, 5 rats were divided into control rats ($n = 2$) and DEN-induced rats ($n = 3$). It should be noted that our DEN treatment protocol was considered as midterm treatment, which allows the promotion of pre-neoplasia lesions in liver.^{19,20} According to the experiment plan (as summarized in Fig. 1A), all rats were imaged before and after intravenous administration of Fe-TA NPs ($11 \text{ mg kg}^{-1} \text{ b.w.}$), and enhancement of signal intensity was analyzed. Fig. 1B demonstrates percentage of the mean contrast enhancement of liver in coronal and axial planes after intravenous injection. Obviously, the greatest contrast enhancement is clearly found in DEN-3, while those observed in DEN-1 and DEN-2 are not significant, as compared to control rats. Fig. 1C shows typical T_1 -weighted MR images of liver rats in the Control-1 and DEN3 before and after injection of Fe-TA NPs, which clearly demonstrates the enhancement occurring in DEN-3. Next, we attempted to determine iron accumulation in the livers of each rat. The quantitative analysis was determined by ICP-OES and was found to be 0.718 ± 0.59 , 0.76 ± 0.95 , 0.56 ± 0.22 , 0.83 ± 0.12 , and 1.02

Fig. 1 (A) The experimental protocol for MRI examination of DEN induced liver pre-neoplasia in rats. (B) Percentage of MRI signal enhancement in liver of different rats after being intravenously administrated with Fe-TA NPs. (C) Typical T_1 -weighted images of Control-1 and DEN-3 rats before and after injection of Fe-TA NPs. (D) Iron content in liver of different rats after intravenous injection of Fe-TA NPs for 1 hour (error bar obtained from 3 measurements of different liver lobes of each rat). (E-I) Prussian blue stained liver sections of Control-1, Control-2, DEN-1, DEN-2 and DEN-3, respectively. (Scale bar 100 μm).

$\pm 0.23 \text{ mg g}^{-1}$ for rat in Control-1, Control-2, DEN-1, DEN-2, and DEN-3, respectively. In addition to ICP-OES analysis, qualitative accumulation in liver sections was also investigated using Prussian blue staining. As expected, similar trends were observed, whereby the great accumulation was observed in DEN induced group, especially in DEN-3 (Fig. 1D-I).

Although the above results demonstrate the potential application of Fe-TA NPs as molecular MRI agents for hepatic preneoplasia, it is still unclear why only DEN-3 shows the great enhancement. We hypothesized that contrast enhancement might be associated with particular pathological lesions found in the liver. To determine this, pathological analysis of DEN induced rats was carried out. It is reported that glutathione *S*-transferase placental type (GST-P) is hardly detectable in normal rat livers, but it is found to be expressed in preneoplastic liver foci. GSTP is a member of the glutathione *S*-transferase supergene family that plays a role in detoxification of xenobiotics including DEN. It is markedly elevated during hepatocarcinogenesis and thus, GST-P positive foci is considered as an endpoint marker for liver preneoplasia.^{8,20} Herein, we determined GST-P positive foci in liver sections in DEN-induced rats using immunohistochemistry (summarized as cartoon in Fig. 2A).

Fig. 2B shows different characteristics of GST-P positive foci including size of foci, area of foci/total area, and number of foci of DEN induced rats. Of course, no GST-P positive foci were observed in Control-1 and Control-2. In DEN-1, GST-P foci/total area was determined to be $0.14 \text{ mm}^2 \text{ cm}^{-2}$, while the number of foci was 5 and the average area was 0.09 mm^2 . In DEN-2, GST-P foci/total area was $1.96 \text{ mm}^2 \text{ cm}^{-2}$, while the number of foci was 51 and average area was 0.14 mm^2 . In DEN-3, GST-P foci/total area was $1.78 \text{ mm}^2 \text{ cm}^{-2}$, while the number of foci was 19 and average area was 0.33 mm^2 . Not surprisingly, there are different characteristics of GST-P positive foci in different DEN-induced rats, indicating that induction of hepatic pre-neoplasia in each rat by DEN is different. It is important to note that not only size of foci but all areas of foci/total area and number of

	Area of GST-P positive foci (mm^2/cm^2)	Size of GST-P positive foci (mm^2)	Number of GST-P positive foci
Control-1	0	0	0
Control-2	0	0	0

Table 1 Correlation analysis between different characteristics of GST-P positive foci and liver iron content as well as % enhancement of MRI signal

Parameters	Area of GST-P positive foci (mm ² cm ⁻²)	Size of GST-P positive foci (mm ²)	Number of GST-P positive foci
Iron content	Strong positive correlation ($R^2 = 0.85$)	Strong positive correlation ($R^2 = 0.91$)	Weak positive correlation ($R^2 = 0.36$)
% enhancement (axial)	Strong positive correlation ($R^2 = 0.79$)	Strong positive correlation ($R^2 = 0.95$)	Weak positive correlation ($R^2 = 0.25$)
% enhancement (coronal)	Weak positive correlation ($R^2 = 0.54$)	Strong positive correlation ($R^2 = 0.99$)	No correlation ($R^2 = -0.08$)

foci are critical to take into account because DEN might act in different ways in different rodent models, leading to variation on lesions.²¹ This encouraged us to further analyze the correlation between different characters of GST-P positive foci and MRI signal as well as iron accumulation. The correlation analysis is shown in Table 1. It can be seen that GST-P foci/total area has strong positive correlation with iron content in liver and percentage of signal enhancement in axial plane. However, it is weakly correlated to the % enhancement in coronal plane. For the size of GST-P foci, there are strong positive correlations to all parameters. When considering number of foci, it has only weak positive correlation to iron content in livers while there is no correlation with % enhancement in both coronal and axial plane. From the above results, it can be pointed out that lesion size does matter for accumulation of Fe-TA NPs as well as MRI contrast enhancement.

Next, we tried to figure out why the Fe-TA NPs preferentially accumulate in hepatic pre-neoplasia. At first, we carefully

analyzed characteristic of iron accumulation in liver sections stained by Prussian blue assay. Fig. 3A–D shows Prussian blue staining images of different areas of liver tissue taken from Control-2. It can be seen that Prussian blue is present within hepatic sinusoids, rather than in liver parenchyma, implying that the Fe-TA NPs cannot easily penetrate into liver parenchyma or hepatocytes. However, those in DEN-3, the Fe-TA NPs are found to distribute throughout the section with a higher level of accumulation (Fig. 3E and F) when compared to the Control-2, indicating that distribution of Fe-TA NPs occurs more efficiency. Similarly, Fe-TA NPs accumulation is also found in preneoplastic lesions (GST-P+), as shown in Fig. 3G–I. From these results, we hypothesized that enhanced accumulation of Fe-TA NPs might be due to leaky vascularization induced by DEN. To determine if this is the case, we analyzed liver sinusoidal architecture in Control-2 and DEN-3. It is generally recognized that hepatic sinusoids play a crucial role in hepatic microcirculation and that abnormalities of hepatic sinusoidal

Fig. 3 (A–D) Prussian blue staining of different liver sections from control rat (Control-2). (E and F) Prussian blue staining of different liver sections from DEN induced rat (DEN-3). morphology and architecture can occur under pathological conditions including carcinogen induction.²² As the results show in Fig. 4, H&E staining and SEM imaging demonstrate sinusoidal morphology alterations in DEN-3 (red arrow head), compared to control (green arrow head). The alterations include sinusoidal dilation and congestion, sinusoidal swelling, and sinusoidal capillarization (unorganized sinusoids). Similarly, CD34 staining, endothelial cell markers clearly show the CD34-positive capillaries and sinusoids of liver tissue in the control rats, but not for DEN induced rats, implying that there are abnormalities of liver sinusoidal endothelial cells (LSECs).²³ Because hepatic sinusoid acts as a selective barrier between the blood and liver parenchyma, alteration of sinusoidal functions and morphologies might lead to leakage of hepatic capillaries and sinusoids, thereby causing Fe-TA NPs to penetrate liver

parenchyma. In addition to abnormalities of hepatic sinusoids, capable of taking up of Fe-TA NPs by hepatocytes is also critical implications for their accumulation and MRI enhancement efficiency. In our recent work, we investigated cellular uptake mechanisms of Fe-TA NPs using bioinformatic analysis and we found that molecular functions and biological processes are related to organic anion transporter (OAT) activities that were upregulated in Fe-TA NPs treated liver cell line. Moreover, an inhibitory study on Fe-TA NPs uptake using organic anion transporter (OAT) inhibitors also confirmed the bioinformatic results.¹⁵ This implies that organic anion transporter (OAT) family plays a crucial role in taking up the Fe-TA NPs. As far as expression of OAT is concerned, it has been reported that OAT expression on hepatocyte membranes is upregulated during the early stages of carcinogenesis including the pre-neoplastic stage and early dysplastic stage.⁷ Therefore, it was expected that the

Fig. 5 OAT immunohistochemistry of different liver sections of (A and B) healthy rat and (C and D) DEN induced rat.

Fig. 6 Schematic illustration of Fe-TA NPs accumulation within liver preneoplasia.

OAT expression on the membrane of preneoplastic hepatocytes is high. To confirm above hypothesis, we performed immunohistochemical staining of different liver sections of healthy rat and DEN induced rat using OAT antibody. As the results shown in Fig. 5, it is clearly found that OAT is elevated in DEN induced rats. This can be implied that a high expression of OAT might play a role in cellular internalization and accumulation of Fe-TA NPs in liver preneoplasia. Fig. 6 shows schematic illustration of Fe-TA NPs accumulation within liver preneoplasia, which might be due to the dysfunction of liver sinusoids along with cellular uptake capability of pre-neoplastic hepatocytes mediated by OAT. However, the exact mechanism for Fe-TA NPs accumulation is still not clear, especially *in vivo*.

Conclusion

There is no doubt that MRI is an efficient tool for the detection of different stages of liver cancer. Much effort has been done to improve sensitivity and specificity of measurement with less invasion, including the development a new class of MRI agents to achieve desired results. In this research, nanoparticles of iron-tannic complexes (Fe-TA NPs) are capable of enhancing MRI signals in liver preneoplasia, depending on the characteristics of pre-neoplastic lesion. Although there are some limitations inherent in this study, our report reveals that Fe-TA NPs are potential candidates to be developed as an efficient MRI agent for risk assessment of early stage liver cancer. This is particularly true for people requiring a first-line diagnosis approach for early detection of liver cancer. However, additional work on different aspects need to be carried out in order to confirm the clinical feasibility of our agent. Indeed, we are currently investigating these concerns in our research group.

Conflicts of interest
