Efficient fluorophores with easy synthetic routes and fast responses are of great importance in clinical diagnostics. Herein, we report a new, rigid pentacyclic pyrylium fluorophore, PS-OMe, synthesised in a single step by a modified Vilsmeier–Haack reaction. Insights into the reaction mechanism facilitated a new reaction protocol for the efficient synthesis of PS-OMe which upon demethylation resulted in a “turn-on” pH sensor, PS-OH. This new fluorescent probe has been successfully used to monitor intracellular acidification at physiological pH. From the fluorescence image analysis, we were able to quantify the intracellular dynamic pH change during apoptosis. This new pH probe is a potential chemical tool for screening, drug discovery and dose determination in cancer therapy.

Introduction

Molecular probes that serve as an effective tool for imaging biological tissues and cells play an important role in disease diagnostics and treatment modalities.1,2 Over a period of time, a large number of fluorescent probes have been developed for various analyte sensing and imaging applications. However, most of these probes are essentially derived from ‘core scaffolds’ such as squaraine, rhodamine, coumarin, BODIPY etc. In this context, developing a new core scaffold with easy synthesis, high yield, and good photophysical properties, stability and biocompatibility is of paramount importance. This may set up a platform for developing new probes with novel sets of advantages for sensing and imaging of cells and tissues for disease diagnosis and therapy.3

Imaging of pH variations in cells is important for proper diagnosis of several types of cancers. The imbalance of pH in cancerous cells during apoptosis caused by chemotheraphy needs to be monitored in real time for post treatment wellness of patients.4 The extent of pH decrease provides insights into the effectiveness of therapeutic agents, pathways, doses and time needed for apoptosis.5 Owing to the significant roles of pH in many physiological processes within intracellular organelles, enormous efforts have been made for the development of new pH imaging chemical probes with improved optical properties.6,7 The imbalance of functional pH within cellular microenvironments is also associated with dysfunctions of enzymes and cellular events. For example, variations of the cytosolic pH are closely associated with cell migration, cellular proliferation and apoptosis. It is evident that extracellular acidic pH is highly favourable for regular growth of cancer cells and metastasis of tumours.8 Thus, accurate measurement of pH imbalance in cells is of paramount importance in clinical analysis and disease diagnostics.

Considering its advantages in terms of high sensitivity, simplicity, real-time monitoring, applicability to microenvironments and non-invasive detection with high spatiotemporal resolution, fluorescent imaging is now in the forefront as a diagnostic tool.9,10 Fluorescent probes based on organic small molecules are particularly preferred owing to their biocompatibility, solubility and ease of synthetic modifications.11 ‘Turn-on’ pH probes have gained attention as they can easily discriminate between “on-off” states during the imbalance of pH. Several “off-on” probes are reported in the literature; however, majority of them have limited use due to difficult synthetic access,12 poor solubility and partial or strong background fluorescence at physiological pH. Therefore, new fluorescent probes which are easily accessible and highly stable with bright fluorescence are necessary for the advancement of biological imaging and diagnostic applications. Pyrylium derivatives are known as highly fluorescent chromophores, used for a wide range of applications.13–15 Herein, we report a modified Vilsmeier–Haack reaction for the synthesis of a pentacyclic pyrylium fluorophore PS-OMe which is a precursor of a turn-on fluorescent probe PS-OH. A mechanistic
understanding of the synthesis of PS-OMe resulted in an alternate efficient route for its synthesis and subsequent demethylation to PS-OH. We further describe the use of the new probe for the real time monitoring of pH imbalance during chemotherapy or apoptosis by the fluorescence ‘on–off’ technique.

Results and discussion

Design and synthesis of the pyrylium fluorophore

The main points considered for the design of the new probe were (i) a simple synthetic strategy to produce an efficient fluorescent probe for pH detection, (ii) to monitor intracellular pH (pHᵢ) imbalance during apoptotic cellular dysfunction by fluorescence variation and (iii) the real time monitoring of dynamic pH change during the treatment of cells with apoptotic reagents or anticancer drugs. We hypothesized that this approach may provide a unique opportunity to develop an effective sensor to monitor pH imbalance during apoptosis. To achieve these objectives, we have designed a new synthetic protocol for the preparation of the fluorescent pyrylium derivative PS-OH, using the modified Vilsmeier–Haack reaction. As illustrated in Scheme 1, we started with 6-methoxy tetralone which is a key intermediate for many heterocyclic syntheses with diverse pharmaceutical properties. The Vilsmeier–Haack formylation reaction of 6-methoxy tetralone (1) at 80 °C produces a reactive 1-chloro-6-methoxy-3,4-dihydro-7-carbaldehyde (T-CHO) when dimethyl formamide (DMF) and phosphorus oxychloride (POCl₃) were premixed to obtain the Vilsmeier–Haack iminium salts (N-(chloromethylene)-N-methylmethanaminium). In contrast, dropwise addition of POCl₃ to 6-methoxytetralone in DMF at 80 °C led to an additional product of 4-chloro-1,2-dihydro-7-methoxy-naphthalene (T-Cl) along with T-CHO. It is noted that if Vilsmeier–Haack iminium salts are not prepared through a premixed protocol, the formylation reaction is suppressed. In contrast, here a part of 6-methoxy tetralone reacts directly with POCl₃ to render a reactive intermediate (T-Cl) along with the expected T-CHO regardless of the reaction temperature. However, a high temperature (80 °C) leads to better yield (~35%) of T-Cl compare to the previous reports¹⁶,¹⁷ (Scheme 1).

Interestingly, when the concentrated ethyl acetate extract of the reaction mixture was kept in the ambient atmosphere, a bright yellow fluorescence emitting fluorophore was formed. This serendipitous observation revealed that, the vinyl chloride of T-Cl was hydrolysed in contact with moisture to form an unstable enol, T-OH (Fig. 1) which undergoes cyclocondensation with T-CHO to provide a pentacyclic symmetric pyrylium fluorophore named PS-OMe. To confirm the reaction pathway, firstly, the isolated compounds (T-CHO, T-Cl) were mixed and kept under inert conditions; however, we could not observe the formation of the pyrylium fluorophore even after one week. The proposed mechanism of PS-OMe formation is in good agreement with previous reports which suggest that the vinyl chloro functional group is the one which is labile towards nucleophiles.¹⁸,¹⁹ PS-OMe was isolated by column chromatography over silica gel using 6% methanol in chloroform as the eluent in 28% yield. To confirm the reaction pathway in the second step of the mechanism, we chose a few catalysts including Brønsted and Lewis acids since the proposed mechanism (Fig. 1) involved aldol type condensation. Hence, we performed acid catalysed condensation of isolated T-CHO and 6-methoxy tetralone in the presence of Brønsted and Lewis acids (Scheme 2). AlCl₃ was found to be the best acid catalyst (~70%) followed by triflic acid (~61%) among other catalysts. The results are summarized in Table 1.

PS-OMe is composed of a donor–acceptor–donor (D–A–D) system where the highly electron deficient pyrylium ring acts as a good acceptor and the corresponding two anisole rings connected to the 2 and 6 positions of the pyrylium ring act as strong donors. Furthermore, the six membered bridges play a crucial role in improving rigidity of the structure to enhance the fluorescence quantum efficiency. The fluorescent probe PS-OH was obtained by the demethylation of PS-OMe by treating with boron tribromide (Scheme 1). All new products

obtained were characterized by various spectroscopic techniques such as \(^1\)H NMR, \(^{13}\)C NMR, and HRMS analyses. PS-OMe was further crystalized in DMF with the addition of a few drops of perchloric acid. The structure of PS-OMe was unambiguously confirmed from single crystal X-ray analysis as C\(_2\)H\(_7\)ClO\(_7\) (Fig. S1†).

**Photophysical properties**

The absorption and emission spectra of PS-OMe and PS-OH in organic and aqueous solutions are shown in Fig. S2 and S3.† The absorption maximum (\(\lambda_{\text{max}}\)) of PS-OMe is shifted to \(\lambda_{\text{max}}\) 490 nm for PS-OH in chloroform which is attributed to a weak intramolecular charge transfer (ICT) from the donor to the acceptor pyrylium ring. The photophysical properties including maximum absorbance (\(I_{\text{max}}\)), emission (\(L_{\text{max}}\)), stokes shift, absolute quantum yield (\(\Phi_f\)) and molar extinction coefficient (\(\varepsilon\)) are summarized in Table S1.† Both PS-OMe and PS-OH have higher Stokes shift when compared to fluorescein and rhodamine B, which can be an added advantage for imaging applications as it can help in setting filter and reduce autofluorescence (Table S2†). The solubility of PS-OMe and PS-OH in PBS buffer (pH 4) was found to be excellent as it shows a linear increase in absorbance till 55 \(\mu\)M and 80 \(\mu\)M for PS-OMe and PS-OH respectively (Fig. S4 and S5†). Subsequently, the absorption and emission spectra were measured with varying pH values in the buffer solution. At first, we checked the pH response of the control molecule, PS-OMe. At pH 4, the molecule exhibited a \(\lambda_{\text{max}}\) at 490 nm with a high molar absorptivity (\(\varepsilon = 1.17 \times 10^4\) L mol \(^{-1}\) cm \(^{-1}\)) and exhibited an emission maximum at 560 nm with a 2551 cm \(^{-1}\) Stokes shift. With an increase in pH up to 8, there was no shift in either the absorbance or the emission maximum (Fig. S6†).

The maximum absorbance of PS-OH at 460 nm was gradually decreased with increasing pH and a new maximum at 570 nm appeared, indicating the deprotonation of the phenolic –OH (Fig. S7†). In the acidic pH, PS-OH exhibited an intense yellow fluorescence at 560 nm with a large Stokes shift (3882 cm \(^{-1}\)) in the acidic region and became almost non-fluorescent at normal physiological pH (pH 7.4). The gradual decrease of the fluorescence intensity with increasing pH from 4 to 7.4 indicates the potential of PS-OH for monitoring apoptosis. Above pH 8, a new peak with a maximum at 640 nm appears which is very weak when compared to the 560 nm emission (Fig. 2a).

For a better insight on the “turn on” emission of PS-OH, the frontier orbital energy calculation was performed. The ground and excited state properties of PS-OH and the mono deprotonated PS-OH have been studied by using time-dependent density functional theory (TD-DFT) at the B3LYP/6-31G level using the Gaussian 16 program and compared with experimental absorption and emission spectra. The calculated absorption and emission spectra of PS-OH were well correlated with the experimental results (Fig S8†). However, deprotonation, structural optimizations and subsequent frequency calculations revealed that a mixed state electronic transition from the unsymmetrical highest occupied molecular orbital (HOMO) to the symmetrical lowest unoccupied molecular orbital (LUMO) and LUMO+1 also correlates with the absorption bands. Due to a mixed excited state, there are at least two emissions with very minimum oscillator strength (\(f\)) indicating the non-emissive nature of PS-OH under neutral to basic conditions.

**pH monitoring and imaging**

The pK\(_a\) of PS-OH, calculated from the fluorescence titration curve using nonlinear regression by fitting the Boltzmann function was found to be 6.2 ± 0.03 (Fig. 2b). The emission intensity showed good linearity (\(R^2 = 0.9962\) ) from pH 7.2 to 5.6 with a 48-fold enhancement, as shown in Fig. 2b (inset). Interestingly, the decrease of pH by 0.4 unit from normal cellular pH 7.4, enhanced the fluorescence intensity by 5.5-fold. Thus, even a minute fluctuation of the pH of a normal cell can be monitored with PS-OH.

For monitoring the dynamic pH change, a molecule should respond quickly towards pH variation, have good reversibility and photostability. The response of PS-OH was very fast towards

\(^a\) Conditions: reaction of 6-methoxy tetralone (1.0 mmol) and T-CHO (1.0 mmol) using different catalysts in toluene at 80 °C. \(^b\) Isolated yield.
H^+ as it reaches a maximum fluorescence intensity within 9 s from pH 7.4 upon addition of trifluoroacetic acid (20 μL) (Fig. 2c). The retention of fluorescence intensity after four cycles between pH 4 and 7.4 (Fig. 2d) indicates that PS-OH is a good candidate for monitoring dynamic pH changes in the cellular system. The absolute quantum yields in the PBS buffer of pH 4 and 7.4 were found to be 0.11 and 0.03 respectively. In addition, photostability of PS-OMe and PS-OH was compared with rhodamine B and fluorescein by irradiation with a 200 W mercury lamp using a 455 nm long pass filter for 60 min. PS-OMe and PS-OH showed stability similar to rhodamine B and better than fluorescein (Fig. S9†).

The selectivity of the PS-OH towards different biologically relevant analytes including metal ions (Na^+, K^+, Ca^{2+}, Al^{3+}, Mg^{2+}, Zn^{2+} and Fe^{3+}), anions (AcO^−, OH^−, and OCl^−), reactive oxygen species (H_2O_2 and O_2^−), biothiols (Cys and GSH) and H_2S at pH 4 and 7.4 was tested. None of the analytes interfered with the fluorescence property of PS-OH (Fig. S10 and S11†). The observation indicates the potential for further exploring the response of PS-OH as a pH probe in live cells. The cytotoxicity of the probe using the human lung adenocarcinoma cancer cell line A549 was checked by incubating with PS-OH up to 10 mM concentration for 48 h. More than 90% cells were unaffected indicating the excellent biocompatibility of the probe (Fig. S12†). Also, the photobleaching of PS-OMe in the cell was compared with Mitotracker green and Lysotracker red. From the fluorescence intensity data, we could clearly see a comparable stability with Mitotracker green but less stability when compared to Lysotracker red (Fig. S13†).

Owing to the high turn-on sensitivity at acidic pH and good biocompatibility, the probe was used to investigate the intracellular pH response in the A549 cell line. At pH 7.4, there was almost no fluorescence observed with a green emission filter at 20 μM PS-OH. Nigericin was used to maintain the pH equilibrium between cells and the medium. With a decrease in pH to 7, a detectable fluorescence signal was observed (Fig. 3a). On further decrease of the pH, the intensity of fluorescence increased gradually (Fig. 3b). The fluorescence intensity obtained from the cells was plotted against pH which shows a good co-linearity with the photophysical data.

The quantitative data of the fluorescence response towards pH imbalance in live cells indicates the efficacy of the probe in cell imaging. Thus, PS-OH can be used to quantitatively determine the pH of the cell depending on its fluorescence response (Fig. 3c).

Various anticancer drugs and apoptotic agents target cells in different signalling pathways, varying the pH in each case. For example, it is reported that lipopolysaccharide (LPS) decreases intracellular pH (pHi) to around 6.26 and cisplatin induces only a slight decrease in pHi of the cytoplasm,21 whereas Mdivi-1 causes apoptosis via mitochondrial hyperfusion which does not acidify the cell cytoplasm.22 We tried to evaluate pH imbalance by using the new probe during the treatment of these anticancer drugs or apoptotic agents. Cells were first incubated with PS-OH (c = 20 μM) for 10 minutes, followed by the treatment of Mdivi-1 (100 μM) LPS (1 μg mL⁻¹), and cisplatin (10 μM) separately for 12 h. The fluorescence images of cells were analysed and it was found that in the case of Mdivi-1, there was no detectable change in fluorescence intensity (Fig. 4a–c). However, in the case of cisplatin, there was a slight change owing to minute acidification of the cells (pH ~ 6.49) compared to that of the control (pH ~ 7) (Fig. 4g–i), and for LPS treatment, the fluorescence intensity was significantly increased and the
final pH was found to be ~6.07 (Fig. 4d-f). These results show a very good agreement with the previous reports,\textsuperscript{20-22} underlining the sensitivity and applicability of the new probe for the pH monitoring of cellular environments after chemotherapy.

Dynamic pH change monitoring with a molecular probe is undoubtedly an important aspect of cancer treatment modality. Thus, we investigated how the new probe can monitor the dynamic pH change in cells during apoptotic treatment. For this purpose, \( \text{H}_2\text{O}_2 \) was chosen as a reactive oxygen species which causes rapid cell death.\textsuperscript{23,24} In the selectivity test, we have found that \( \text{H}_2\text{O}_2 \) does not affect the fluorescence response directly. Therefore, initially the cells were treated with the probe \( \text{PS-OH} \) for 10 min and then 500 \( \mu\text{M} \) of \( \text{H}_2\text{O}_2 \) was added to the medium. At 0, 5, 15, 30 and 60 min, fluorescence images were taken (Fig. 5a). An obvious increase in fluorescence was found within 5 min. With increase in time, the intensity further increased which is attributed to the continuous pH value decrease of the cells (Fig. 5b). This result proves the capability of the probe in monitoring the dynamic cellular pH change. From the previously calibrated graph, we could quantify the pH change at each time point (Fig. 5c).

**Conclusions**

In conclusion, we have established a new synthetic protocol to prepare a “core scaffold” of a pentacyclic pyrylium dye \( \text{PS-OMe} \). A mechanistic understanding of the reaction pathways helped to establish an alternate efficient synthetic protocol of \( \text{PS-OMe} \) with nearly 70% yield. The pyrylium fluorescent probe \( \text{PS-OH} \) exhibited an ‘on-off’ response against the pH variation in cells during apoptosis. The strong acceptor at the centre ring of pyrylium, connected through two hydroxyl groups is the key to the bright fluorescent dye with excellent photophysical properties, including photostability, high molar absorptivity and large Stokes shifts. \( \text{PS-OH} \) exhibited an exceptional ‘turn-on’ pH response in the window of biological relevance both in solution state and in live cells. The new probe is capable of monitoring even a minute change of physiological pH (7.4) in cells during the therapeutic process with chemo drugs or apoptotic agents in real time.
