Electrochemical oxidative decarboxylation and 1,2-aryl migration towards the synthesis of 1,2-diaryl ethers†

Faxiang Bu,^{‡a} Lijun Lu,^{‡a} Xia Hu,^a Shengchun Wang,^a Heng Zhang^{Ⓜ*ab} and Aiwen Lei^{Ⓜ*ab}

Carboxylic acid compounds are important chemicals and are widely present in various natural products. They are not only nucleophiles, but also radical precursors. Classic transition-metal-catalyzed and photochemical decarboxylation have shown their excellent site selectivity in radical chemistry. However, electrochemical decarboxylation with a long history hasn't got enough attention in recent years. In this work, the electrochemical oxidative decarboxylation and 1,2-aryl migration of 3,3-diarylpropionic acids have been introduced to construct C–O bonds with alcohols. Remarkably, this transformation can proceed smoothly without metal catalysts and external oxidants.

Introduction

1,2-Diaryl compounds are important structures in some pharmaceuticals. For example, dextropropoxyphene is an analgesic in the opioid category, and eslicarbazepine acetate is an anti-convulsant medication.¹ Directly using benzyl halides to construct 1,2-diaryl compounds is a difficult process.² In contrast, 1,2-aryl migration can afford 1,2-diaryl compounds easily.³ The 1,1-diaryl ethyl radical is the key intermediate for achieving 1,2-aryl migration. Previous reports have described some methods for producing 1,1-diaryl ethyl radicals (Scheme 1A). The first method is obtaining radical species by dehalogenation or decarboxylation.⁴ The second method is adding extra radicals to olefins to produce radical species.⁵ Intramolecular radical addition is similar to the second method.⁶ The fourth method is the direct oxidation of the C–H bond to give radical species.⁷ The addition of radicals to olefins comprises the most common method. But their products have extra functional groups, which influences their further modification. The intramolecular radical addition and C–H oxidation methods are usually limited in terms of the substrate scope, while the decarboxylation process of the first method is relatively simple and efficient.

Carboxylic acids are common precursors of pharmaceuticals, agrochemicals and fine chemicals.⁸ They are commercially available at low cost and with more structural diversity. Also, they can be prepared through many mature methods.⁹

Scheme 1 (A) The 1,2-aryl migration of different substrates. (B) Electrochemical oxidative decarboxylation and 1,2-aryl migration reaction.

Carboxylic acids with the advantages of being non-toxic, stable to air and water, and easy to store and operate are the promising substitutes for organic halides due to the good site selectivity.¹⁰ In the past decade, decarboxylative cross-coupling reactions have undergone rapid development in both academia and industry. For example, Macmillan and co-workers made great contributions in photochemical decarboxylative functionalization.¹¹ On the other hand, many breakthroughs have also been achieved in the transition-metal-catalyzed decarboxylative functionalization.¹²

Recently, electrochemical synthesis has become a hot topic again owing to its mild reaction conditions, which meets the requirement of green and sustainable chemistry.¹³ Kolbe electrolysis is one of the most famous electrochemical reactions, and involves the anodic oxidation of alkyl carboxylates to afford alkyl radicals.¹⁴ Compared with transition-metal-catalyzed and photochemical decarboxylation, electrochemical decarboxylative functionalization can proceed smoothly without transition-metal catalysts, photocatalysts, external oxidants or high temperature. In addition, CO₂ and H₂ are the only byproducts.¹⁵ Due to the above merits, electrochemical decarboxylation is an ideal method to obtain radical species from carboxylic acids. Herein, we report an electrochemical oxidative decarboxylation and 1,2-aryl migration of 3,3-diarylpropionic acids to synthesize a series of 1,2-diaryl ethers (Scheme 1B).

Results and discussion

3,3-Di(2-chlorophenyl)-propionic acid (**1a**) and MeOH (**2a**) were selected as model substrates (Table 1). With the combination of

carbon cloth as the anode, platinum plate as the cathode, and ⁿBu₄NOAc as the electrolyte and base in the mixed solvent of MeOH and HFIP (hexafluoroisopropanol), 80% GC yield of the desired product (**3aa**) was obtained at 15 mA current and room temperature in 3.5 hours (entry 1). The base was important for this transformation. The yield sharply decreased to 21% with ⁿBu₄NBF₄ as the electrolyte (entry 2). Replacing ⁿBu₄NOAc with other bases, such as KOMe, Li₂CO₃ or ⁿBu₄NOH, gave lower yields (entries 3–5). Using MeOH and DCE (1,2-dichloroethane) as co-solvents, the yield decreased to 70% (entry 6). Reducing the current to 10 mA didn't influence the reaction (entry 7). Notably, only a trace amount of product was detected upon utilizing a platinum plate as the anode (entry 8). When a nickel plate was used as the cathode, the reaction also proceeded smoothly (entry 9). In addition, when the reaction was carried out in air (entry 10) or at 0 °C (entry 11), the yields decreased slightly.

With the optimized conditions in hand, we investigated the substrate scope of this transformation. Firstly, a variety of alcohols were tested (Scheme 2). Primary, secondary and tertiary alcohols could all be tolerated (**3aa–3aj**, **3ba–3bf**). The examples of **3ac** and **3bc** were noteworthy due to the widespread existence of the trifluoroethoxy group in drug molecules. Then, we focused our attention on the diarylpropionic acids. Diarylpropionic acids with *ortho*-substituted functional groups, such as methyl, fluorine and bromine, afforded satisfactory yields (**3ca–3ea**). Substrates with *para*-substituted electron-donating functional groups, such as methyl (**3ga**), *tert*-butyl (**3ka**) and trifluoromethoxy (**3ma**), and electron-withdrawing functional groups, such as fluorine (**3ha**), chlorine (**3ia**), bromine (**3ja**) and trifluoromethyl (**3la**), were all well compatible in this system. *Meta*-substituted diarylpropionic acids were also transformed into the desired product (**3fa**). It is worth mentioning that *ortho*-substituted diarylpropionic acids usually gave higher yields than *para* or *meta* substituted ones as they could inhibit the formation of side-products (ESI Schemes S1–S5†). Subsequently, we turned to study the 1,1-diarylpropionic acids with different substituted aryl groups. However, the migration selectivity between different aryl groups was unsatisfactory (**3na–3ta**, ESI Schemes S6–S8†).

Moreover, we explored the applicability of the carboxylic acids with additional α - and β -site substituted groups (Scheme 3). The diarylpropionic acids with an α - or β -methyl group could afford the corresponding products (**3ua–3wa**). Triphenylpropionic acid gave 76% yield (**3xa**). Remarkably, this transformation could still proceed when one of the two aryl groups was replaced with a methoxyl or benzyl group (**3ya**, **3za**). The wide substrate compatibility made this protocol promising for application in organic synthesis.

To gain further insight into the reaction mechanism, some related experiments were conducted. Firstly, the oxidation potentials of the substrates were measured by using cyclic voltammetry (ESI Fig. S1†). There was no obvious oxidation peak for 3,3-diphenylpropionic acid (**1b**) alone. However, the oxidation peak could be observed by adding a base into the solution of 3,3-diphenylpropionic acid (**1b**), which suggested that 3,3-diphenylpropionic carboxylate could be oxidized easily. In addition, 3,3-

Scheme 3 Substrate scope of carboxylic acids. Reaction conditions: 1 (0.4 mmol), 2a (12.0 mL), ⁿBu₄NOAc (1.5 equiv. based on 1), HFIP (700 μL), room temperature, constant current, *I* = 15 mA, 3.5 h. All yields are isolated yields.

diphenylpropionic carboxylate and ⁿBu₄NOAc have similar oxidation potentials, which might indicate that they could be oxidized simultaneously during the reaction (ESI Scheme S14†).

Furthermore, EPR experiments were performed to investigate the radical intermediate produced by the oxidation of 3,3-diphenylpropionic carboxylate. With the addition of radical spin trapping reagent DMPO (5,5-dimethyl-1-pyrroline-*N*-oxide), a mixed signal of DMPO trapping carbon radicals ($g = 2.0068$, $A_N = 14.30$ G, $A_H = 21.00$ G) and hydrogenated DMPO ($g = 2.0068$, $A_N = 14.65$ G, $A_{H1} = 19.54$ G, $A_{H2} = 19.54$ G) was identified (Fig. 1A, ESI Fig. S3C†). Meanwhile, the reaction system of the EPR trapping experiment was also tested by high resolution electrospray ionization mass spectrometry (ESI Fig. S3D†). The results demonstrated the possible existence of a carbon radical intermediate (Fig. 1C III or IV) according to the coincidence of the molecular weight of DMPO trapping products. Moreover, BrCCl₃ and O₂ were used as radical trapping reagents, respectively. 22% yield of 1,1-diphenyl-2-bromoethane and 16% yield of benzophenone were obtained in the respective experiments, which indicated the possibility of the involvement of the 1,1-diphenylethyl radical (Fig. 1C III) in the transformation (ESI Schemes S15 and S16†).

In order to understand the process of the aryl migration, DFT calculations were conducted (Fig. 1B). According to the calculated free energy barriers, 1,2-aryl migration (13.8 kcal mol⁻¹) of

Fig. 1 (A) EPR spectrum. (B) Free energy barriers for the 1,2-aryl migration vs. 1,2-H transfer of the radical intermediate. (C) Proposed mechanism.

1,1-diarylethyl carbon radical **1** was much easier than 1,2-H transfer (31.6 kcal mol⁻¹), which matched with the experimental results. Another possibility was that 1,1-diarylethyl carbon radical **1** was oxidized to form a 1,1-diarylethyl carbocation firstly, which further underwent 1,2-aryl migration to give the desired product. However, DFT calculation results indicated that the 1,2-H transfer is more favourable than 1,2-aryl migration for this carbocation intermediate, which didn't meet with experiment results (ESI Fig. S4[†]).

Based on the above mechanistic experiments and previous reports, a plausible mechanism was proposed (Fig. 1C). Firstly, 3,3-diphenylpropionic acid (**1b**) is deprotonated in the presence

Scheme 4 (A) Further functionalization of 1-methoxy-1,2-diphenyl ethane. (B) Derivatization of **5aa**. (C) Gram scale electrochemical synthesis of **3ba**.

of acetate to produce carboxylate **I**, which was oxidized at the anode to generate carboxyl radical **II**. The following decarboxylation can afford the primary carbon radical **III**. Subsequently, benzyl carbocation **V** was formed through successive 1,2-aryl migration and anodic oxidation. Finally, the reaction between benzyl carbocation **V** and methanol can yield the desired product **3ba** with the help of acetate. The acetate can be regenerated at the cathode with the liberation of dihydrogen concomitantly.

The product 1-methoxy-1,2-diphenyl ethane (**3ba**) could be further modified to get useful chemicals. For example, **3ba** reacted with azidotrimethylsilane or allyltrimethylsilane to construct a C–N or C–C bond (Scheme 4A, **6a**, **6b**) by Fe-catalysis.¹⁶ In addition, the elimination reaction of **3ba** afforded a C–C double bond with the leaving of the methoxy group (**6c**).¹⁷ Notably, the methoxy group could act as the directing group to achieve *ortho*-C–H olefination of **3ba** (**6d**).¹⁸ When 3-phenyl-3-(2-bromophenyl)propionic acid was used as the substrate, two isomers were obtained (Scheme 4B, **5aa**, ESI Scheme S13[†]). When the mixture was employed as a starting material directly in the palladium-catalyzed intramolecular cyclization, the sole product 9,10-dihydro-9-methoxy-phenanthrene was obtained (**6f**).¹⁹ Remarkably, this reaction could proceed smoothly on the gram scale. 1.17 g **3ba** was obtained by using 50 mA current without changing the size of the electrodes (Scheme 4C).

Conclusions

In summary, the strategies of decarboxylation and 1,2-aryl migration have been integrated to achieve electrochemical oxidative cross-coupling between 3,3-diarylpropionic acids and alcohols to yield 1,2-diaryl ethers under mild conditions in one step. The good substrate compatibility and the diversified

further functionalization of the target 1,2-diaryl ethers demonstrate the potential application of this protocol.
