Simple and scalable synthesis of hierarchical porous carbon derived from cornstalk without pith for high capacitance and energy density†

Jiaming Li,† Qimeng Jiang,‡ Lansheng Wei, Linxin Zhong † and Xiaoying Wang †*

A sustainable one-pot route for the synthesis of hierarchical porous carbons (HPCs) from cornstalk without pith is developed. Calcium carbonate (CaCO₃) as a hard template can promote the activation process and manipulate the pore structure. The interaction of CaCO₃ and the activating agent (potassium oxalate) gives rise to an etching effect and gasification, which can tailor the porosity of the carbon. The removal of loose and spongy pith can improve the meso/micropore ratio, significantly increasing the electrochemical capacitance and rate capability. The as-prepared cornstalk rind-based hierarchical porous carbon (CRHPC) with an interconnected pore structure exhibits a high capacitance of 461 F g⁻¹ at 0.5 A g⁻¹ in 1 M H₂SO₄. Meanwhile, it displays good cycling stability, with a high capacitance retention of 90.4% at 10 A g⁻¹ after 10 000 cycles. Furthermore, the symmetric supercapacitor shows a high energy density of 42.5–33.3 Wh kg⁻¹ at a power density of 0.4–9.3 kW kg⁻¹ and superior rate capability (78.0% capacitance retention at 20 A g⁻¹). The simple removal of loose pith endows the carbon materials with an increased mesopore ratio and graphitization degree, which greatly contribute to rapid ion transportation, low internal resistance and high capacitance and energy density. This low-cost strategy holds great promise in the large-scale production of highly porous carbons from lignocellulose for advanced and efficient energy storage.

1. Introduction

Carbon materials including carbon nanospheres, carbon nanofibers, carbon aerogels and porous carbons have aroused great interest in diverse applications including catalysis,¹–³ adsorption,⁴,⁵ and energy storage and conversion.⁶–⁸ Among them, porous carbons are highly attractive as electrode materials for supercapacitors, especially for electrode double-layer capacitors (EDLCs) in view of the tunable pore structure, excellent electrical conductivity, large specific surface area (SSA) and high chemical and cycling stability.⁹,¹⁰ Particularly, hierarchical porous carbons (HPCs) with a multimodal pore distribution (micro-/meso-/macropores) are the most promising candidates for high-performance supercapacitors, because they can provide shorter pathways for ion diffusion and abundant active sites for ion storage.¹¹,¹² Unfortunately, most HPCs display limited supercapacitance and unsatisfactory rate capability due to an irrational pore ratio, which restricts their application in energy storage.¹³ Therefore, it is crucial to find out effective approaches to fabricate HPCs with a rational porous structure for advanced EDLCs.

Currently, biomass has become the most promising carbon source due to its natural abundance, unique structure, renewability and low cost.¹⁴ Numerous biomass materials, such as rice straw,¹⁵ sorghum stalk,¹⁶ hemp stem,¹⁷ bamboo,¹⁸ corn cob,¹⁹–²² corn husk,²³–²⁴ corn silk,²⁵–²⁶ corn leaf,²⁷ corn grains²⁸ and soybean,²⁹ have been utilized as carbon precursors to prepare carbon materials for supercapacitors. Especially, cornstalk with an inherent interconnected structure has undoubtedly been an ideal carbon source for HPCs in recent years.³⁰–³²

For instance, Wang et al. fabricated porous graphitic carbon nanosheets (PGCSs) from cornstalks via an in situ self-generating template strategy. The as-prepared carbon (PGCS1100) displayed a specific surface area (SSA) of 540 m² g⁻¹ and an improved specific capacitance of 213 F g⁻¹ at 1 A g⁻¹. Besides, Yu et al. synthesized porous carbon nanosheets (aCSs) with cornstalk by carbonization and KOH activation. The two dimensional (2D) sheet-like structure composed of abundant micropores increased the SSA up to 1736 m² g⁻¹, endowing the aCS with a stable and extended voltage window (0–1.6 V). Wang et al. also developed a green and scalable route to prepare hierarchical porous carbon sheets (HPCSs) from cornstalk using non-toxic NaCl and KCl mixed salt as the reaction media. The as-obtained HPCS exhibited a high SSA of 1588 m² g⁻¹ and an enhanced specific capacitance.
Nevertheless, cornstalk derived carbons display limited ion-accessible area and sluggish ion diffusion for supercapacitors due to their intrinsic non-fibrous structure, leading to unsatisfactory rate capacity and energy density.\textsuperscript{34} Cornstalk is composed of densely packed rind and loose pith.\textsuperscript{35} To be specific, cornstalk rind mainly consists of staggered long fibers, while its pith possesses an inherent non-fibrous structure which generates a micropore dominating structure during the activation process and leads to an irrational micro-/mesopore ratio. The overnumbered micropores eventually limit the supercapacitance, rate capacity and energy density of porous carbons.\textsuperscript{12,36,37} In this regard, a simple and scalable synthesis approach that makes good use of cornstalk for high performance electrode materials is desirable.

Herein, for the first time, cornstalk rind (CR) was employed to prepare HPCs through a one-pot method by using potassium oxalate (K$_2$C$_2$O$_4$) as an activating agent and calcium carbonate (CaCO$_3$) as a hard template. The as-prepared cornstalk rind-derived hierarchical porous carbon (CRHPC) has a high specific surface area of 1910 m$^2$ g$^{-1}$ and a mesopore ratio of 86.89%. The removal of loose pith can significantly improve the electrochemical capacitance and rate capability. The as-prepared CRHPC displays an exceptionally high capacitance of 461 F g$^{-1}$ at 0.5 A g$^{-1}$. Notably, the symmetric supercapacitor delivers a high energy density of 42.5–33.3 W h kg$^{-1}$ at a power density of 0.4–9.3 kW kg$^{-1}$, also with a superior rate capability of 78.0% capacitance retention at 20 A g$^{-1}$. This work offers a simple and green method which endows the lignocellulose derived carbon with high energy storage performance and satisfactory rate capability, showing great promising potential in supercapacitors.

2. Experimental section

2.1 Materials

Cornstalk (CS) was obtained from a local farm in Shandong province, China. The CS was separated into pith and rind respectively and both were cut into small pieces and then filtered through a stainless steel mesh (60 mesh). Potassium oxalate monohydrate (K$_2$C$_2$O$_4$), calcium carbonate (CaCO$_3$), and hydrochloric acid (HCl) were of analytical grade and used without purification.

2.2 Synthesis of hierarchical porous carbons

Cornstalk (entire plant), rind and pith were utilized as precursors for the synthesis of hierarchical porous carbons. In a typical procedure, cornstalk powder (3.0 g) was thoroughly mixed in an agate mortar with K$_2$C$_2$O$_4$ and then milled with CaCO$_3$ nanoparticles (the weight ratios of the carbon precursor, K$_2$C$_2$O$_4$, and CaCO$_3$ were $X = 1 : 1 : 1$, $1 : 1.5 : 1$, and $1 : 2 : 1$, respectively). Afterward, the mixture was carbonized in a tube furnace first at 300 °C for 1 h and then heated to 800 °C (5 °C min$^{-1}$) and held for 2 h under a nitrogen gas flow. After cooling to room temperature, the carbon samples were thoroughly washed with 1 M HCl solution and deionized water to completely remove the residual inorganic impurities (i.e., calcium oxide and potassium compounds). Finally, the carbon was collected by filtration and then freeze-dried for 48 h. The resultant samples were denoted as C-$X$, where $X$ refers to the weight ratio of K$_2$C$_2$O$_4$ to cornstalk ($X = 1, 1.5$, and $2$), C refers to activated carbon (Table S1$^\dagger$). In addition, cornstalk rind was carbonized and activated under the same conditions ($X = 1.5$ and $2$) and the samples were named R-$X$. For comparison, the pith separated from raw cornstalk was activated using the same procedure and the resultant product was named P-1.5. Raw cornstalk carbonized under the same conditions without an activating agent and templates was adopted as the control sample, namely BC.

2.3 Characterization

The morphologies and microstructures of all samples were characterized by scanning electron microscopy (SEM Merlin, Zeiss) at an accelerating voltage of 5 kV and transmission electron microscopy (TEM, JEM-2100F) at an accelerating voltage of 200 kV. The fiber morphologies of cornstalk rind and pith were examined with an Olympus BX51 research microscope. Prior to observation, cornstalk rind and pith were cut into 1 mm wide and 10 mm long strips, respectively, and treated with a mixture of acetic acid and 30% hydrogen peroxide (1 : 1, v/v) at 60 °C for 48 h for cell dissociation. After the samples turned white, the macerated fibers were filtered and thoroughly washed with deionized water and then stained with safranin O. X-ray diffraction (XRD) measurement was performed on a Bruker D8 diffractometer using Cu-Kz radiation as an X-ray source (40 kV and 40 mA, $X = 0.15418$ nm). The defective nature of the as-prepared samples was examined from Raman scattering spectra using laser excitation at 532 nm (LabRAM ARAMIS-Horiba Jobin Yvon). Elemental analysis (VarioEL III, Elementar) was performed to examine the elemental contents. Surface elements of samples were studied by X-ray photoelectron spectroscopy (Thermo Scientific ESCALAB 250Xi spectrometer) with an exciting source of Al Kz (1286.6 eV). The nitrogen adsorption–desorption isotherms were obtained at −196 °C on a Micromeritics ASAP 2460 surface area and porosity analyzer. Prior to measurement, each sample was degassed under vacuum at 300 °C for 12 h. The specific surface area (SSA) was determined by the Brunauer–Emmett–Teller method (BET) and pore size distribution (PSD) was calculated using a non-local density functional theory (NLDFT) model. CO$_2$ adsorption in a low pressure range of up to 1 bar was performed using a Micromeritics ASAP 2460 instrument at 0 or 25 °C. Before the measurement, the samples were degassed at 150 °C under vacuum for 24 h to remove moisture and CO$_2$ molecules adsorbed in the pores. After the samples were cooled down to 0 or 25 °C, CO$_2$ was introduced into the system.

2.4 Electrochemical measurements

The electrochemical measurements were carried out on a CHI660E (Shanghai Chenhua, China) in 1 M H$_2$SO$_4$ solution and 1 M Na$_2$SO$_4$. The working electrodes were prepared by coating 0.02 mg carbon sample on a glassy carbon (GC)
The electrochemical performance of a supercapacitor fabricated with the same mass as the three-electrode system corresponds to the applied potential window (V).

Three-electrode system tests were carried out in 1 M H2SO4 aqueous solution with a Ag/AgCl electrode as the reference electrode and a slice of platinum as the counter electrode. The electrochemical performances of the three-electrode system were determined by cyclic voltammetry (CV), galvanostatic charge–discharge (GCD) tests and electrochemical impedance spectroscopy (EIS) measurements. The CV curves were obtained at potential sweep rates of 5–200 mV s⁻¹ and the GCD measurements were performed at current densities of 0.5–20 A g⁻¹ within the potential window of 0–0.8 V. The EIS measurements were conducted over a frequency range from 10 mHz to 100 kHz with an amplitude of 5 mV. The cycle stability was evaluated by GCD measurements at a current density of 5 A g⁻¹ for over 10 000 cycles.

The specific capacitances of the electrodes at different scan rates were obtained according to the following equation:

\[ C = \frac{\int I dV}{m\Delta V} \]  

(1)

where \( I \) is the current (A), \( \nu \) refers to the scan rate (V s⁻¹), \( m \) represents the mass of the active material (g), and \( \Delta V \) corresponds to the applied potential window (V).

The specific gravimetric capacitances of the electrodes at various current densities were calculated from GCD curves using the following equation:

\[ C = \frac{\int I d\tau}{m\Delta V} \]  

(2)

where \( I \) represents the current loaded (A), \( \Delta \tau \) is the discharge time (s), \( m \) refers to the mass of the active material (g), and \( \Delta V \) corresponds to the applied potential window (V).

In a two-electrode system, the working electrodes were fabricated with the same mass as the three-electrode system and were measured as a symmetrical supercapacitor in 1 M Na2SO4 aqueous solution. The electrochemical performance of the two-electrode system was determined by CV and GCD. The specific capacitance for the single electrode was calculated based on the following equation:

\[ C = \frac{4I\Delta \tau}{m\Delta V} \]  

(3)

where \( I \) is the current (A), \( \Delta \tau \) refers to the discharge time (s), \( \Delta V \) corresponds to the applied potential window (V), and \( m \) is the total mass of the active material in two electrodes (g).

The energy density and power density of symmetrical supercapacitor systems were estimated according to the following equations:

\[ E = \frac{C\Delta V^2}{2 \times 3.6} \]  

(4)

\[ P = \frac{3600E}{\Delta \tau} \]  

(5)

where \( E \) is the specific energy density (W h kg⁻¹), \( C \) refers to the specific capacitance of the total symmetrical system (F g⁻¹), \( \Delta V \) represents the applied potential window (V), \( P \) corresponds to the specific power density (W kg⁻¹) and \( \Delta \tau \) is the discharge time (s).

### 2.5 Assembly of the symmetric supercapacitor

The obtained cornstalk porous carbon was used to assemble symmetric capacitors with 1 M sodium sulfate as the electrolyte, nickel foam as the current collector, and a sulfonated diaphragm as the separator. The assembly process is as follow. First, the viscous slurry containing 80 wt% cornstalk porous carbon, 10 wt% carbon black and 10 wt% PTFE was evenly dispersed by mechanical and ultrasonic stirring, and then dried at 80 °C in a vacuum oven. Subsequently, the resulting sample was rolled and pressed into a sheet using a roll mill. The sheet was cut into a 1 × 1 cm square and nickel foam was cut into 1 × 2 cm strips with a guillotine, respectively. The electrode was obtained by pressing the thin carbon sheet on nickel foam. After the carbon sheet side was soaked in the electrolyte overnight, the sulfonated diaphragm was placed between two electrodes and the symmetric capacitor was finally obtained.

### 3. Results and discussion

A facile strategy for the preparation of hierarchical porous carbon from cornstalk rind is briefly illustrated in Fig. 1. Cornstalk, as a typical lignocellulosic biomass, is composed of three main biopolymers, namely, cellulose, hemicelluloses and lignin. In the botanical structure, raw cornstalk mainly consists

![Fig. 1 Schematic fabrication process of the HPCs from cornstalk rind in a one-pot manner (the inserted SEM images are (a) cornstalk (b) cornstalk pith (c) cornstalk rind).](image)
of two parts, i.e. rind and pith.\textsuperscript{33} As shown in Fig. 1a, the raw cornstalk possesses a vascular-like skeleton with flakes piling up onto the flat surface. Cornstalk rind mainly consists of a staggered network structure in which long fibers are densely arranged, while the pith possesses an inherent loose and non-fibrous structure. The existence of light pith tissues easily induces a micropore dominating structure and increases the micro-/mesopore ratio during the activation process, which inevitably limits the supercapacitance and rate capacity of porous carbons.\textsuperscript{32,33,67} Therefore, cornstalk pith was removed from the whole plant and cornstalk rind powder was ground with potassium oxalate monohydrate (K\textsubscript{2}C\textsubscript{2}O\textsubscript{4}) and calcium carbonate (CaCO\textsubscript{3}) until they were evenly mixed. For comparison, cornstalk pith and whole cornstalk were treated with the same procedure. The mixture was carbonized to obtain hierarchical porous carbons respectively.

The N\textsubscript{2} adsorption–desorption isotherms and pore size distributions of all samples are shown in Fig. 2a and b, respectively. The isotherms of all samples exhibit a relatively high nitrogen uptake at low relative pressure, demonstrating the existence of plentiful micropores. Moreover, no obvious hysteresis loop is observed in the isotherms of BC, C-1, and R-2, indicating numerous micropores (\(V_{\text{mic}}/V_{t} = 43.36\%, 42.66\%\) and 43.62\%, respectively).\textsuperscript{35,36} Other carbon samples with activation show apparent hysteresis loops at medium relative pressure (\(P/P_{o} = 0.4–1.0\)), suggesting that along with abundant micropores, a large quantity of mesopores were generated as well.\textsuperscript{39}

Particularly, the isotherms of C-1.5, R-1.5 and C-2 display a slight increasing tendency at relatively high pressure (\(P/P_{o} = 0.95–1.0\)), indicating the presence of a few macropores.\textsuperscript{40} Among all samples, C-1.5 displays the highest nitrogen uptake with plentiful micropores, abundant mesopores and a few macropores. The pore size distribution curves (Fig. 2b) calculated using the DFT model reveal that the samples mainly consist of abundant micropores (<2 nm) and small mesopores (2–6 nm), which contribute to fast ion transport for high electric double-layer capacitance.\textsuperscript{12,13} Particularly, C-1.5 and R-1.5 exhibit sharp peaks at 0.5 nm and 1.3 nm for micropores and intense peaks at 2.4 nm and 2.6 nm for mesopores, respectively, demonstrating a larger pore volume than the other carbon samples.

The SSA and pore structure parameters of the as-prepared cornstalk hierarchical porous carbons (CHPCs) are shown in Table 1. The specific surface area of C-1 (1419 m\textsuperscript{2} g\textsuperscript{-1}) is much higher than that of C300-800 (482 m\textsuperscript{2} g\textsuperscript{-1}) without activation. Moreover, the SSA and total pore volume of C-1.5 increase with the weight ratios of the carbon precursor, K\textsubscript{2}C\textsubscript{2}O\textsubscript{4}, and CaCO\textsubscript{3}, varying from 1 : 1 : 1 to 1 : 1.5 : 1, while those of C-2 slightly decrease with further increase of K\textsubscript{2}C\textsubscript{2}O\textsubscript{4} to 1 : 2 : 1. The SSAs of C-1, C-1.5 and C-2 are 1419 m\textsuperscript{2} g\textsuperscript{-1}, 2054 m\textsuperscript{2} g\textsuperscript{-1} and 1492 m\textsuperscript{2} g\textsuperscript{-1}, while their total pore volumes are 0.3704 cm\textsuperscript{3} g\textsuperscript{-1}, 1.382 cm\textsuperscript{3} g\textsuperscript{-1}, and 1.043 cm\textsuperscript{3} g\textsuperscript{-1}, respectively. Compared with C-1.5, C-2 displays a lower SSA and pore volume, which can probably contribute to the collapse of the pore structure under a higher activating agent content. These results show that the dosage of K\textsubscript{2}C\textsubscript{2}O\textsubscript{4} is the dominating factor for the development of the pore structure.\textsuperscript{41} The removal of cornstalk pith could also regulate the SSA and porosity of the samples. Although C-1.5 exhibits an SSA of 2054 m\textsuperscript{2} g\textsuperscript{-1} and a total pore volume of 1.382 cm\textsuperscript{3} g\textsuperscript{-1}, which are slightly higher than those of R-1.5 (1910 m\textsuperscript{2} g\textsuperscript{-1} and 1.198 cm\textsuperscript{3} g\textsuperscript{-1}), R-1.5 displays a high \(V_{\text{mic}}/V_{t}\) ratio of 86.89\%. Besides, R-2 exhibits a lower SSA and total pore volume than those of C-2, which confirms that the removal of pith from cornstalk leads to the decrease of the SSA. It can be indicated that the intrinsic loose structure of pith is conducive to generate carbon materials with a high mesopore/micropore ratio.\textsuperscript{14,42} Thus, the removal of pith from cornstalk plays a crucial role in the formation of the hierarchical structure with rational mesopore volume.

The CO\textsubscript{2} capture capacities of the CHPCs at 273 K and 298 K were measured, as shown in Fig. 2c and d and Table 2. CHPCs have large CO\textsubscript{2} uptakes of 2.35–2.70 mmol g\textsuperscript{-1} (103.40–118.80 mg g\textsuperscript{-1}) and 3.34–4.23 mmol g\textsuperscript{-1} (146.96–182.16 mg g\textsuperscript{-1}) at 298 K and 273 K, respectively. The CO\textsubscript{2} capture capacities of C-1, C-1.5 and C-2 are 2.36, 2.49, and 2.68 mmol g\textsuperscript{-1} at 298 K, and 3.51, 4.14, and 4.01 mmol g\textsuperscript{-1} at 273 K, respectively, which are higher than those of BC (2.35 mmol g\textsuperscript{-1} at 298 K and 3.34 mmol g\textsuperscript{-1} at 273 K). The results reveal that the CO\textsubscript{2} capture capacity is associated with both SSA and porous structures.\textsuperscript{41} In addition, R-1.5 with a high SSA exhibits an extremely high CO\textsubscript{2} capture capacity (2.70 mmol g\textsuperscript{-1} at 298 K and 4.23 mmol g\textsuperscript{-1} at 273 K). These results suggest that the CHPCs have promising application in CO\textsubscript{2} capture.

CaCO\textsubscript{3} can act as the hard template embedded in the carbon structures to generate hierarchical pores. The following reactions are involved during the high-temperature activation:

\[
\text{K}_2\text{C}_2\text{O}_4 \rightarrow 2\text{K}_2\text{CO}_3 + \text{CO} \quad (6)
\]

\[
\text{K}_2\text{CO}_3 + \text{CaCO}_3 \rightarrow \text{K}_2\text{Ca}(_2\text{CO}_3)_2 \quad (7)
\]

\[
\text{K}_2\text{Ca}(_2\text{CO}_3)_2 + \text{CaCO}_3 \rightarrow \text{K}_2\text{Ca}_2(_2\text{CO}_3)_3 \quad (8)
\]

The cell morphologies of cornstalk pith and rind are shown in Fig. 3k and l. Obvious difference can be observed in the light microscopy images. The cells of the pith are most non-fibrous spongy tissues in a pillow-like and round shape with thin cell walls (Fig. 3k), while the cells of the rind possess a staggered claviform structure with thicker walls and thinner vessels (Fig. 3l). Therefore, cornstalk rind can mostly retain its original shape after carbonization.

Elemental analysis was also conducted to investigate the chemical composition of the CHPCs, and the results are shown in Table 1. It is clearly seen that C-1, C-1.5, and C-2 have a higher C content (83.63 wt%, 84.56 wt%, and 86.73 wt%) than C300-800 (77.68 wt%). BC shows the highest O content of 14.04%, which demonstrates a large amount of oxygen due to the incomplete carbonization of the cornstalk precursor without activation. With the increase of activators, the oxygen concentrations of C-1, C-1.5, and C-2 decrease gradually from 12.01 wt% to 11.45 wt% and eventually to 10.20 wt%, respectively. The C contents of C-1.5, R-1.5, C-2, and R-2 do not show remarkable difference. Particularly, R-1.5 displays the highest C content of 11.45, and P-1.5 clearly reveal that the cornstalk derived carbons obtained from different raw materials present interconnected pore structures. C-1.5 derived from raw cornstalk exhibits a hierarchical cellular structure (Fig. 3a and d) and R-1.5 synthesized from cornstalk without pith displays a staggered and interconnected network structure (Fig. 3b and e). The obtained P-1.5 from pith presents a velvet like structure (Fig. 3c and f). The interconnected macropores of C-1.5 and R-1.5 may serve as ion-buffering reservoirs and ion transport channels, while these densely packed pore walls can provide a large specific surface area for charge storage.30 Besides, raw cornstalk possesses a vascular skeleton with small amounts of pores (Fig. 3g), and the skeleton is broken after carbonization (BC, Fig. 3h). The TEM images (Fig. 3i and j) of C-1.5 and R-1.5 show a large amount of small mesopores and worm-like micropores, which well agrees with the results from \(N_2\) adsorption–desorption isotherms. Particularly, R-1.5 (Fig. 3j) demonstrates abundant randomly opened mesopores with a larger size than those in C-1.5, which are well connected with the worm-like micropores. Among them, the mesopores can provide fast diffusion channels and short diffusion distance for ions, while the micropores can offer a large SSA to increase the electrical double layer capacitance.31,32 The cell morphologies of cornstalk pith and rind are shown in Fig. 3k and l. Obvious difference can be observed in the light microscopy images. The cells of the pith are most non-fibrous spongy tissues in a pillow-like and round shape with thin cell walls (Fig. 3k), while the cells of the rind possess a staggered claviform structure with thicker walls and thinner vessels (Fig. 3l). Therefore, cornstalk rind can mostly retain its original shape after carbonization.
87.67 wt%, with a N content of 0.55 wt% and an O content of 9.87 wt%. With the addition of K$_2$C$_2$O$_4$, the O contents of C-2 and R-2 decrease to 10.20 wt% and 9.48 wt%, as compared with C-1.5 (11.45 wt%) and R-1.5 (9.87 wt%), which can be attributed to the removal of chemically absorbed oxygen and water from carbon materials with the increase of the activator. Compared to C-1.5 and C-2, the O contents of R-1.5 and R-2 decrease, which can be assigned to the removal of pith from cornstalk. The loose and spongy pith with a large amount of non-fibrous structures contains 70% hybrid cells and rich crude fat, protein and carbohydrates. The unique structure and abundant functional groups can impart the product with high oxygen content.\textsuperscript{19,32,35,53}

XPS analysis was carried out to further investigate the chemical composition and functional groups of the CHPCs. The XPS survey spectra display two obvious peaks at 284.6 and 533.0 eV, assigned to C 1s and O 1s (Fig. 4a), respectively. Their XPS composition and the relative concentrations of O species obtained by fitting the O 1s spectra are summarized in Table S1.\textsuperscript{†} The C/O atomic ratios of BC, C-1, C-1.5 and C-2 are 1.23, 1.50, 2.20 and 4.64, respectively, indicating the decrease of oxygen content and the increase of graphitization degree. Compared to C-1.5, the C/O atomic ratio of R-1.5 decreases to 2.82, suggesting the reduction of oxygen content and the increase of graphitization degree due to the removal of pith. The O 1s peaks located at 531.8 eV (O1), 532.6 eV (O2) and 533.5 eV (O3) in Fig. 4b–e further demonstrate the existence of quinone and ketone groups (C=O), phenol groups (C–OH) and/or ether groups (C–O–C), and chemisorbed oxygen and/or water, respectively.\textsuperscript{54} These oxygen-containing functional groups can greatly improve the reactivity and wettability and enhance the conductivity of CRHPCs, increasing their active surface area and inducing pseudo-capacitance in charge and discharge processes.\textsuperscript{32,55} Particularly, quinone/ketone oxygen, carbonyl and ether oxygen have been considered as important oxygen functionalities on carbon with regard to their electrochemical activity, and the quinone oxygen has been confirmed as the main source of pseudocapacitance.\textsuperscript{56,57} The X-ray diffraction (XRD) patterns of the CHPCs are shown in Fig. 4f. The two typical broad peaks at around 2$\theta$ = 23.4$^\circ$ and 43.5$^\circ$ are assigned to the (002) and (100) reflection peaks of amorphous carbon, suggesting that the carbon products have a low degree of graphitized carbon.\textsuperscript{58} The (002) peaks of C-1, C-1.5, R-1.5, C-2 and R-2 slightly shift to a lower diffraction angle (2$\theta$ = 22.5$^\circ$, 22.5$^\circ$, 23.3$^\circ$, 23.3$^\circ$ and 23.2$^\circ$, respectively) owing to K$_2$C$_2$O$_4$ activation. After chemical activation, the (002) peak in activated carbons weakens, indicating the destruction of their crystal structure by introducing abundant micropores.\textsuperscript{59} Raman spectroscopy was conducted to further elucidate the graphitization degree and specific structural features of the CRHPCs, and the results are presented in

**Fig. 3** SEM images of C-1.5 (a and d), R-1.5 (b and e), P-1.5 (c and f), raw cornstalk (g) and BC (h). TEM images of C-1.5 (i) and R-1.5 (j). Cell morphology by light microscopy of cornstalk pith (k) and rind (l).
increasing the disorder degree of carbon materials. Stalk pith can promote defects during activation, thus resulting in a higher graphitization degree of R-1.5, which is in accordance with the XPS values of R-1.5 and C-1.5 are 0.75 and 1.04, respectively, indicating a higher graphitization degree of carbon. The \( \frac{I_D}{I_G} \) values of BC, C-1, C-1.5, and C-2 are 0.95, 1.00, 1.04 and 1.01, respectively, suggesting that the increase of K2C2O4 dosage (ratio of carbon precursor to K2C2O4 by weight) from 1 : 1 to 1 : 1.5 can induce more defects and disorder in the carbon, while further increasing K2C2O4 dosage (1 : 2) can enhance the graphitization degree of carbon. The \( \frac{I_D}{I_G} \) values of R-1.5 and C-1.5 are 0.75 and 1.04, respectively, indicating a higher graphitization degree of R-1.5, which is in accordance with the XPS result. It is likely that the loose and spongy structure of cornstalk pith can promote defects during activation, thus increasing the disorder degree of carbon materials.\(^{25-26}\) The \( \frac{I_D}{I_G} \) values of R-2 and C-2 are 0.95 and 1.01, respectively, which further demonstrate that the as-obtained carbons from cornstalk without pith have a higher graphitization degree.

The electrochemical performances of CHPCs were first investigated using a three-electrode system in 1 M H2SO4 aqueous solution. As shown in Fig. 5a, the CV curves of CHPCs display quasi-rectangular shapes with an obvious hump at 0.2–0.6 V at a scan rate of 20 mV s\(^{-1}\). The hump in the CV plot measured in a three-electrode system indicates redox reactions, which mainly result from the quinone oxygen groups.\(^{26}\) R-1.5 exhibits the largest encircled area among all the carbon samples, revealing the highest capacitance. Fig. 5b shows the GCD curves of the CHPCs at 1.0 A g\(^{-1}\) and all samples exhibit quasi-linear and symmetrical triangular profiles. Apparently, C-1.5 and R-1.5 display longer discharge times, indicating their better supercapacitances. The specific capacitances calculated from the discharge curves of the samples are illustrated in Fig. 5c. C-1.5 and R-1.5 exhibit superior specific capacitances of 337 F g\(^{-1}\) and 387 F g\(^{-1}\) at 1.0 A g\(^{-1}\), respectively, which are obviously higher than those of BC (155 F g\(^{-1}\)), C-1 (211 F g\(^{-1}\)), C-2 (197 F g\(^{-1}\)), and R-2 (237 F g\(^{-1}\)). As for C-1.5 and R-1.5, the interconnected porous structure facilitates ion transportation, while the high SSA (2054 m\(^2\) g\(^{-1}\) and 1910 m\(^2\) g\(^{-1}\)) provides sufficient electrode–electrolyte interface for charge storage and the large amount of mesopores is beneficial to the retention and immersion of the electrolyte ions, providing convenient channels for electrolyte penetration and ion transportation.\(^{22}\) Meanwhile, the abundant oxygen-containing functional groups provide additional pseudo-capacitance for the samples.\(^{40}\) Therefore, C-1.5 (337 F g\(^{-1}\)) and R-1.5 (387 F g\(^{-1}\)) show superb gravimetric specific capacitance among all the CHPCs. Compared with C-1.5, R-1.5 exhibits a higher mesopore ratio (86.89%) and graphitization degree after the removal of pith, which greatly contributes to a higher specific capacitance. In order to compare and further elucidate other electrochemical performances of C-1.5 and R-1.5, CV and GCD measurements at different scan rates and current densities are conducted. Fig. 6a and b show the CV curves of C-1.5 and R-1.5 at scan rates ranging from 5 to 200 mV s\(^{-1}\), respectively. The CV curves of C-1.5 (Fig. 6a) exhibit a quasi-rectangular shape, while the CV curves of R-1.5 (Fig. 6b) display a rectangular shape with a hump at 0.2–0.6 V, which can be attributed to the redox reactions induced by the high content of quinone oxygen groups.\(^{28}\) The specific supercapacitances of C-1.5 and R-1.5 calculated from the CV curves are summarized in Fig. 6c. The specific capacitances of C-1.5 and R-1.5 at 5 mV s\(^{-1}\) are as high as 551 F g\(^{-1}\) and 618 F g\(^{-1}\), respectively. Even at a high scan rate (200 mV s\(^{-1}\)), R-1.5 still displays a high specific capacitance of 447 F g\(^{-1}\), which is much larger than that of C-1.5 (273 F g\(^{-1}\)), indicating a high rate capacity and rapid charge transfer capability. Fig. 6c
The CNLS method is displayed in Fig. 7a (the inset). The whole equivalent circuit model by the coupled nonlinear equation shown in Fig. 6f, \( C-1.5 \) displays a very high specific capacitance but an exceptionally high capacitance retention, which can be attributed to its improved mesopore ratio resulting from the removal of pith. Interestingly, \( R-1.5 \) possesses high specific capacitances of 461 \( \text{F g}^{-1} \) at 0.5 \( \text{A g}^{-1} \) and 291 \( \text{F g}^{-1} \) at 20 \( \text{A g}^{-1} \), with 63.1% capacitance retention. Compared with \( C-1.5 \), \( R-1.5 \) shows a similarly large specific capacitance but an exceptionally high capacitance retention, which can be ascribed to its higher mesopore ratio resulting from the removal of pith. Electrochemical impedance spectroscopy (EIS) was conducted to further study the cornstalk-based carbon electrodes. The Nyquist plots of \( C-1.5 \) and \( R-1.5 \) electrodes in the frequency range from 10 \( \text{mHz} \) to 10 \( \text{kHz} \) are displayed in Fig. 7a. The Nyquist plots of \( C-1.5 \), \( R-1.5 \), and \( C-2 \) (a) and cycle stabilities of \( R-1.5 \) at a current density of 10.0 \( \text{A g}^{-1} \) (b).

Fig. 6 CV curves of C-1.5 (a) and R-1.5 (b) at different scan rates; GCD curves of C-1.5 (c) and R-1.5 (d) at different current densities; specific capacitances calculated from CV curves (e) and GCD curves (f).

Fig. 7 Nyquist plots of C-1.5, R-1.5 and C-2 (a); and cycle stabilities of R-1.5 at a current density of 10.0 \( \text{A g}^{-1} \) (b).

A symmetric device is assembled with \( R-1.5 \) by employing two identical electrodes in 1 M \( \text{Na}_2\text{SO}_4 \) aqueous electrolyte. As shown in Fig. 8a, the \( R-1.5 \) symmetric electrode displays quasi-rectangular shapes as the potential window increases and can be operated at 2.0 \( \text{V} \) with no obvious increase in the anodic current. The CV profiles of the symmetric electrode in Fig. 8b display good rectangular shapes without apparent distortion at a sweep rate of 5–200 \( \text{mV s}^{-1} \). The GCD plots (Fig. 8c) of the symmetric electrode show quasi-triangular charge–discharge shapes in a wide range of current density from 0.5 \( \text{A g}^{-1} \) to 20 \( \text{A g}^{-1} \), indicating excellent electrochemical reversibility. The

R-1.5 symmetric electrode displays a high specific capacitance of 306 F g\(^{-1}\) at 1 A g\(^{-1}\) and 240 F g\(^{-1}\) at 20 A g\(^{-1}\) from GCD plots, suggesting a superior capacitance performance and an outstanding rate capability. A high retention rate of 78.0% demonstrates the superior rate capability of R-1.5 due to the efficient ion transportation.\(^{14}\) The specific capacitances of R-1.5 at different current densities are summarized and compared with other biomass-based carbon materials, as shown in Fig. 8d. R-1.5 displays an ultrahigh specific capacitance that exceeds that of most biomass-derived carbons (coloured dots), such as corn stalk core (300 F g\(^{-1}\) at 0.1 A g\(^{-1}\))\(^{50}\) broad beans (129 F g\(^{-1}\) at 10 A g\(^{-1}\))\(^{44}\) corn husk (260 F g\(^{-1}\) at 1.0 A g\(^{-1}\))\(^{50}\) and so on.\(^{31,65-69}\) The Ragone plot in Fig. 8e depicts that R-1.5 has a high energy density of 42.5 W h kg\(^{-1}\) at a power density of 374.1 W kg\(^{-1}\) and 33.3 W h kg\(^{-1}\) at a very high output power density of 9.3 kW kg\(^{-1}\), exceeding those of other biomass-based carbons (coloured dots in Fig. 8e).\(^{50,60,69-75}\) To further demonstrate the practical application of R-1.5 as an electrode material, a green light-emitting diode (LED) was connected to three as-assembled R-1.5 supercapacitor devices in series. As shown in Fig. 8f, the green LED was lit up brightly for more than 3 min, revealing its practical application for high-performance energy storage systems.

Based on the above discussion, the removal of pith especially endows R-1.5 with a high mesopore ratio and graphitization degree, which are favourable for a decreased internal resistance and an enhanced capacitive behavior. The superior electrochemical performances of R-1.5 benefit from the following features. (i) A large specific area provides abundant active sites for electrolyte ion storage, which leads to high supercapacitance and energy density. (ii) The hierarchical pore structure (micro-, meso- and macropores) offers fast pathways for ion diffusion, which minimizes transport resistances for electrolyte ion movement inside the inner nanopores, thus leading to remarkable rate capability and power density. (iii) The amorphous structure and relatively low graphitization degree of the carbon matrix provide sufficiently long distance for ion shuttling, resulting in low internal resistance and enhanced electrical conductivity, thereby maintaining the high rate performance. (iv) Abundant oxygen-containing groups improve the wettability of active materials, giving rise to the high accessible surface area for ions and extra pseudo-capacitance. These features endow R-1.5 with high specific capacitance, outstanding rate capability, excellent cycling stability and high energy density, which make it a promising candidate as an electrode material for high-performance supercapacitors.

4. Conclusions

In summary, hierarchical porous carbons are successfully prepared from cornstalk without pith for the first time using a facile and scalable approach. With the simple removal of pith, the obtained carbon materials display an improved mesopore ratio and enhanced graphitization degree, resulting in fast ion diffusion and superior rate capability of the carbon electrode. In addition, the reaction of CaCO\(_3\) and the activating agent K\(_2\)C\(_2\)O\(_4\) (potassium oxalate) gives rise to an etching effect and gasification, which can tailor the porosity of the carbon. Benefiting from the large specific surface area and oxygen content, the symmetric device assembled with 1.5XAC-300800 possesses an ultrahigh specific capacitance, excellent rate capability, long-term cycling stability, and high energy density. The simple strategy of pith removal from cornstalk provides a scalable route for low-cost production of advanced hierarchical porous carbons with superior capacitance, energy density and rate capacity.
