Mechanisms of carbon dioxide reduction on strontium titanate perovskites

Umberto Terranova,^{ab} Francesc Viñes,^c Nora H. de Leeuw^{ad} and Francesc Illas^c

Strontium titanate (SrTiO₃) is a promising material for the light-driven conversion of carbon dioxide (CO₂) into renewable fuels. However, the mechanisms of the relevant reactions are not yet well understood. In this work, we have used density functional theory calculations to explore CO₂ reduction on the (001) surface of the SrTiO₃ photocatalyst. Our results indicate that, in contrast to COOH, the formation of a HCOO or CO₂[−] intermediate is thermodynamically hindered, which is consistent with the fact that formic acid (HCOOH) is not a major product in the experiments reported in the literature. We show that a pathway to carbon monoxide (CO) is instead possible, and that the formation of COOH is the rate-limiting step. Finally, we suggest that substitutional doping of Sr ions represents a promising approach to lower the energy barrier of the COOH formation.

1 Introduction

To reduce the still increasing CO₂ emissions responsible for global warming and the concomitant climate change remains one of the biggest challenges of our era. The catalytic technologies currently being explored to utilise the CO₂ molecule by converting it into useful hydrocarbons include heterogeneous^{1–4} and electrochemical^{5–7} catalysis. Approaches such as photocatalysis,^{8,9} mimicking the natural process of photosynthesis, are particularly attractive, as they are achieved at room temperature and require only the harnessing of solar light as a source of energy. However, the achievement of photocatalytic conversions suitable to industrial applications remains a difficult challenge,¹⁰ which motivates the continuous search for new and improved photocatalytic materials.

Since their first use in heterogeneous catalysis in 1952,¹¹ perovskite oxides have attracted significant interest in a diverse range of reactions,¹² especially because they are cheaper and easier to prepare than metal-based catalysts such as platinum or palladium.¹³ Compared to other widely investigated oxide photocatalysts, *e.g.* ZrO₂ and Ga₂O₃, perovskite oxides have bandgaps with a better overlap with the solar spectrum. In addition, owing to the unique flexibility of their structure, perovskite oxides have bands edges which can be tuned to

facilitate both the reduction of CO₂ and the oxidation of water during the photocatalytic process.⁹

Because of their striking photochemical stabilities, titanate perovskites are particularly promising for CO₂ photocatalysis.¹⁴ Taking inspiration from leaves, Zhou *et al.* have developed an artificial photosynthetic system based on titanate perovskites which generates carbon monoxide and methane from CO₂ and water.¹⁵ These materials have also been investigated in combination with other semiconductors, co-catalysts and dopants, in the effort to improve their conversion efficiencies. For example, Li *et al.* obtained CO and H₂ by loading SrTiO₃ with noble metals,¹⁶ while CaTiO₃ samples loaded with Ag exhibited stable photocatalytic activities for CO₂ reduction to CO using water as an electron donor.¹⁷ The photoreduction of CO₂ on SrTiO₃-based nanocomposite systems has also been demonstrated, with CH₄ as the major product.¹⁸ The generation of oxygen vacancies enhances the adsorption of CO₂ on SrTiO₃, leading to higher yields of CH₄,¹⁹ while NaTaO₃ doped with Ba, Ca, and Sr has shown high activity towards CO₂ reduction to CO in water.²⁰

Detailed atomistic knowledge of the light-triggered catalytic reaction mechanism is crucial to help design better photocatalysts.²¹ For example, it allows us to ascertain the limiting reaction steps, featuring the higher activation energy barriers in a catalytic pathway, which elucidates ways of fine-tuning the perovskite structure to lower these activation barriers. However, in contrast to the most investigated anatase TiO₂ photocatalysts,²² the elementary reaction steps occurring after the adsorption of CO₂ on titanate perovskites are yet to be clarified.

Here, we provide this missing piece of information on the textbook SrTiO₃ perovskite, one of the most commonly investigated members of the titanate perovskite family, which, with a tunable bandgap of 3.2 eV (ref. 23) (identical to that of

anatase) and remarkable charge transport properties,¹⁴ holds great potential as a photocatalyst.^{19,24–27} Using simulations within the density functional theory (DFT), we first aim to achieve the description of a realistic reaction pathway for the experimentally observed reduction of CO₂ to CO. Afterwards, we take advantage of the fresh insights into the system to put forward a doping approach aimed at improving the efficiency of the photocatalytic reaction.

2 Models and methods

The most-stable SrTiO₃ (001) surface can have two different competitive terminations, namely SrO and TiO₂.²⁸ In this study, we have focussed on the SrO termination only, since its equivalent has been shown generally to be the favoured plane in a wide diversity of perovskites.^{29,30} Our (001) surface model, built from an optimised primitive cell, consists of a 2 × 2 × 4 supercell, and contains 80 atoms located within 8 layers. Surface slabs were separated by a vacuum region of 15 Å along the normal direction to avoid spurious interactions between periodic images. All structures were drawn with the visualization for electronic and structural analysis (VESTA) program suite.³¹

The adsorption energy of CO₂ was evaluated according to the formula

$$E_{\text{ads}} = E_{\text{slab/mol}} - E_{\text{slab}} - E_{\text{mol}}, \quad (1)$$

where $E_{\text{slab/mol}}$ is the energy of the supercell with the adsorbed CO₂, while E_{slab} and E_{mol} are the energy of the same supercell with, respectively, only the surface slab or a CO₂ molecule. In addition to the DFT energy E , in order to take into account the effect of temperature and pressure in the reaction mechanism, we have considered the Gibbs free energy G . For a condensed phase structure, G is defined as

$$G = E + F_{\text{vib}} + pV, \quad (2)$$

where F_{vib} is the vibrational contribution to the free energy, which we have estimated using the frequencies at the Γ -point. The pV term can be neglected, as it is of the order of meV under standard working conditions.³² The Gibbs free energy of a gas-phase molecule corresponds to its chemical potential μ , which can be derived from³³

$$\mu(T, p) = \mu_{\text{ref}}(T_0, p_0) + \Delta H(T, p_0) - T\Delta S(T, p_0) + k_{\text{B}}T \log(p/p_0), \quad (3)$$

where ΔH and ΔS are the enthalpy and entropy variations from the reference chemical potential μ_{ref} and $k_{\text{B}}T \log(p/p_0)$ includes the effect of pressure on the chemical potential with respect to the standard one. If $T_0 = 0$ K, μ_{ref} can be approximated by the DFT energy of the molecule in the gas-phase, including the zero point energy contribution. Thus, eqn (3) allows us to calculate the chemical potential of CO₂, CO, H₂O and H₂ at given temperature and pressure by using their respective tabulated enthalpy and entropy values at the standard ambient pressure p_0 .³⁴

The substitutional energy for the dopant X (X = Ba or Ca) was calculated according to

$$E_{\text{subs}}(\text{X}) = E(\text{doped}) + E(\text{Sr}) - E(\text{undoped}) - E(\text{X}), \quad (4)$$

where $E(\text{doped})$ and $E(\text{undoped})$ are the energies of doped and pure SrTiO₃ surfaces, respectively, while $E(\text{Sr})$ and $E(\text{X})$ are the energies of single Sr and X atoms.

All DFT calculations were performed with the VASP 5.3 package^{35,36} using the Perdew–Burke–Ernzerhof (PBE) functional.³⁷ We have employed the projector augmented wave method to model the core–electron interaction,³⁸ treating explicitly the following electrons: Sr 4s 4p 5s; Ti 3d 4s; O 2s 2p; Ba 5s 5p 6s; Ca 3s 3p 4s. All calculations were performed with a plane wave cutoff of 500 eV, which guarantees that the absolute energies of bulk SrTiO₃ are converged within 2 meV per atom. Calculations were stopped when the forces acting on the ions were less than 10^{−2} eV Å^{−1}. After finding that a 6 × 6 × 6 Monkhorst–Pack grid³⁹ ensures that the absolute energies of bulk SrTiO₃ are converged to better than 1 meV per atom, we scaled the grids of the surface calculations inversely with the dimension of the unit cells to 3 × 3 × 1. We have also undertaken test calculations to make sure that the atomic relaxations in the surface slab are converged with respect to its thickness. Transition states were located with the climbing image nudged elastic band algorithm.⁴⁰ The number of images used varied from one to four, depending on the elementary reaction step. We have calculated vibrational frequencies under the harmonic approximation and with Hessian matrix elements estimated from finite differences of analytical gradients with displacements of 0.015 Å in length. Only the degrees of freedom of the adsorbate species and the atoms in the topmost atomic layer of the surface have been included in the vibrational analysis.

3 Results and discussion

3.1 Adsorption of CO₂

A sufficiently large number of different adsorption configurations for CO₂ on the SrO-terminated SrTiO₃ (001) surface have been probed to ensure that realistic minimum energy structures would be obtained. Following optimisation, all configurations relaxed towards the structure depicted in Fig. 1, where the arrangement of the atoms at the adsorption site resembles that of a CO₃^{2−} carbonate ion. In particular, each carbonyl oxygen forms a bridging bond with two surface Sr ions, whereas the remaining oxygen, O_s, is significantly displaced from its surface position. The C–O and C–O_s bond lengths are 1.27 and 1.36 Å, respectively, while the O₁–C–O₂ angle of 122.4° confirms the strong interaction with the surface, as shown by the large adsorption energy of −1.82 eV. All of these values are in line with a CO₂ capture and activation process.⁴¹ Both the geometry and the energetics, which are summarised in Table 1, are comparable to those found in a previous DFT investigation by Sopiha *et al.*,⁴² who also showed that the adsorption geometry of CO₂ slightly changes, while its interaction becomes stronger, when the size of the surface unit cell is increased from a 2 × 2 to a 3 × 3 supercell. As the structure in Fig. 1 is the only stable on

Fig. 1 Top (upper panel) and side (lower panel) views of the adsorption structure of CO₂ on the SrO-terminated (001) surface of SrTiO₃. Colour code: Sr – green, Ti – blue, O – red, C – brown.

Table 1 Adsorption energy and main geometrical parameters of the adsorption structure of CO₂ on the SrO-terminated (001) surface of SrTiO₃ depicted in Fig. 1

E_{ads} (eV)	C–O ₁ (Å)	C–O ₂ (Å)	C–O _s (Å)	O ₁ –C–O ₂ (°)
–1.82	1.27	1.27	1.36	122.4

the 2×2 unit cell which we adopted, we assume that any reaction pathway must include it as a reactant configuration. However, we stress that other starting configurations, potentially leading to different reduction mechanisms, may also be possible at lower CO₂ coverages.

It is instructive, at this point, to compare the adsorption energy of this structure with that of a water molecule. Regardless of the initial configuration and in line with the literature,⁴³ we found that water spontaneously dissociates on the SrO-terminated (001) surface of SrTiO₃. The dissociated water molecule is adsorbed with an energy of –1.26 eV, which is considerably less negative than the –1.82 eV value found for CO₂. As a result, we expect SrTiO₃ to be preferentially covered by CO₂ rather than by water, which in turn suggests that the CO₂ reduction process should be more favourable than the competing hydrogen evolution reaction.¹⁰ Future detailed studies can now build on these findings to confirm the selectivity of SrTiO₃ towards the reduction of CO₂, rather than water.

3.2 Thermodynamics of intermediates

The photocatalytic conversion of CO₂ takes place in the presence of a photoexcited electron which reduces the SrTiO₃

surface. When the carbonate-like structure described above is adsorbed on the reduced surface, which we have modelled by adsorbing a H atom on SrTiO₃ as in previous works,^{22,44} a hydrogen bond between a carbonyl oxygen and the proton on the surface is formed, which is illustrated in Fig. 2a. However, the geometry changes with respect to the neutral surface, *e.g.* the elongation of the two C–O bonds, are only marginal, as can be seen from the parameters reported in Table 2.

TiO₂ is arguably the prototype photocatalyst,⁴⁵ and many efforts have been devoted to the elucidation of the molecular mechanisms yielding fuels from CO₂ using TiO₂ polymorphs. He *et al.* concluded that the formation of an activated CO₂[–] radical adsorbed in a bridging configuration is the first step towards hydrogenation and the formation of formic acid on anatase.²² In search of a possible similar mechanism, we have relaxed such a structure. While not stable on a neutral surface, interestingly, in the presence of a reducing electron, this bent geometry converged to one with a O₁–C–O₂ angle of 140.4°, see Fig. 2b and Table 2, which highlights the importance of photogenerated electrons on the activation of the molecule. However, its energy resulted to be 1.96 eV higher than that of the carbonate-like structure in Fig. 2a, which makes it an unlikely candidate as a possible intermediate, while indicating that catalytic mechanisms different than those of TiO₂ are at play in SrTiO₃.

Fig. 2 Side views of the structures discussed in the text. CO₂ adsorption on a reduced surface (a); activated CO₂ in a bridging bidentate configuration similar to that observed in anatase TiO₂ (b); HCOO structure with hydrogenation at the C atom (c); COOH structure with formation of a O–H bond (d); Colour code: Sr – green, Ti – blue, O – red, C – brown, H – white.

Table 2 Relative energies and main geometrical parameters of the different CO₂ adsorptions on the SrO-terminated (001) surface of SrTiO₃. Labels refer to Fig. 2

Label	E (eV)	C–O ₁ (Å)	C–O ₂ (Å)	C–O _s (Å)	O ₁ –C–O ₂ (°)
(a)	0.00	1.29	1.30	1.32	121.6
(b)	1.96	1.23	1.23	—	140.4
(c)	2.55	1.38	1.38	1.45	110.6
(d)	1.15	1.41	1.25	1.27	117.3

Next, we assessed whether hydrogenation of CO₂ could occur *via* a different intermediate. Thus, we detached the adsorbed H species from the surface site of Fig. 2a, creating a new H-C bond, see Fig. 2c. However, we found the energy of the resulting configuration to be 2.55 eV higher than that of the original structure, which clearly excludes its participation in any reaction mechanism.

Finally, we relaxed the structure in Fig. 2d, where we simulated the H transfer from the surface site of structure of Fig. 2a to the closest CO₂ oxygen. The formation of a COOH group changes the adsorption geometry to that of a bridging bidentate, having an energy 1.15 eV higher than the initial structure, taken as reference, as shown in Table 2.

On the basis of thermodynamic (energetic) considerations, we can conclude that only the COOH intermediate can participate in the reduction of CO₂, while pathways involving either CO₂[−] and/or HCOO should be discarded. However, we cannot rule out the existence of other, in principle less favoured, pathways where two or more electrons and/or proton are transferred.²² The high energy penalty for hydrogenation through the carbon atom explains why HCOOH is not detected in CO₂ photochemical reactions on SrTiO₃. Instead, the COOH species that can be reached energetically points to a pathway towards CO,¹⁰ in agreement with experimental findings on titanate perovskites.^{15,16}

3.3 Reaction pathway to CO

With the information gained in the previous section, we have derived a realistic pathway for the reduction of CO₂ to CO, which we present in the top panel of Fig. 3, whereas reaction geometries are shown in Fig. 4. The formation of the COOH intermediate proceeds *via* TS1 and has an activation energy barrier for the hydrogen transfer of 1.22 eV. Only 0.75 eV is required to reach TS2 (where the C–O distance is 1.56 Å), break the C–O bond and form the CO and OH species at the surface. Note, however, that the barrier for CO and OH recombination is lower, which may indicate that, from a kinetic point of view, a substantial part of reactions will go backwards, with forward direction favoured by fast CO and OH diffusions. The subsequent release of CO is endothermic by merely 0.12 eV, and the process leaves a hydrogen-bonded H⁺ and OH[−] couple. In the last step of the reaction mechanism, as a result of a proton transfer in TS3, a H₂O molecule forms. This water molecule interacts with the surface by means of two hydrogen bonds, and its desorption raises the energy by 0.86 eV. The entire reaction cycle, CO₂ + 2H⁺ + 2e[−] → CO + H₂O, is endothermic by 0.73 eV. Obviously, the energy profile provides a preliminary picture of the overall mechanism, allowing to discard the HCOO intermediate. However, to unravel the amount of CO formed and the effect of H₂O requires further analysis that is beyond the scope of the present work. Note also, that the models used represent the ideal (001) surface, whereas the real material may be more complex. In any case, the present results provide some clear and unbiased hints that explain experimental observations.

In the bottom panel of Fig. 3, we plot the Gibbs free energy of the pathway above, taking into account temperature (300 K) and

Fig. 3 Reaction pathways for the reduction of CO₂ to CO on SrTiO₃. Structures are labelled according to the state of the species. (a) indicates that the species is adsorbed on the surface, while (g) indicates that the species is modelled in the gas-phase and does not interact with the surface. Transition states are indicated as TS1, TS2 and TS3. The zero of the energies are taken as those of structure CO₂(g) + H₂(g). Activation energies (E_a) are shown.

pressure (1 bar) effects. The profile flattens compared to that in the top panel of Fig. 3, although the endothermicity of the reaction is not much affected. The flattening can be explained by the larger entropy contributions carried by the gaseous species compared to their adsorbed counterparts. For example, the gain due to the adsorption of CO₂ increases drastically, from −2.11 to −1.40 eV, when the Gibbs free energy, rather than the DFT energy, is considered. However, the rate limiting step remains the formation of the COOH group, whose activation energy barrier remains virtually unchanged at 1.23 eV, which is in line with the low photoreduction rates typical of titanate perovskites.⁴⁶ Note, however, that once pressure and temperature effects are taken into account, the thermodynamics will tend to drive the reaction backwards since now some transition states are located above the desorption limit. This is an issue deserving further attention through macroscopic simulations including all elementary steps and searching for the optimum operating conditions as well.

3.4 Substitutional doping

Having established that the formation of the COOH intermediate (more favoured than its desorption from the surface by around 0.1 eV, as shown in Fig. 3), is the rate-limiting step in the production of CO on the pure SrTiO₃ (001) surface, we have carried out further calculations to explore how the activation energy of this elementary reaction step is affected by surface doping. Similar to the study by Carlotto *et al.*,⁴⁷ we have only

Fig. 4 Side views of the structures participating in the reaction pathway illustrated in Fig. 3. Colour code: Sr – green, Ti – blue, O – red, C – brown, H – white.

Fig. 5 Energetics of the rate-limiting COOH formation step of Fig. 3, with and without substitutional doping of Sr ions. Structures are labelled according to the state of the species. (a) indicates that the species is adsorbed on the surface. The transition state is indicated as TS1. The zero of the Gibbs free energy is taken as that of structure $\text{CO}_2(\text{a}) + \text{H}(\text{a})$. Activation energies (E_a) and differences in Gibbs free energies (ΔG) are also included.

focussed on the top surface layer. In particular, we have considered the substitution of one of the four Sr ions by a Ba or Ca ion. We have chosen these dopants because their ionic radii in the 2+ charge state, at 149 and 114 pm, respectively, are close to the 132 pm ionic radius of Sr,⁴⁸ which implies that they should be accommodated easily within the SrTiO_3 material, both geometrically and in terms of charge. Moreover, BaTiO_3 and CaTiO_3 are the most common titanate perovskites after SrTiO_3 , which should ensure the successful replacement of Sr by Ba and Ca ions during the synthesis of the photocatalyst. The stability of the doped materials is suggested by the negative

substitutional energies of both dopants, *i.e.* -0.26 and -0.09 eV, respectively, for Ba and Ca.

Fig. 5 shows the activation energy barriers of the elementary steps and the difference in Gibbs free energy between the two intermediates. While Ba dopants change the thermodynamics of the reaction step without altering its kinetics, the substitution of Sr by Ca ions has the opposite effect, with the activation barrier being lowered from 1.23 to 1.15 eV. Although the effect is small, it clearly indicates that cation doping is a conceivable way to accelerate the reaction rate for CO production over the SrTiO_3 photocatalyst, as shown here by Ca.

4 Conclusions

We have presented a theoretical investigation of the adsorption and reaction of CO_2 on the SrO-terminated (001) surface of SrTiO_3 , a perovskite compound of significant technological interest. We have shown that the possible intermediates towards the formation of HCOOH are very high in energy, which explains why the formation of HCOOH is not normally reported in photocatalytic experiments. Instead, the reduction of CO_2 to CO appears to be feasible, in agreement with experimental observations, thus pointing towards the use of SrTiO_3 as a photocatalyst for the reduction of CO_2 . The reaction occurs *via* the formation of a COOH species (the associative mechanism in the reverse water gas shift reaction³), with an activation energy of about 1.2 eV, corresponding to the rate-limiting step of the overall reaction.

However, a more firm statement will require a systematic analysis of adsorption/desorption rates, the rates for diffusion of the various species and their comparison to reaction rates for all the steps in the mechanism. While such simulations are left for subsequent work, the present results provide compelling evidence that the barrier for the likely rate determining step is sensitive to the nature of the surface cations, and therefore can be lowered by means of a doping strategy, for example where smaller Ca ions substitute for Sr ions. Future experimental studies along with macroscopic simulations will be important to validate these predictions.
