Liquid crystalline copper(i) complexes with bright room temperature phosphorescence†

Raquel Giménez,^a Olga Crespo,^b Beatriz Diosdado^b and Anabel Elduque^{*b}

Phosphorescence in the liquid crystal state with one of the highest quantum yield values, 42%, at room temperature is reported. This property is achieved with cyclic trinuclear copper(i) complexes prepared using 3,5-dimethyl-4-(trialkoxypheyl)pyrazolate ligands. The compounds show well-organized hexagonal columnar mesophases that are stable at room temperature or near room temperature with intracolumnar order at distances of 3.6 Å, red emission and lifetimes consistent with the excimeric metal-centered phosphorescence typical of copper trinuclear pyrazolato complexes. A non-mesogenic analogue shows similar properties, and the single crystal structure is formed by stacked molecules forming a supramolecular extended structure with two different intermolecular Cu...Cu contacts, 3.368 Å and 3.666 Å, which are in the range of previously reported weak cuprophilic interactions. The results demonstrate that metallomesogens with efficient room temperature phosphorescence can be obtained with metal complexes other than the widely explored and precious metal-based iridium or platinum complexes.

Introduction

Phosphorescent materials bearing transition metal complexes are intensively investigated for applications in phosphorescent organic light emitting diodes (PhOLEDs).^{1–3} Theoretically, such materials can emit with 100% internal quantum efficiency due to the possibility of harvesting singlet and triplet excitons, a much higher value than that for fluorescent materials, which only emit through singlet excitons and, therefore, can only reach a theoretical efficiency that is four times smaller. In addition, the large Stokes shift and the long lifetime emission of phosphorescence is advantageous for sensing applications as it avoids interferences from scattered light and short-lived fluorescence.⁴

In the last two decades, the field of luminescent liquid crystalline metal complexes, a particular class of metallomesogens,⁵ has developed significantly.^{6–8} The liquid crystal state offers interesting properties such as the control of the organization and anisotropy combined with better solubility and processing.⁹ Indeed, a controlled orientation of phosphorescent molecules in active

layers has become a crucial topic to improve solid-state emission and efficiency in electronic devices.¹⁰ The compounds derived from precious heavy metals such as iridium or platinum are the most widely studied with respect to phosphorescence emission. However, the study of the efficiency (quantum yield) in the liquid crystal phase has been largely overlooked.⁷ Nowadays, the goal of attaining low temperature liquid crystals with high emission efficiencies in the liquid crystalline state is fostering the search for new molecules.

Copper(i) complexes have not been widely exploited as luminescent materials in the solid state,¹¹ but they have a variety of possible structures and luminescence ranges with great potential.^{12,13} Furthermore, copper is more abundant and is therefore a more affordable alternative to iridium or platinum complexes. With respect to liquid crystalline properties, very few copper(i) metallomesogens have been described and they show a broad structural diversity and varied ligands derived from tetrathiamacrocycles,¹⁴ diiminobipyridine,¹⁵ diiminopiridine,¹⁶ alkylthiolate,¹⁷ terpyridine,¹⁸ isocyanide,^{19–22} bis(pyrazolyl)-ethyl ether,²³ phenanthroline,^{24,25} pyrazolate,²⁶ phosphine,²⁷ thiolate,²⁸ benzoylthiourea²⁹ or biquinoline.³⁰ Moreover, the luminescent properties of copper(i) metallomesogens have hardly been analysed^{26,27,30} and only two studies have reported quantum yield measurements, with the maximum values of up to 2.4% in the columnar phase³⁰ or 8% in the glassy smectic A phase.²⁷

In order to obtain efficient copper-based liquid crystalline emitters our attention was focused on cyclic trinuclear complexes (CTCs) with the general structure of [Cu(μ-pz)]₃ (pz = pyrazolate).

Copper(I) CTCs show phosphorescence due to emission from a metal-centered triplet state (^3MM) of an excimer,^{31,32} and only very recently has it been reported that very high quantum yields, *i.e.*, over 75%, are affordable in the crystal state at room temperature.^{33–36} Although the planar structure of the metallacycle could facilitate the formation of columnar liquid crystal phases, liquid crystalline behaviour was not observed for copper(I) CTCs even on using the same ligands as those used for liquid crystalline silver(I) and gold(I) CTCs.³⁴ For example, silver(I) and gold(I) complexes with the 4-hexyl-3,5-dimethylpyrazolate ligand are liquid crystalline, but the copper(I) complex has a lower melting point and exhibits direct transition to the isotropic liquid. This behaviour has been attributed to weaker metallophilic interactions. To our knowledge, there is only one study that has reported about liquid crystallinity in copper(I) CTCs, and this was concerned with complex dendritic pyrazolate ligands. A columnar mesophase was claimed; however, its appearance required an aging process to develop the material without crystallization and the quantum yield value was not measured.²⁶

Based on the above precedents showcasing great potential for research on novel copper(I) phosphorescent metallomesogens we carried out our study with the following aims: (1) to obtain a stable and well-organized liquid crystalline phase for copper(I) CTCs using structurally simple ligands, (2) to stabilize the mesophase at room temperature or near room temperature, and (3) to obtain bright phosphorescence at room temperature in the liquid crystal state. We report here the synthesis and characterisation of these novel compounds (Scheme 1) along with the study of the mesophases and their luminescent properties.

Results and discussion

Synthesis and single crystal structure of Cu1

Two copper complexes with a total of nine long alkoxy chains, **Cu10** and **Cu14**, were prepared from 3,5-dimethyl-4-trialkoxyphenylpyrazoles.³⁷ By adapting a synthetic procedure,³⁸ triethylamine was mixed with the pyrazole ligand in acetone and then reacted with $[\text{Cu}(\text{CH}_3\text{CN})_4]\text{BF}_4$ to yield the trinuclear

complex (Scheme 1). Experimental details and characterisation data are provided in the ESI,[†] and the data are consistent with the expected trinuclear stoichiometry.

An analogous compound with nine methoxy substituents, **Cu1**, was synthesized under the same reaction conditions. Long colourless needles were obtained by slow diffusion of hexane into a concentrated solution of the compound in dichloromethane at room temperature. Albeit the needles were unstable during manipulation, it was possible to obtain structural information about **Cu1**· CH_2Cl_2 . Details of data collection and refinement are shown in Table S1 (ESI[†]).

Cu1· CH_2Cl_2 crystallised in the monoclinic space group $P2_1/n$. The unit cell contains four molecules of **Cu1** and four molecules of dichloromethane near the peripheral methoxy groups. The crystal structure confirms the trinuclear stoichiometry of the complex (Fig. 1a and b), which consists of an almost flat metallacycle core formed by the three pyrazolate rings and the three copper atoms. The values of the N–Cu (1.865–1.846 Å) and intramolecular Cu··Cu distances (3.185–3.226 Å) are in agreement with those found for reported copper(I) complexes derived from 3,5-dimethylpyrazolates,^{35,39–41} with N–Cu–N angles close to the ideal linear coordination (177.4 – 179.8°). All phenyl rings located at the 4-position of the pyrazolate rings do not have the same disposition; one of them is coplanar with the metallacycle whereas the other two are twisted by 40° and 56° (Fig. 1c). This lack of planarity has been previously documented to occur in a variable range of 33 – 76° but in all these structures the three phenyl substituents were out of plane.^{42–44}

As far as the crystal packing is concerned, the main structural characteristic of **Cu1** is that the molecules are stacked along the *b* axis (Fig. 1b). The *b* axis and the normal to the average molecular plane make an angle of *ca.* 24° , therefore the molecules are tilted inside the stack, with alternating sense in the nearest stacks. Inside each stack the molecules are arranged in a slipped antiparallel fashion. In such a way the pyrazolate ligands spread around the columnar axis. The shortest Cu··Cu intermolecular distances measured between closest neighbours alternate between 3.368 Å (Cu(1)··Cu(2')) and 3.666 Å (Cu(1)··Cu(3')). Based on previous reports that use a re-evaluated van der Waals radius of 1.92 Å,¹² these Cu··Cu distances lie in the range of weak intermolecular cuprophilic interactions (attractive interactions between closed shell d^{10} copper(I) atoms), although this assumption is made here without evidence of real attractive interactions. Considering these values, and in similarity to previous reports,⁴¹ a supramolecular extended structure is formed along the stack in which each molecule establishes two contacts at distances of 3.368 Å with one neighbour, and two contacts at distances of 3.666 Å with the other neighbour, with one copper atom engaged in two interactions (Fig. 1d).

Liquid crystalline properties

Complexes **Cu10** and **Cu14** show thermodynamically stable liquid crystal phases. The results obtained from the optical and thermal studies are presented in Table 1 along with the XRD data for the mesophases. Textures observed between crossed polarisers using

Scheme 1 Illustration of the copper complexes described in this work and their synthetic procedure.

Fig. 1 **Cu1-CH₂Cl₂** single crystal structure. (a) ORTEP drawing with atom numbering (elipsoids at 50%). (b) Unit cell view along the *b* axis. (c) Side view of one molecule. (d) Stacking of four molecules in a column with the shortest intermolecular Cu...Cu distances indicated in green color.

an optical microscope show focal-conic and dendritic defects that are typical of columnar mesophases (Fig. 2a and b).

Control of the mesophase stability and temperatures is achieved by varying the length of the alkoxy chains. A chain with a length of 10 carbon atoms stabilises the mesophase over a wider range of temperatures, *e.g.*, **Cu10** has a higher clearing point and a lower melting point with respect to **Cu14**, which means that the mesophase is stable over a range of 108 °C on heating from 20 °C and remains in the mesophase down to 8 °C in the cooling cycle (Fig. 2c).

XRD patterns of the liquid crystal phase show a rich set of sharp reflections in the small angle region, up to seven for **Cu10**, that are in a ratio of 1:(1/√3):(1/√4):(1/√7):(1/√9):(1/√12):(1/√13) and are indexed to a 2D hexagonal lattice (Table 1 and Fig. 2d). This aspect also indicates a long-range correlation of the 2D arrangement of the columns. In the wide-angle region a broad reflection was observed at a distance of around 4.5 Å. This reflection corresponds to the diffuse halo typical of the liquid crystalline state owing to the fluctuations of the molten chains. All this information allowed us to unambiguously assign the liquid crystal phase to a hexagonal columnar mesophase. In addition to the above, an intense and sharp reflection was observed at 3.6 Å and this indicates a periodicity of the molecules within the columns (intracolumnar order) that extends over quite large distances. A similar behavior was observed for **Cu14** (Fig. S1, ESI†), albeit with larger lattice parameters because of the longer peripheral side chains.

A self-assembly model can be proposed by estimating the number of molecules *Z* in a columnar stratum of thickness *c*. The volume of the columnar stratum of thickness *c* can be calculated from X-ray data to be *V*_{cell} = *c S*_{col}, where *c* = 3.6 Å, is the stacking periodicity, and *S*_{col} is the columnar cross-section

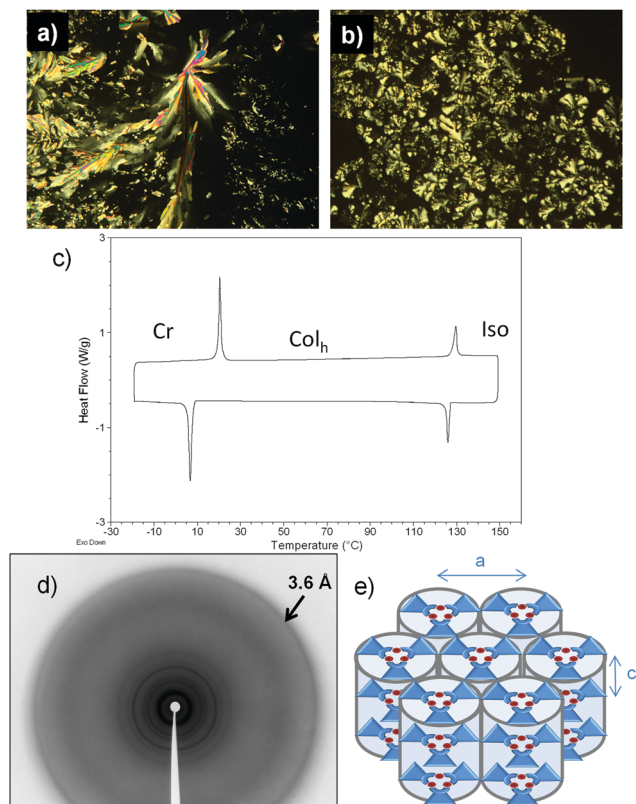

Fig. 2 (a) Microphotograph of the region between crossed polarisers observed for the texture of the Col_h phase of **Cu10** on cooling the isotropic liquid at 126 °C. (b) The same for **Cu14** on cooling the isotropic liquid at 98 °C. (c) DSC thermogram of **Cu10**. (d) XRD patterns of the Col_h phase of **Cu10**. The arrow indicates the halo corresponding to the stacking distance. (e) Self-assembly in the hexagonal columnar mesophase.

of the hexagonal lattice ($S_{\text{col}} = a^2 \sqrt{3}/2$). The Z value is then obtained from the equation $V_{\text{cell}} = Z V_m$, where V_m is the molecular volume. Considering a density of 1 g cm⁻³ in the mesophase, the molecular volume can be calculated as $V_m = M/0.6022$, where M is the molecular weight. From these equations Z values of 1.0 and 1.08 are obtained for **Cu10** and **Cu14**, respectively.

Therefore, both compounds self-assemble into columns that are arranged in a very well-organized 2D hexagonal network with a single molecule stacked along this column (Fig. 2e). In addition, the stacking distance of $c = 3.6$ Å along the column could also be compatible with weak intermolecular cuprophilic interactions, similar to those observed in the single crystal structure of **Cu1**, and this is reflected in the photoluminescence properties (see below).

Photoluminescence properties

The emission properties of the complexes were studied by preparing neat thin films on quartz plates. Both **Cu10** and **Cu14** showed orange-red coloured emissions at room temperature and the photoluminescence spectra exhibited a broad band centred at around 661–664 nm (Fig. 3 and Fig. S2, ESI†). A lifetime of 26–28 microseconds with a monoexponential

Fig. 3 Photoluminescence spectrum in the columnar mesophase for **Cu10** at 25 °C (excitation wavelength 290 nm), and emission of the film observed under irradiation with a 254 nm handheld lamp (overexposed picture, exact color is given by CIE 1931 color space coordinates in Table 2).

decay was measured at room temperature. This fact and a large Stokes shift are consistent with phosphorescence (Table 2 and Fig. S3, S4, ESI†).

It is interesting to note that **Cu10** and **Cu14** show similar behaviour even though the measurements at room temperature were performed in different phases, the liquid crystal state for **Cu10** and the crystal phase for **Cu14**. To further confirm this similarity, photoluminescence spectrum and lifetime were measured at 50 °C for **Cu14**, *i.e.*, a temperature at which the compound is in the same liquid crystal state as **Cu10**. Emission wavelength remained unchanged and only a decrease of the emission intensity as shown in Fig. S5 (ESI†), and a slight decrease of lifetime were observed as consequence of the increased temperature (Fig. S3, ESI†). Decrease of the emission intensity, as shown in Fig. S5 (ESI†) is, of course, not quantitative. As the quantum yield at 50 °C could not be measured, the real effect of temperature in k_{nr} may not be discussed, although data could point to a small increment.

Cu1 also shows similar behaviour to the liquid crystalline compounds in color coordinates and emission maxima, albeit with a bi-exponential decay. The decay experiment allows to calculate the intensity averaged lifetime, and this is slightly shorter than for the liquid crystalline compounds. Quenching processes may be not simple and calculated averaged lifetimes (intensity- or amplitude-) and constant k_r and k_{nr} values must be interpreted with care (Table 2 and Fig. S6, ESI†).^{45,46}

The obtained spectra and lifetimes are consistent with an excimer ³MM centred emission of cofacially arranged molecules described for crystalline Cu CTCs,^{31,32} and in accordance with the self-assembly proposed for the liquid crystal phase and the XRD structure of **Cu1**. Indeed, the emission spectra of isolated molecules (in dilute THF solutions) are quite different, with only one band in the UV-A region at 356–359 nm (Fig. S7, ESI†), which is similar to the emission shown by the 1*H*-pyrazole precursors.³⁷

For compound **Cu10**, the emission measured at 25 °C corresponds to the hexagonal columnar mesophase. Remarkably, a high QY value, 42%, was measured in the liquid crystalline

Standard deviations calculated for **Cu1** (1.9), **Cu10** (0.8), and **Cu14** (0.7). ^e Calculated radiative constant ($k_r = \text{QY}/\tau$) and non-radiative constant ($k_{\text{nr}} = (1 - \text{QY})/\tau$).

state, the highest value reported for a copper metallomesogen, and surpassing the QY values obtained for the scarce number of phosphorescent complexes measured in the liquid crystal phase.⁷ Notably, this value is also higher than the ones obtained for the crystalline states of **Cu14** and **Cu1**.

The high QY of **Cu10** is favoured by a higher radiative constant and a lower non-radiative constant than that of **Cu14**. The radiative constant value is comparable to previously reported ones for copper(i) pyrazolates.³⁶

Conclusions

A novel luminescent copper(i) metallomesogen that shows phosphorescence in the liquid crystalline state with a quantum yield of 42% at room temperature is reported.

3,5-Dimethyl-4-(trialkoxypheyl)pyrazolate ligands enable the arrangement of copper(i) CTCs in a well-organized 2D hexagonal network of columns, in which the molecules are stacked with a high degree of intracolumnar order compatible with weak cuprophilic intermolecular interactions. This supramolecular organization of cofacially assembled molecules at distances of 3.6 Å in the liquid crystal phase is capable of providing the red emission derived from excimer-like ³MM transitions.

Within the copper metallacycles, it is possible to control the mesophase temperature ranges by tuning the terminal chain substitution.

These results show that room temperature bright phosphorescent metallomesogens can be attained using earth-abundant non-precious copper complexes, thus widening the prospects for the application of metallomesogens as efficient emissive materials.
