Vanadium-doped cobalt oxide materials have emerged as a promising class of catalysts for the oxygen evolution reaction. Previous studies suggest vanadium doping in crystalline Co spinel materials tunes the electronic structure and stabilizes surface intermediates. We report a CoV$_2$O$_4$ material that shows good activity for the oxygen evolution reaction. However, postmortem characterization of the catalyst material shows dissolution of vanadium resulting in an amorphous CoO$_x$ material, suggesting that this vanadium-free material, and not CoV$_2$O$_4$, is the active catalyst. This study highlights the importance of postmortem characterization prior to mechanistic and computational analysis for this class of materials.

The sluggish kinetics of the oxygen evolution reaction (OER) hinders the development of practical water-splitting technologies, and has driven the search for efficient OER electrocatalysts comprised of earth-abundant materials that operate with high current densities at low overpotential with long-term operational stability.$^1$–$^4$ V-Doped Co oxide materials have recently emerged as a promising class of alkaline OER catalysts. Previous studies of V-doped Co oxide materials show increased activity for the OER at low overpotentials,$^5$–$^{14}$ and typically suggest that this increased activity is a result of changes to the catalyst’s electronic structure and/or in increased stabilization of adsorbed OER intermediates.$^5$–$^8$

In this study, we report a CoV$_2$O$_4$ material that shows exceptional specific activity per BET surface area for the OER based on as-synthesized characterization data. However, materials characterization conducted after OER electrolysis shows the CoV$_2$O$_4$ precatalyst transforms into a V-free amorphous Co-based material during the OER. This suggests that V ions are not present in the active catalyst material, and rather, CoV$_2$O$_4$ serves as a template for the generation of an active amorphous CoO$_x$ species. Our study highlights the need for careful postmortem characterization of electrocatalytic materials to ensure continued catalyst integrity prior to conducting detailed mechanistic interpretations.

CoV$_2$O$_4$ was prepared by solid state synthesis from CoO and V$_2$O$_5$ metal precursors. A 1:1 molar ratio of CoO and V$_2$O$_5$ was ground and mixed, compressed into a pellet, and heated at 800 °C for 20 h under Ar. Selected characterization parameters of the as-synthesized materials are summarized in Table S2 (ESI†). The powder X-ray diffraction (PXRD) pattern of the as-synthesized CoV$_2$O$_4$ matches that of the CoV$_2$O$_4$ reference with minor contributions from V$_2$O$_5$ impurities as shown in Fig. 1a. Note that V$_2$O$_5$ is not OER active (see Fig. S1, ESI†), so we do not expect trace V$_2$O$_5$ impurities to affect our OER measurements. The sharp diffraction peaks suggest a highly crystalline specimen with a large domain size which might be the product of particle agglomeration due to the high temperatures and long times in the solid-state synthesis preparation. The large grain size is supported both by transmission electron microscopy (TEM) analysis which show particles > 100 nm in size (Fig. 1b) and the catalyst's small surface area of only 0.80 m$^2$ g$^{-1}$ as determined by BET gas adsorption analysis – two orders of magnitude smaller than that of Co$_3$O$_4$ (Table S2, ESI†). Elemental mapping experiments with TEM-energy dispersive X-ray analysis (TEM-EDX) show relatively uniform distribution of Co, V, and O in the as-synthesized material (Fig. 1b).

The as-synthesized CoV$_2$O$_4$ material was further characterized with X-ray photoelectron spectroscopy (XPS). XPS core scans of the as-synthesized CoV$_2$O$_4$ material in the Co 2p, V 2p, and O 1s
regions are shown in Fig. 1d–f, and in the C 1s region in Fig. S2 (ESI†). In the Co 2p spectra of the as-synthesized material (Fig. 1d), two peaks centered at 780.8 and 796.6 eV are assigned to Co 2p3/2 and Co 2p1/2 respectively, and the two shoulder peaks at 785.3 and 802.5 eV suggest the Co is in a CoO-like (Co2+) environment.15 In the V 2p spectra (Fig. 1e), there is a peak at 516.5 eV assigned to V 2p 3/2, which resembles that of reported V2O3 samples and suggests V is in a 3+ oxidation state.16,17 There is a complicated O 1s peak at ~531.5 eV (Fig. 1f) consistent with a mixed species of O on the surface (metal oxide/hydroxide/adsorbed water), but due to the convoluted nature, the peak cannot be used in O or Co oxidation state estimations.18 The Co/V ratio based on XPS analysis was 0.58. This XPS characterization is consistent with other synthesized CoV2O4 materials.5,19

OER activity measurements were performed using previously reported protocols.20,21 Catalyst inks were prepared by mixing the as-synthesized catalyst particles and Nafion in a water–isopropanol solution, and the resulting inks were dropcast onto polished glassy carbon electrode surfaces (0.196 cm2) resulting in films with mass loadings of 0.84 mg cm−2. The putative CoV2O4 catalyst shows promising activity for the OER, operating with increased activity per geometric area compared to the parent Co3O4 as shown in Fig. 2a, and dramatically increased specific activity per BET surface area compared to Co3O4 as shown in Fig. 2b. Activity descriptors for the putative CoV2O4 catalyst compared to other representative OER catalysts are shown in Table S3 (ESI†). The long-term performance stability of the putative CoV2O4 system was confirmed by rapid potential cycling measurements and long-term controlled-current electrolysis experiments (CCE) which showed minimal change in activity over 10,000 cycles and 28 h controlled current measurements (Fig. 2c). The faradaic efficiency for the OER was measured as 90 ± 5% using an in situ O2 probe (Fig. S4, ESI†).

The activity measurements for the putative CoV2O4 catalyst suggest it shows remarkable stability and activity, particularly specific activity per BET surface area, for the OER. Sequential cycles of RDEVs at 1600 rpm of the putative CoV2O4 catalyst in 1 M NaOH are shown in Fig. 2d. In the first cycle, there is a large oxidative feature negative of the OER electrocatalytic onset, and this oxidative feature decreases with subsequent scans before approaching a steady-state peak current after six cycles. RDEVs conducted under identical conditions for V2O3 show a similar oxidative feature in the first cycle that disappears in subsequent cycles (Fig. S5, ESI†), which is consistent with previous studies that show V2O3 dissolves under oxidation when exposed to alkaline conditions.22 Our RDEV studies suggest that the large oxidative feature observed for CoV2O4 is likely due to oxidative dissolution of V, and the steady-state redox feature after six cycles is assigned to the Co2+/3+ redox couple of the resulting CoOx material.23 The stability of the catalytic performance of the putative CoV2O4 suggests that dissolution of V has a minimal effect on the OER activity.

To confirm the postulated V dissolution during our experiments, we conducted a series of postmortem characterization studies on the putative CoV2O4 catalyst. TEM-EDX conducted on a sample after the CCE measurements show a dramatic loss of V consistent with oxidative V dissolution during electrocatalytic studies. Similarly, ICP-MS measurements taken after
an amorphous, V-free CoO$_x$ material. We postulate that the CoV$_2$O$_4$ material undergoes a structural rearrangement under electrocatalytic conditions forming a soluble VO$_x$ phase, possibly V$_2$O$_5$, consistent with the Pourbaix diagram for V.$^{26,27}$ Upon dissolution of VO$_x$, the CoV$_2$O$_4$ lattice collapses resulting in an amorphous CoO$_x$ material that is presumed to be the active species for the OER. This process is qualitatively similar to electrochemical dealloying previously used to make porous battery materials and catalysts.$^{28-33}$ We postulate that the increased observed activity for our catalyst compared to Co$_3$O$_4$ may be due in part to an increased surface area after V-dissolution. Unfortunately, we were not able to harvest sufficient amounts of material post-CCE for BET gas adsorption measurements. Moreover, we do not use electrochemical double-layer capacitance measurements to estimate surface area for OER materials – we believe such measurements are of questionable utility due to the well-documented fallibility of that approach applied to metal oxide catalysts.$^{21,34-37}$ We did estimate average particle sizes based on the TEM images in Fig. 1, and we observe a decrease in the average (and median) particle size post-CCE that is qualitatively consistent with our postulated increase in surface area assuming no loss of material (Table S1, ESI$^†$). However, the measured decrease in average particle size does not account for any changes in porosity or mass-loss from V dissolution that would also influence the overall surface area, and so it is reported here only as a qualitative metric.

Previous studies have reported that V-doped Co oxide materials show higher activity for the OER than their parent oxide materials.$^{5-13}$ In many cases, this observed higher OER activity compared to the V-free parent materials is attributed to specific changes in the physical and/or electronic structure upon V incorporation resulting in changes to material conductivity, adsorption energy of OER intermediates, and/or the rate determining step in the catalytic mechanism. In the case of V-doped amorphous Co$_x$O$_y$ films,$^{7,9}$ crystalline V-doped CoOOH$^6$ and CoFe-based$^{12}$ nanoparticles, and Co-V hydroxide nanostructures,$^{13}$ postmortem characterization shows these materials retain significant concentrations of V after OER stability measurements, consistent with the assertion that the continued presence of V is an important component of the OER mechanism for these materials.$^{7,8,12,13}$

However, in previous studies of crystalline V-doped Co$_{x}$O$_{y}$ based spinel materials, a lack of postmortem characterization introduces ambiguity as to the role of V in the catalytic mechanism. For example, in previous studies of OER by Co$_{x}$V$_{1-x}$Fe$_2$O$_4$ and Co$_3$.V$_x$O$_{4-x}$ nanoparticles, comprehensive mechanistic and computational analysis was conducted with the assumption that V was an important component in the active catalyst species.$^{5,6}$ However, in these studies, either postmortem analysis was not reported to confirm the presence of V in the material after the OER,$^6$ or reported postmortem characterization showing the loss of V during the OER was not considered in the mechanistic analysis.$^5$ Similarly, studies of V-doped CoP materials and Co–Mo–V catalysts both attribute increased catalytic activity to the presence of V in the materials, but did not include postmortem characterization.
CoV2O4 spinel catalyst shows remarkable specific activity based on electrocatalysts for the OER. In our work, we show that a putative possible catalytic mechanisms.

Our findings introduce uncertainty into the formation of amorphous CoO and other reported OER catalysts. However, postmortem characterization to confirm the continued presence of V during the OER. Conducting compositional and stability studies is recommended as a minimum requirement in structural characterization of OER materials after electrocatalytic reviews of best practices for OER measurements.
