The CO<sub>2</sub>-to-CO reduction by carbon monoxide dehydrogenase (CODH) with a [NiFe<sub>4</sub>S<sub>4</sub>] cluster is considered to be the oldest pathway of biological carbon fixation and therefore may have been involved in the origin of life. Although previous studies have investigated CO<sub>2</sub> reduction by Fe and Ni sulfides to identify the prebiotic origin of the [NiFe<sub>4</sub>S<sub>4</sub>] cluster, the reaction mechanism remains largely elusive. Herein, we applied *in situ* electrochemical ATR-FTIR spectroscopy to probe the reaction intermediates of greigite (Fe<sub>3</sub>S<sub>4</sub>) and violarite (FeNi<sub>2</sub>S<sub>4</sub>). Intermediate species assignable to surface-bound CO<sub>2</sub> and formyl groups were found to be stabilized in the presence of Ni, lending insight into its role in enhancing the multistep CO<sub>2</sub> reduction process.

Understanding how carbon dioxide (CO<sub>2</sub>) can be reduced to organic compounds is an important challenge, not only in terms of industrial applications, but also in terms of understanding the chemical processes underlying the biosphere. Of the six known pathways for biological carbon fixation, the Wood-Ljungdahl (W-L) pathway is arguably the simplest due to the absence of autocatalytic cycles and complex multi-carbon compounds.<sup>1</sup> This simplicity, along with its phylogenetic diversity, has led previous studies to suggest the W-L pathway to be the most ancient form of biological carbon fixation which may have been present at the origin of life.<sup>2</sup> Further, the simplicity of the W-L pathway implies that the underlying physicochemical concepts may be more readily applied towards artificial carbon

## *In situ* FTIR study of CO<sub>2</sub> reduction on inorganic analogues of carbon monoxide dehydrogenase†

capture and utilization compared to more complex pathways, such as the Calvin cycle, which is the most widespread carbon fixation pathway in the biosphere today.

Under anaerobic conditions, carbon fixation in the W-L pathway is initiated by the reduction of CO<sub>2</sub> to CO by carbon monoxide dehydrogenase (CODH), which utilizes a highly conserved [NiFe<sub>4</sub>S<sub>4</sub>] cluster as the catalytic site (Scheme 1a).<sup>3</sup> The generated CO can be combined with a methyl group (–CH<sub>3</sub>) to form a thioester, acetyl-CoA, which is a central metabolite of biological carbon metabolism (Scheme 1b).<sup>2,4</sup> The first two-electron reduction of CO<sub>2</sub> is thermodynamically uphill, and therefore, CODH affects the overall efficiency of carbon fixation.<sup>1a,5</sup> Accordingly, although NiFe-CODH is highly sensitive to O<sub>2</sub>, it exhibits superb catalytic properties to generate CO at potentials near the thermodynamic equilibrium with nearly perfect selectivity.<sup>6</sup> The origin of its high catalytic efficiency remains elusive, but it is likely attributable to the mechanisms by which CODH binds and activates CO<sub>2</sub>.<sup>3,7</sup> Namely, previous crystallographic studies have shown that CODH interacts with the CO<sub>2</sub> molecule in a multi-site conformation through both the Ni and Fe atoms within the [NiFe<sub>4</sub>S<sub>4</sub>] cluster (Scheme 1a), where a single Ni center associated with the iron-sulfur cluster specifically coordinates to the carbon atom of the CO<sub>2</sub> molecule.<sup>3</sup>

To identify the prebiotic origin of NiFe-CODH, several research groups have investigated the activity of Fe and Ni

**Scheme 1** (a) The CO<sub>2</sub> molecule interacts with the Ni, Fe, and histidine in the [NiFe<sub>4</sub>S<sub>4</sub>] cluster.<sup>3</sup> (b) The acetogenic W-L pathway converts two molecules of CO<sub>2</sub> into CO and formate, which can be combined to yield the acetyl group of acetyl-CoA.<sup>2b</sup>

sulfides towards CO<sub>2</sub> reduction under hydrothermal conditions.<sup>8</sup> Recently, their electrocatalytic activity has attracted attention, due to their ability to catalyze the formation of C<sub>1</sub> and multi-carbon compounds under conditions similar to deep-sea hydrothermal vents.<sup>9</sup> However, the reaction mechanism remains largely unknown due to the lack of spectroscopic evidence particularly at the conditions where the reactions take place.<sup>10</sup> Herein, we applied *in situ* electrochemical attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy to probe the reaction intermediates of NiFe sulfides during CO<sub>2</sub> reduction. The formation of several surface-bound species was promoted in the presence of Ni, highlighting its possible role in enhancing the multistep CO<sub>2</sub> reduction process.

As inorganic analogues of NiFe-CODH, greigite (Fe<sub>3</sub>S<sub>4</sub>) and violarite (FeNi<sub>2</sub>S<sub>4</sub>), which share the same crystal structure with the space symmetry group *Fd3m* (spinel), were synthesized following the method reported by Roldan *et al.* (ESI†).<sup>9d</sup> Ni-doped Fe sulfides were also synthesized on reduced-graphene oxide (rGO) nanosheets modified with polyaniline (PANI), as the amine groups may interact with NiFe sulfides in a similar way with the histidine coordination environment in the natural enzyme. Hereafter, these samples will be referred to as NiFeS-PANI. All peaks in the XRD patterns of the synthesized greigite and violarite were indexed to Fe<sub>3</sub>S<sub>4</sub> and FeNi<sub>2</sub>S<sub>4</sub>, respectively, while the NiFeS-PANI was found to be a mixture of FeNi<sub>2</sub>S<sub>4</sub>, Fe<sub>3</sub>S<sub>4</sub>, and NiS<sub>2</sub> (Fig. S1, ESI†). Energy-dispersive X-ray spectroscopy (EDX) imaging of NiFeS-PANI indicated that Ni, Fe, and S were uniformly distributed on the surface of polyaniline-coated rGO with a stoichiometric Ni:Fe ratio of 1:3 (Fig. S2–S4, ESI†). The electrostatic interaction of NiFeS with polyaniline was confirmed based on the shift of the IR bands of amine, benzenoid, and quinonoid rings upon the formation of the NiFeS nanoparticles (Fig. S5, ESI†). The interaction of the amine group of polyaniline with NiFeS was also indicated by X-ray photoelectron spectroscopy (XPS) analysis (Fig. S6 and S7, ESI†).

The activity and selectivity of CO<sub>2</sub> reduction on Fe<sub>3</sub>S<sub>4</sub>, FeNi<sub>2</sub>S<sub>4</sub>, and NiFeS-PANI was measured by performing electrolysis for 4 h at different potentials in CO<sub>2</sub>-saturated 0.1 M KHCO<sub>3</sub> at 25 °C (Fig. 1). In this study, all potentials are referenced *versus* the reversible hydrogen electrode (RHE). The selectivity was evaluated based on faradaic efficiency (FE) measurements, which were reproducible across three independent sets of experiments (Fig. S8–S13, ESI†).

In the case of Fe<sub>3</sub>S<sub>4</sub>, hydrogen was the dominant product, and essentially no CO<sub>2</sub> reduction products were detected at all examined potentials (Fig. 1, grey bars: FEs for CO and HCOOH at –1.0 V are 0.05% and 0.014%, respectively). This finding is consistent with previous experiments showing the negligible activity of iron sulfides (FeS and Fe<sub>3</sub>S<sub>4</sub>) towards CO<sub>2</sub> reduction.<sup>9a,b</sup> However, upon doping Ni into Fe<sub>3</sub>S<sub>4</sub> (Fig. 1, red bars), CO was generated as a major product between –0.4 and –1.0 V, and further reduced products such as CH<sub>4</sub> and C<sub>2</sub>H<sub>6</sub> were also observed below –0.7 V. <sup>13</sup>CO was detected when electrolysis was conducted in <sup>13</sup>CO<sub>2</sub>-saturated 0.1 M KH<sup>12</sup>CO<sub>3</sub>, confirming that CO<sub>2</sub> is the substrate for CO production (Fig. S14, ESI†). Introducing PANI into Ni-doped Fe sulfides further increased the CO<sub>2</sub> reduction activity, in terms of

Fig. 1 Performance and analysis of the CO<sub>2</sub> electroreduction products for Fe<sub>3</sub>S<sub>4</sub>, FeNi<sub>2</sub>S<sub>4</sub>, and NiFeS-PANI nanostructures after 4 h of constant potential electrolysis. Calculated FEs are shown for the detected products at each potential. Error bars correspond to the standard error of the mean for at least three independent experiments. FE measurements for Fe<sub>3</sub>S<sub>4</sub> were performed at –0.4, –0.7, and –1.0 V.

both selectivity and overpotential. Namely, NiFeS-PANI reduced CO<sub>2</sub> to CO from –0.35 V, which corresponds to an overpotential of approximately 250 mV (Fig. 1, blue bars). By applying a more negative potential, the FE for CO production increased to 30% at –0.8 V. The increase in selectivity may be due to the interaction of the PANI amine groups with CO<sub>2</sub>, as well as the enhanced hydrophobicity.<sup>9a,11</sup> The partial current density of all products showed essentially the same potential dependence with the FE (Fig. S15–S17, ESI†). The time course of FEs and product concentrations are shown in Fig. S18 and S19 (ESI†). No liquid products other than formic acid were detected at a concentration higher than 0.1 mM in our experimental conditions.

To determine the mechanism by which Ni doping increases the efficiency of CO<sub>2</sub> reduction on Fe sulfides, electrochemical ATR-FTIR spectroscopy was performed under *in situ* conditions with the catalysts coated on a single internal reflection prism (Ge) as the working electrode. The ATR-IR spectra were collected under the same conditions used for the aforementioned electrochemical CO<sub>2</sub> reduction experiments (Fig. 1), except that H<sub>2</sub>O was replaced with D<sub>2</sub>O. The use of D<sub>2</sub>O enables a high signal-to-noise measurement in the spectral region from 1500 to 1700 cm<sup>–1</sup>, where CO<sub>2</sub> related species such as adsorbed CO<sub>2</sub> and HCO<sub>3</sub><sup>–</sup>, exhibit vibrational bands.<sup>12</sup> The ATR-FTIR spectra of Fe<sub>3</sub>S<sub>4</sub>, FeNi<sub>2</sub>S<sub>4</sub>, and NiFeS-PANI measured in CO<sub>2</sub>-saturated KDCO<sub>3</sub> (0.1 M) are shown in Fig. 2. All three samples exhibited IR bands at 1363 cm<sup>–1</sup> at potentials more negative than 0 V. This can be explained by the conversion of DCO<sub>3</sub><sup>–</sup> to CO<sub>3</sub><sup>2–</sup>, considering that the pD at the electrode surface increases when cathodic reactions such as hydrogen evolution and/or CO<sub>2</sub> reduction are occurring (pK<sub>a</sub> of CO<sub>3</sub><sup>2–</sup>/HCO<sub>3</sub><sup>–</sup> is 10.5). The increase of local pD is consistent with the higher FE of CO relative to HCOOH at more negative potentials (Fig. 1).<sup>13</sup> In control experiments using Ar-saturated KDCO<sub>3</sub>, no change in the IR bands of DCO<sub>3</sub><sup>–</sup> and CO<sub>3</sub><sup>2–</sup> were observed (Fig. S20, ESI†).

Upon further inspection of the IR spectra, a new band at 1625 cm<sup>–1</sup> was observed upon the addition of Ni into Fe<sub>3</sub>S<sub>4</sub> (Fig. 3a, black and red lines). Although this band was visible

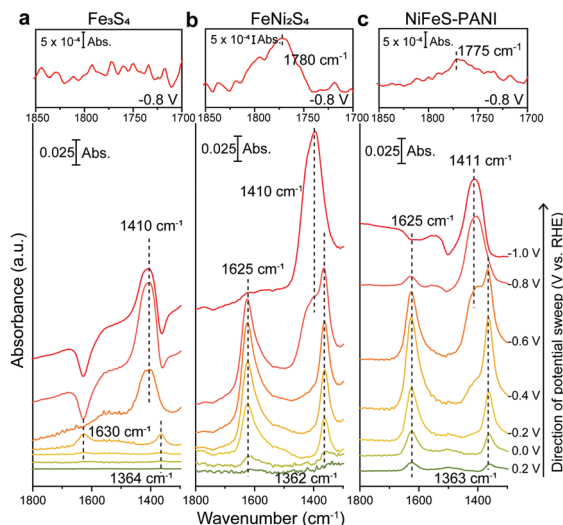

Fig. 2 *In situ* ATR-FTIR spectra of (a)  $\text{Fe}_3\text{S}_4$ , (b)  $\text{FeNi}_2\text{S}_4$ , and (c)  $\text{NiFeS-PANI}$  were recorded during electrochemical  $\text{CO}_2\text{RR}$  in  $\text{CO}_2$ -saturated 0.1 M  $\text{KDCO}_3$ . The insets in the upper panel of (a–c) show magnification of the 1700–1850  $\text{cm}^{-1}$  region at  $-0.8$  V vs. RHE were used as the reference.

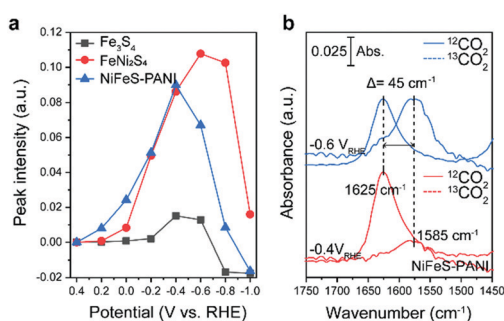

Fig. 3 Analysis of the chemical species observed at  $1625\text{ cm}^{-1}$ . (a) The potential dependence of the absorption intensity at  $1625\text{ cm}^{-1}$  relative to the baseline absorption value taken at  $1700\text{ cm}^{-1}$ . Adding Ni and PANI enhanced the formation of this species. (b) *In situ* ATR-FTIR spectra of  $\text{NiFeS-PANI}$ . An isotope shift of the species with  $^{13}\text{C}$ -labeled  $\text{CO}_2$  at  $1625\text{ cm}^{-1}$  was observed at  $-0.4$  and  $-0.6$  V vs. RHE.

even in the case of  $\text{Fe}_3\text{S}_4$  at  $-0.4$  V, the intensity was an order of magnitude lower and also appeared across a smaller potential range. This band was also observed on  $\text{NiFeS-PANI}$  and exhibited a similar potential dependence (Fig. 3a, blue lines). Furthermore, exchanging  $^{12}\text{CO}_2$  with  $^{13}\text{C}$ -labeled  $\text{CO}_2$  resulted in a clear isotopic shift from  $1625$  to  $1580\text{ cm}^{-1}$  on both  $\text{FeNi}_2\text{S}_4$  and  $\text{NiFeS-PANI}$  (Fig. 3b and Fig. S21, ESI<sup>†</sup>). Therefore, the band at  $1625\text{ cm}^{-1}$  is attributable to a reaction intermediate derived from the  $\text{CO}_2$  molecule.<sup>7a,12,14</sup>

The observed spectral position and isotopic shift value of  $45\text{ cm}^{-1}$  are consistent with the asymmetric vibration of metal-associated  $\text{CO}_2$ .<sup>7a,14,15</sup> Considering that the intensity of the  $1625\text{ cm}^{-1}$  band was largely increased upon Ni doping, a possible assignment to this species is adsorbed  $\text{CO}_2$  on the doped Ni site. Although bicarbonate also shows a vibrational band at a similar wavenumber,<sup>16</sup> the intensity of the  $1625\text{ cm}^{-1}$

band is independent of the bicarbonate bands at  $1362$  and  $1410\text{ cm}^{-1}$ , indicating that this band is not due to bicarbonate. The absence of the  $1625\text{ cm}^{-1}$  band in the case of  $\text{Fe}_3\text{S}_4$ , despite clearly observable bicarbonate peaks, also supports that the  $1625\text{ cm}^{-1}$  band is not due to bicarbonate.

In addition to the IR band at  $1625\text{ cm}^{-1}$ , another potential-dependent IR band was detected at  $1780\text{ cm}^{-1}$  (inset of Fig. 2b and c). The formation of this band becomes evident at potentials more negative than  $-0.8$  V and showed a clear isotopic shift to  $1763\text{ cm}^{-1}$  upon exchanging  $^{12}\text{CO}_2$  with  $^{13}\text{CO}_2$  (Fig. S22, ESI<sup>†</sup>). This band is absent for Fe sulfide without Ni doping (inset of Fig. 2a). The observed band is located in the spectral region of the C=O stretching of carbonyl, and close to that of surface-bound formyl, CHO, formed by electrochemical  $\text{CO}_2$  reduction.<sup>13,17</sup> The possibility of assigning the band to the C=O stretching of HCOOH can be ruled out because the deprotonated form is expected to become dominant under the reaction condition ( $\text{p}K_a$  of  $\text{HCOO}^-/\text{HCOOH}$  is 3.74).

Based on the electrochemical analysis and *in situ* ATR-FTIR observations, we propose a multistep reaction depicted in Fig. 4 as a possible mechanism for  $\text{CO}_2$  reduction on the surface of Ni-doped Fe sulfide. As seen from the evolution of the  $1625\text{ cm}^{-1}$  band from  $+0.4$  V, a surface-bound  $\text{CO}_2$  species forms on Ni-doped Fe sulfide prior to the initiation of  $\text{CO}_2$  reduction. The coverage of this species increases upon scanning the potential negatively, likely due to the enhanced nucleophilicity of the Ni site to coordinate to the carbon atom of  $\text{CO}_2$ . The Fe site may act as an electrophilic center to interact with the oxygen atom of  $\text{CO}_2$ .<sup>7a,18</sup> The role of the Ni center to facilitate  $\text{CO}_2$  adsorption is consistent with recent DFT calculations by Posada-Pérez *et al.*,<sup>19</sup> where the weak interaction of  $\text{Fe}_3\text{S}_4$  with  $\text{CO}_2$  was attributed to the repulsion between the lone pair electrons of the oxygen atoms within the  $\text{CO}_2$  molecule and the spatially extended electronic clouds of the surface sulfur atoms.<sup>19</sup> Posada-Pérez *et al.* also demonstrated that the partial substitution of Fe atoms by Ni strengthens the  $\text{CO}_2$  binding on Fe sulfides.<sup>19</sup> Upon further scanning the potential negatively, the surface-bound  $\text{CO}_2$  species are reduced to CO, which is accompanied with the formation of a surface-bound formyl species (H-C=O). This species has been proposed as an intermediate to facilitate the downstream reaction of CO to form  $\text{CH}_4$  and  $\text{C}_2\text{H}_6$  compounds.<sup>13,17a,20</sup> As a support for this hypothesis, when electrolysis was conducted in a CO saturated solution,  $\text{CH}_4$  and  $\text{C}_2\text{H}_6$  productions were confirmed (Fig. S23, ESI<sup>†</sup>). Thus, the potential dependent formation of the carbonyl species, together with the concomitant production of  $\text{CH}_4$  and  $\text{C}_2\text{H}_6$ , suggests that surface-bound formyl species plays a role in facilitating the multi-electron reduction of CO on Ni-doped Fe sulfide.

Fig. 4 Proposed pathway for electrochemical  $\text{CO}_2$  reduction to CO, HCOOH,  $\text{CH}_4$ , and  $\text{C}_2\text{H}_6$  on Ni-doped Fe sulfide.

In summary, we have identified the role of Ni during the electrochemical reduction of CO<sub>2</sub> to CO by Fe sulfides. Ni enhances the formation of an intermediate assignable to surface-bound CO<sub>2</sub>, which leads to a substantial increase in the electrochemical selectivity. This intermediate is further reduced to surface-bound formyl species, which leads to products such as CH<sub>4</sub> and C<sub>2</sub>H<sub>6</sub>. Recent studies have intensively argued the possibility that CO formation by NiFe-CODH is the oldest pathway of biological carbon fixation and was therefore involved in the origin of life.<sup>8a,b,9a-c,21</sup> In this scenario, the reduction of CO<sub>2</sub> to CO is proposed to proceed on the surfaces of metal sulfide minerals, either electrochemically<sup>15-17</sup> using geochemically generated pH and temperature gradients as the driving force<sup>21,22</sup> or hydrothermally, using H<sub>2</sub> or metals as the electron source.<sup>8b</sup> Several Ni-containing Fe sulfides, such as violarite (FeNi<sub>2</sub>S<sub>4</sub>),<sup>9a</sup> pentlandite (Fe<sub>4.5</sub>Ni<sub>4.5</sub>S<sub>8</sub>),<sup>9c</sup> and awaruite (Ni<sub>3</sub>Fe),<sup>8b</sup> have been tested as possible prebiotic catalysts, but there is a lack of understanding of how CO<sub>2</sub> can be converted to CO and multi-carbon compounds. The present study is the first to provide molecular level insight into the origin of the marked increase in CO<sub>2</sub> reduction activity on iron sulfides by Ni doping. This will not only promote the development of biomimetic catalysts, but also yield a clue to identify prebiotic carbon fixation reactions.
