A monomeric methyllithium complex: synthesis and structure†‡

Nathan Davison,§ Emanuele Falbo, ‡§ Paul G. Waddell, Thomas J. Penfold and Erli Lu *

Methyllithium (MeLi) is the parent archetypal organolithium complex. MeLi exists as aggregates in solutions and solid states. Monomeric MeLi is postulated as a highly reactive intermediate and plays a vital role in understanding MeLi-mediated reactions but has not been isolated. Herein, we report the synthesis and structure of the first monomeric MeLi complex formed by a new hexadentate neutral amine ligand.

Since the pioneering work by Wilhelm Schlenk and Joanna Holtz in 1917,1 organolithium complexes (RLi; R= alkyl, aryl, alkenyl, and alkynyl) have enabled numerous organic, inorganic, organometallic and polymerization reactions, acting as the cornerstone of organometallic chemistry,2–5 and are still an active research frontier.6 RLi complexes exist as aggregates in solutions and solid states.7–11 On the one hand, these aggregates stabilise the highly polar and reactive Li–C bonds; but in general, these aggregates also deactivate the RLi reagents.12 Breaking the aggregates into the corresponding RLi monomer is postulated as the key step in RLi-mediated reactions.7 Therefore, the synthesis and structural studies of RLi monomers are of crucial importance to understand the mechanism of these RLi-mediated reactions and are hence germane to physical organic and organometallic communities.

To break RLi aggregates, Lewis basic ligands, such as amines and ethers, are necessary.8 Ligand-supported RLi monomers have been pursued by coordination chemists for decades, but there is still a significant knowledge gap. All such reported isolable RLi monomers are stabilised by sterically bulky alkyls (R), i.e. \(-\text{CH}_2\text{SiMe}_3\),12 \(-\text{CH}(_2\text{SiMe}_3)_3\),13,16 tert-butyl,14,15 sec-butyl16 and isopropyl,17 electronically delocalised aryls18–21/benzyls,22 or heteroatom-substituted alkyls.23 Methyllithium (MeLi) is the parent archetypal member of the RLi family,1,24,25 which has been widely used as a methyl synthon, a nucleophilic reagent and a strong Brønsted base.26 However, to the best of our knowledge, an isolable ligand-supported MeLi monomer is unknown.

Though a ligand-free MeLi monomer has been observed in an inert gas matrix27 or as a short-lived species in sub-millimeter spectroscopy,28 all previous attempts to synthesize ligand-supported MeLi monomers resulted in dimers. For instance, the \(N,N,N',N'\)-pentamethyldiethylenetriamine (PMDTA) and \((R,R)-N,N',N',N'-\text{tetramethyl}-1,2\text{-diaminocyclohexane}\) \([[(R,R)\text{-TMCD}A]\] supported MeLi dimers were reported by Strohmann and co-workers in 200729 and 2020,29 respectively (Chart 1a and b). The state-of-the-art bi- and tri-dentate ligands, such as \((R,R)\text{-TMCD}A\) and PMDTA, which though working for bulkier alkyls (e.g. tert-butyl), are proven to be insufficient to stabilize the MeLi monomer against dimerization. In this work, with a bespoke hexadentate ligand, \(N,N',N'-\text{tris}(2\text{-N-diethylaminoethyl})-1,4,7\text{-triAzacycloNonane}\) (DETAN) (1), we report the first isolable monomeric MeLi complex \([\text{Li(CH}_3\text{)}(k^1-N,N',N'-\text{DETAN})]_2\) (Chart 1c).

The DETAN ligand 1 is designed and synthesized (Scheme 1) by combining a rigid macrocyclic backbone and three flexible pendant arms. Meanwhile, 1 is composed of only inert C–H, C–C and N–C bonds to avoid ligand lihintion.30,31 These features are essential to stabilize highly reactive species such as the MeLi monomer. The following reaction between 1 and MeLi requires a careful design. For example, cyclic ethers such as tetrahydrofuran (THF) must be avoided due to their liability of C–H activation and ring-opening decomposition with allyllithium reagents.32,33 Gratifyingly, a 1:1 reaction between 1 and MeLi (1.6 M in \(\text{Et}_2\text{O}\)) in hexane/\(\text{Et}_2\text{O}\) (20/1) mixed solvents at lower temperatures (–80 to –30 °C) produced the desired MeLi monomer \([\text{Li(CH}_3\text{)}(k^1-N,N',N'-\text{DETAN})]_2\) (2) as colourless crystals in 25% yield (Scheme 1). Complex 2 is stable as colourless crystals under –20 °C for several days but decomposes at room temperature within 15 minutes, possibly via the \(\alpha\)- or \(\beta\)-deprotonation of the DETAN ligand (similar to the
PMDTA/TMCDA ligands). Once crystallized, complex 2 is insoluble in aliphatic solvents and decomposes in ethereal and aromatic solvents, e.g. THF and toluene, at -20 °C. The instability prevents us from obtaining reliable NMR spectra and CHN elemental analysis data. It is noteworthy that similar experimental challenges were reported in the PMDTA-supported MeLi dimer, [(R,R)-TMCDA]-supported 'PrLi dimer and 'BuLi monomer.

The instability of 2 was rationalised by a room temperature reaction between 1 and MeLi (Scheme 1). Instead of 2 from the low-temperature reaction, a complex mixture was obtained, among which N,N-diethyl ethenamine (3) and 1 can be identified using the 1H NMR spectrum (Fig. S3, ESI†). It should be noted that the mixture is heterogeneous, containing a minor amount of white solid insoluble in d6-benzene, which is possibly a mixture of [MeLi]n and other decomposition products. At least two decomposing pathways can be postulated: (1) C–H and N–C cleavages to produce 3 and (2) de-coordination to produce [MeLi]n and 1 (Fig. S3, ESI†). Similar ligand C–H and N–C cleavages were reported in a tBuLi monomer and a scandium imido complex but not in the MeLi dimers. In general, MeLi was considered to be less reactive than tBuLi and nBuLi. However, the facile decomposition of 2 suggests that the MeLi reactivity is enhanced by forming a monomer.

The solid state structure of complex 2 is elucidated by single-crystal X-ray diffraction (SCXRD), which confirms its monomeric nature (Fig. 1). Complex 2 crystallises in the trigonal P3 space group with the Li1–C1 bond orientated along a three-fold axis such that only one-third of the molecule is crystallographically independent. The most salient structural feature of 2 is the monomeric MeLi unit. Unlike the higher MeLi aggregates, there are no intermolecular Me–Li interactions in 2. In fact, the intermolecular interactions in the solid state packing structure of 2 are dominated by van der Waals
and dispersion forces without observable hydrogen bonds or Me···Li interactions. The methyl group is terminally coordinated to the Li centre, which is at the short end of all reported Li–C bond lengths. The Li1–C1 bond in 2 is at the short end of all reported Li–C bond lengths.\(^a,\)\(^{37}\) It is much shorter than the Li–C\(^{Bu}\) bonds in the previous MeLi dimers (2.18–2.28 Å),\(^{16,29}\) reflecting the monomeric nature of 2, and is slightly shorter than the Li–C\(^{Bu}\) bond (2.114(4) Å) in a [Li(Bu)\((\text{--})\text{sparteine}\)] monomer.\(^{14}\) The Li1–C1 bond length in 2 is only superseded by the [Li(Bu)\((R,R-\text{TMCDA})\)] monomer (Li–C\(^{Bu}\) = 2.064(15) Å), which is likely a result of the relatively small \((R,R-\text{TMCDA})\) ligand.\(^{18}\) Besides the methyl group, the Li centre is coordinated by three neutral nitrogen atoms (N1A) in the macrocyclic ring via the Li ← N\(^{RING}\) dative bonds (2.106(4) Å), forming a Li-centred tetrahedral geometry. The macroyclic backbone provides the essential structural rigidity to support the monomeric MeLi unit by forming a protected cavity. This is clearly illustrated by the space-filling model (top-view and side-view along the Li1–C1 bond) of complex 2 (Fig. 1b and c). In comparison, the N\(^{X}\)/N\(^{N}\)-trimethyl-1,3,5-triazacyclononane (Me\(^3\)TACN) ligand, which bears a similar macrocyclic TACN backbone but does not have the pendant arms, was reported to form a tert-butyllithium trimer \([\text{[BuLi]}_3\text{[Me}^3\text{TACN]}]\).\(^{38}\)

Figure optimisations using density functional theory (DFT) calculations within the approximation of the \(\omega\)B97x-D\(^3\) exchange and correlation functional and a def2-TZVP\(^{10}\) basis set were conducted to gain structural insights into the MeLi monomer 2. The bond lengths and angles obtained compared well to those obtained using SCXRD (Fig. S5, ESI\(^\text{t}^\)).\(^{42–44}\) However, atoms-in-molecule (AIM) analysis gives a Li and C Me atomic charges of +0.451, while the C Me atomic charge is +0.854 and −0.400, respectively (Table S4, ESI\(^\text{t}^\)).\(^{40,51}\) Caution must be taken when interpreting the bonding character using atomic charge values alone: as shown, different methods can give rise to very different values.\(^{42}\) Thus, orbital and topology analyses are conducted to gain an overview of the Li–C bonding picture.

Natural population analysis (NPA) (\(\omega\)B97x-D\(^3\)/def2-TZVP\(^{10}\)) gives a Li atomic charge of +0.451, while the C Me atomic charge is −1.313. The Li NPA atomic charge of +0.451 may suggest some Li–C bond covalency,\(^{42–44}\) however, atoms-in-molecule (AIM) analysis gives a Li and C Me atomic charges of +0.854 and −0.400, respectively (Table S4, ESI\(^\text{t}^\)). The percentage of atomic orbital (AOs) contribution to the HOMO was computed through the NBO analysis.

The Kohn–Sham highest occupied molecular orbital (HOMO) of complex 2 at the \(\omega\)B97x-D3\(^{38}\)/def2-TZVP\(^{37}\) level of theory. MO isovalue = 0.03. The percentage of atomic orbital (AOs) contribution to the HOMO was computed through the NBO analysis.

Possible interactions between ‘filled’ Lewis-type NBOs (donors) and ‘empty’ non-Lewis NBOs (acceptors) and estimating their energetic significance using the 2nd-order perturbation theory. It was found that the lone pair anti-bonding (LP\(^*\)) of the Li atom and the lone pair (LP) of C Me give the strongest stabilisation energy in 2 (78.87 kcal mol\(^{−1}\)), compared to much weaker N → Li dative interactions (11.97 kcal mol\(^{−1}\)). These results clearly suggest that the Li–C\(^{Me}\) bond in 2 is not purely ionic (electrostatic) in nature but with non-negligible orbital overlapping and substantial electron density sharing.

Despite the NBO analysis suggesting evidence for Li–C covalency, to address the discrepancy between the NPA and AIM atomic charge calculations, we conducted quantum theory of atoms in molecules (QTAIM) and electron localisation function (ELF) analyses. Both of these analyses were conducted with the electron density obtained from DFT (\(\omega\)B97x-D3\(^{38}\)). The combination of QTAIM and ELF methods has been successfully used to address the bonding covalency/ionicity problem.\(^{50,51}\)

For 2, the QTAIM\(^{52}\) analysis returned a Li–C bond critical point (BCP) closer to the Li atom than to the C Me atom (Fig. 3a), with the electron density \((\rho)\) and Laplacian \((\nabla^2\rho)\) values (a.u.) at BCPs of 0.034 and 0.134, respectively. The values of 0.036 \((\rho)\) and 0.202 \((\nabla^2\rho)\) for the Li–CH\(_3\) bonds were obtained from the QTAIM analysis. This demonstrates that Li–Me bonds are not purely ionic interactions, but with substantial electron density sharing. The QTAIM\(^{52}\) analysis returned a Li–C bond critical point (BCP) closer to the Li atom than to the C Me atom (Fig. 3a), with the electron density \((\rho)\) and Laplacian \((\nabla^2\rho)\) values (a.u.) at BCPs of 0.034 and 0.134, respectively. The values of 0.036 \((\rho)\) and 0.202 \((\nabla^2\rho)\) for the Li–CH\(_3\) bonds were obtained from
coupled cluster single-double (CCSD) calculations. These values, in agreement with the AIM atomic charge values, suggest a highly ionic Li-C bond. To corroborate the relevance between the QTAIM and the Li–C bonding, we were able to isolate the parent organolithium, methylithium, in its monomeric form. The QTAIM-supported MeLi monomer, [Li(CH3)(C2N2N2N2=N2-DETA)] (2), features a short terminal Li–C bond (2.099(5) Å), which was found to be predominantly ionic and polarised but with a non-negligible orbital overlap-driven covalency. Further reactivity studies of 2, as well as those on its heavier group 1 metal congeners, are underway.

N. D. and E. L. thank Professor Andrew C. Bennistron and Dr Keith Ixod (both are from Newcastle University) for their support in laboratory infrastructure. The authors thank Professor Yaofeng Chen (Shanghai Institute of Organic Chemistry-Chinese Academy of Sciences) and Professor Stephen T. Liddle (University of Manchester) for their insightful discussions. E. L. acknowledges the Newcastle University Academic Track (NUaCT) Fellowship and The Royal Society of Chemistry Research Enablement Grants (E20-5153) for financial support. T. J. P. thanks the EPSRC for funding (EP/R021503/1). The authors thank the Faculty of Science, Agriculture and Engineering (SAGe) Mass Spectrometry Facility at Newcastle University for the mass spectroscopy service.
