π-Topology and ultrafast excited-state dynamics of remarkably photochemically stabilized pentacene derivatives with radical substituents

Building blocks depict the photochemical stability: π-topologically different Pn derivatives with both π-radical- and TIPS-substituents are synthesized, which showed remarkably improved photochemical stability (at least 10^2 times higher than that of TIPS-Pn). Ultrafast intersystem crossing within sub-pico second for the purely organic compounds is realized without heavy atoms by effective π-conjugation. The relationship between π-topology and the photochemical stability is also discussed based on the excited-state dynamics. A synergetic effect exists between the radical photo-stabilization and TIPS electronic-stabilization.

The paper discusses the photochemical stability of pentacene derivatives with both \( \pi \)-radical- and TIPS-substituents (1m and 1p) and their photochemical properties and excited-state dynamics. The pentacene-radical-linked systems 1m (1p) showed a remarkable improvement in photochemical stability, which was 187 (139) times higher than that of 6,13-bis(trisopropylsilyl-ethynyl)pentacene. Transient absorption spectroscopy showed that this remarkable photostabilization is due to the ultrafast intersystem crossing induced by effective \( \pi \)-conjugation between the radical substituent and pentacene moiety. The relationship between \( \pi \)-topology and the photochemical stability is also discussed based on the excited-state dynamics.

**Introduction**

Pentacene (Pn) derivatives have been intensively studied as promising candidates for organic field-effect transistors (OFETs), organic thin-film transistors (OTFTs), and organic light-emitting diodes (OLEDs) owing to their high hole mobility in the solid state. In addition, it is also a promising spin-current transport material that is useful for spintronics. Improving the photochemical stability of Pn derivatives is an important issue because the Pn framework easily decomposes by reacting with oxygen under ambient light. A typical stabilization methods involves the use of a bulky and/or electron-withdrawing substituent(s) to the Pn moiety. We reported a different strategy for the photochemical stabilization (radical photostabilization) that utilized the unique excited-state spin dynamics induced by the attachment of the \( \pi \)-radical substituent(s) to the Pn moiety. Thus, Pn derivatives with one or two \( \pi \)-radical substituents were significantly more stable against photodegradation because of the enhanced/accelerated intersystem crossing (EISC) of the Pn moiety.

In this study, we report the design and synthesis of new Pn derivatives (1m and 1p in Fig. 1) with both \( \pi \)-radical and TIPS substituents, which have different \( \pi \)-orbital networks (i.e., \( \pi \)-topology). We evaluated their photochemical properties and their excited-state dynamics in the relation to the \( \pi \)-topology. The spin-state ordering and dynamics in the photoexcited states expected according to the spin-density distributions in the pohotoexcited states are also shown in Fig. 1. The \( \pi \)-radical-linked Pn derivatives (1m and 1p) showed remarkable improvement in photochemical stability much over the previous reported radical-linked pentacene derivatives (2, 3, and 4) or TIPS-Pn (Fig. 1). This remarkable photochemical stability has been ascribed to the ultrafast (femtosecond) EISC induced by the effective \( \pi \)-conjugation between the radical substituent and the pentacene moiety owing to the molecular planarity.

**Results and discussion**

1m was synthesized from 6,13-pentacenedione as the starting material, according to the procedures shown in Scheme 1. 5 was synthesized from 6,13-pentacenedione according to the similar procedures described in the literature. 6m was synthesized from 5 by a lithiation reaction with 40% yield and, then, reduced in the dark to 7m under acidic condition with 74% yield. A condensation reaction of 7m with 1,3-diamino-1,3-dimethylurea in a (CH\sub{2}Cl\sub{2})/
methanol mixture afforded 1mpre. Finally, oxidation of 1mpre by Ag2CO3 on Celite (48 wt%) produced 1m as a greenish-blue powder after recrystallization (19% yield). 1p was synthesized using similar procedures. The detailed synthetic procedures for 1m and 1p are described in the ESL.†

To characterize the electronic structures of 1m and 1p, electron spin resonance (ESR) and cyclic voltammetry (CV) measurements were performed. The obtained and simulated ESR spectra of 1m and 1p are shown in Fig. S13 (ESI†), which was adequately characterized as a dimethyloxoverdazyl radical according to their g values and the hyperfine splitting, which are similar to those of the phenyl-dimethyl-substituted oxoverdazyl radical. 20 The cyclic voltammograms (CV) of 1m, 1p, TIPS-Pn, and 4 are shown in Fig. S14 (ESI†). The CV curves of 2 and 313 are not shown here, but their redox potentials are listed in Table 1, and their photochemical stabilities are discussed later. The first oxidation potential of 1m (1p) is 0.332 V (0.322 V), which is close to the middle between TIPS-Pn (0.402 V) and 2 (0.294 V) or 3 (0.298 V). Notably, the oxidation potential of the verdazyl radical overlaps with that of the pentacene moiety. 21 These findings obtained from the CV data show that the electronic states of the pentacene moiety in their ground state are almost unchanged by the attachment of the radical substituent similar to shown already in our previous work. 13 Although the luminescence of 1m and 1p were completely eliminated by the ultrafast EISC shown later, their ground-state properties of the pentacene moiety are not affected by the radical substituent, leading to the application to OFETs, OTFTs, spintronics devices and so forth. It has been actually shown in our preliminary experiment that 1p acts as the efficient hole transport material in the OFETs (not shown). In addition, the luminescent property of the pentacene is expected to recover by a weak acid treatment after making devices, leading to the possible application for OLEDs.

The photochemical stabilities of 1m and 1p were evaluated by comparing them with TIPS-Pn, 2, 3, and 4 in air-saturated CH2Cl2 solution at room temperature (ca. 20 °C) under irradiation with visible light (light power 70 mW; λex = 650 ± 25 nm for 1m, 1p and TIPS-Pn; λex = 600 ± 25 nm for 2, 3, and 4). The setup of the irradiation system is shown in Fig. S18 (ESI†). Fig. 2a-c show the photoradiation-induced time-variations in the steady-state absorption spectra of 1m, 1p, and TIPS-Pn, respectively, in CH2Cl2. Only a 13(17)% decrease in the absorbance was observed for 1m (1p) for 20 h, showing their remarkable photochemical stabilities. In contrast, TIPS-Pn, a well-known commercially available photochemically stable pentacene derivative, showed a significant decay of the ^1π−π* absorption band of the Pn moiety within 2 h. The time variations in the absorption spectra of the other compounds are provided in the ESL.† The ^1π−π* transition of the Pn moiety in 1m (1p) was observed at the peak wavelength of 653.5 nm (658 nm), which was ca. 10.5 (15) nm red-shifted than that for TIPS-Pn. The molar absorption coefficient (ε) of 1m (1p) in CH2Cl2 was determined to be 35600 M⁻¹ cm⁻¹ at 653.5 nm

where, \(\text{Abs}(t)\) refers to the absorbance at time \(t\). In this eqn, the decrease in the absorbance at the excitation wavelength by the photochemical reaction of the Pn moiety was considered. The characteristic time \((t_{\text{dec}})\) for the decomposition of the Pn moiety by the photochemical reaction with the molecular oxygen was determined by the least-squares fitting. In the case of \(1\text{m}\) and \(1\text{p}\), a small amount of impurity (<4%) with a decomposition time comparable to that of TIPS-Pn was present; therefore, their decay profiles were well analyzed using the following eqn;

\[
\text{Abs}(t) = \text{log}_{10} \left\{ 1 + \frac{10^{\text{Abs}(0) - 1}}{10^{t/\tau_{\text{dec}}} - 1} \right\} 
\]

and

\[
\text{Abs}(t) = \text{log}_{10} \left\{ 1 + \frac{\text{Abs}(0) - 1}{10^{t/\tau_{\text{dec}}} - 1} \right\} + \text{log}_{10} \left\{ 1 + \frac{\text{Abs}(0) - \text{Abs}(1(0))}{10^{t/\tau_{\text{dec}}} - 1} \right\}
\]

were 178 ± 6 h and 132 ± 4 h, respectively, which are significantly longer than the decay times of previously reported radical-linked pentacene derivatives \((2, 3, \text{and } 4)\) and TIPS-Pn. The \(t_{\text{dec}}\) values for \(1\text{m}\) and \(1\text{p}\) were 3.03 ± 0.43 and 0.90 ± 0.16 h, respectively, which are comparable to the decay time of TIPS-Pn (0.950 ± 0.015 h), indicating that these belong to non-radical species having both TIPS and Pn moieties, which are likely to be decomposed products of the radical species. The photochemical stabilization data are summarized in Table 1. Overall, the presence of a radical substituent exerts a remarkable photochemical stability for \(1\text{m} (\text{1p})\), which is approximately 187(139), 242(179), and 11.6 (8.6) times higher than that of TIPS-Pn, 2, and biradical 4 (the most photostable radical-linked pentacene derivative reported previously), respectively. In addition, \(1\text{m}\) and \(1\text{p}\) can be easily dissolved in the common organic solvents such as CH2Cl2, because of the TIPS substituent; the calculated dipole moments of \(1\text{m}, 1\text{p},\) and TIPS-Pn are 0.74, 0.68, and 0.10 Debye, respectively.

We reported that intersystem crossing (ISC) in Pn and anthracene derivatives was enhanced/accelerated by introducing \(\pi\)-radical substituent(s), and a similar phenomenon was observed for ultrafast ISC for perylene-3,4,9,10-tetraicarboximide derivatives with radical substituent(s). The excited singlet states \((^1\text{Pn}^*)\) in \(1\text{m}\) and \(1\text{p}\) were expected to be efficiently converted to the excited triplet state \((^3\text{Pn}^*)\) by the EISC. Thus, the enhanced/accelerated ISC mechanism in the Pn moiety from \(^1\text{Pn}^*\) to \(^3\text{Pn}^*\) works in \(1\text{m}\) and \(1\text{p}\), leading to the observed remarkable photochemical stability, because the photochemical reaction of the Pn derivative with oxygen occurs predominantly in \(^1\text{Pn}^*\) states. The enhancement in the photo-stability was much larger than that of \(2, 3, 4,\) and TIPS-Pn. It should be noted that the increase in the number of radical or TIPS substituents leads to an additional effect on the photo-stability, which is “linearly” (or close to linearly) proportional to the number of substituents. Therefore, the significant increase in the photochemical stability of \(1\text{m}\) and \(1\text{p}\) is due to their molecular planarity, which leads to the ultrafast (enhanced) ISC by the effective \(\pi\)-conjugation between the radical substituent and pentacene moiety. The synergetic effect of the radical photostabilization and the electronic effect of the TIPS substituent may also contribute to this enormous photostability.

To confirm the above speculation and gain further insight into the excited-state dynamics, we performed transient absorption (tRA) measurements. The experimental details are described in the ESI† Fig. 3 shows the color maps of the tRA spectra and time courses at the characteristic wavelengths. Typical time courses of the spectra are provided in the ESI†. The transitions at 446 nm and 574 nm in Fig. 3a correspond to the wavelength of the tRA peaks of \(1\text{m}\) at an early stage, which was assigned to the singlet excited state of the Pn moiety \((^1\text{Pn}^*\)\). The peak wavelength of the triplet excited state of the Pn moiety \((^3\text{Pn}^*)\) corresponds to 497 nm, while that of the bleach corresponds to 644 nm (see ESI†). The time-dependent decays of the tRA intensities (\(\Delta\text{Abs}\)) at 446 nm and 574 nm were analyzed using a double exponential function \((\Delta\text{Abs}(t) = C_0 \exp(-t/\tau_0) + \)
C\textsubscript{1} \exp(-t/\tau\textsubscript{S}) + C\textsubscript{2} \exp(-t/\tau\textsubscript{T}), where, \tau\textsubscript{S} and \tau\textsubscript{T} refer to the singlet state and triplet state lifetimes of Pn* moiety, respectively, showing that the trA spectra of \textsuperscript{1}Pn* and \textsuperscript{3}Pn* overlapped. It should be noted that the total spin states of the whole molecule are singlet-doublet, \textsuperscript{2}(\textsuperscript{1}Pn*–R) for \textsuperscript{1}Pn*, and triplet-doublet \textsuperscript{3}(\textsuperscript{1}Pn*–R) and trip-quatert \textsuperscript{4}(\textsuperscript{1}Pn*–R) for \textsuperscript{3}Pn*, respectively. Therefore, \tau\textsubscript{S} and \tau\textsubscript{T} denote the lifetimes of \textsuperscript{1}Pn*–R and \textsuperscript{3}Pn*–R, respectively. The \tau\textsubscript{S} value was estimated from the fit of the trA decay at 574 nm, where the trA of \textsuperscript{1}Pn* was the most dominant (the \tau\textsubscript{S} estimated from the fit of the trA decay at 446 nm was 560 ± 43 fs which was within the experimental error). The recovery of the bleach at 644 nm was used to estimate the average decay time (\langle \tau\textsubscript{p} \rangle) of \textsuperscript{3}Pn* because the process related to \textsuperscript{3}Pn* is slightly complicated, as follows. The trA intensity at 497 nm first decreased, second increased and then decreased, which may suggest the existence of an indirect pathway from \textsuperscript{3}Pn* to \textsuperscript{3}Pn* (see ESI†). This behavior is difficult to fit using a simple double exponential function. The triplet lifetime (\langle \tau\textsubscript{p} \rangle) was roughly estimated from the fit using a triple exponential function (see ESI†), because the indirect pathway from \textsuperscript{1}Pn* to \textsuperscript{3}Pn* is also indicated from the time course of the trA intensity at 501 nm. The obtained lifetimes (\tau\textsubscript{S}, \tau\textsubscript{T}, and \langle \tau\textsubscript{p} \rangle) are listed in Table 2 along with the lifetimes (\tau\textsubscript{S} and \tau\textsubscript{T}) of 2, 3 and TIPS-Pn. The lifetimes of the precursors (\textsuperscript{1}mpre and \textsuperscript{1}ppre) were similar to those of the TIPS-Pn (see ESI†).

The \tau\textsubscript{S} of \textsuperscript{1}m (\textsuperscript{1}p) was ca. 1.8 × 10\textsuperscript{4} (7.0 × 10\textsuperscript{4}) times shorter than that of TIPS-Pn because of the EISC and 35 (140) times shorter than that of 2 due to the effective π-conjugation, as a result of the molecular planarity (the dependency on the radical species was less than 4 times judging from the \tau\textsubscript{S} of \textsuperscript{1}m and \textsuperscript{1}p). The \langle \tau\textsubscript{p} \rangle of \textsuperscript{1}m (\textsuperscript{1}p) was ca. 8.8 × 10\textsuperscript{4} (5.8 × 10\textsuperscript{4}) times shorter than \tau\textsubscript{T} of TIPS-Pn and 17 (11) times shorter than that of 2. On the discussion related to the photochemical stability, \langle \tau\textsubscript{p} \rangle is better than \tau\textsubscript{T}. It is known that the difference in the exchange-couplings between the unpaired electron on the radical and the electrons in half-filled orbitals on the excited chromophore is important in the EISC rather than the magnitude of the exchange-coupling\textsuperscript{26,27} although the effective π-conjugation is expected to be one of the critical factors in EISC of \textsuperscript{1}m and \textsuperscript{1}p. The detailed discussions of the expected mechanism for the ultrafast quenching of the photoexcited states is described in the ESI†. Because the photochemical stability of \textsuperscript{1}m (\textsuperscript{1}p) is 242(179) times higher than that of 2, a synergetic effect between the radical photo-stabilization and TIPS electronic stabilization seems to exist, but the dominant effect is due to the ultrafast EISC owing to the effective π-conjugation. It should be noted that \tau\textsubscript{S} and \langle \tau\textsubscript{p} \rangle of \textsuperscript{1}m are shorter than those of \textsuperscript{1}p, which is consistent with the spin-state ordering of \textsuperscript{2}(\textsuperscript{3}Pn*–R) and \textsuperscript{4}(\textsuperscript{1}Pn*–R). Thus, as shown in Fig. 1b, the expected lowest excited state of \textsuperscript{1}m is \textsuperscript{4}(\textsuperscript{1}Pn*–R) with a low-lying higher energy \textsuperscript{4}(\textsuperscript{3}Pn*–R) state. Therefore, the spin-allowed transition to the ground-state is expected to occur efficiently from \textsuperscript{4}(\textsuperscript{3}Pn*–R). In contrast, the expected lowest excited state of \textsuperscript{1}p is \textsuperscript{4}(\textsuperscript{1}Pn*–R), from which the transitions to the ground state can occur indirectly via the low-lying higher-energy \textsuperscript{2}(\textsuperscript{1}Pn*–R) state. This indicates that the excited-state dynamics can be controlled by π-topology. Notably, the photochemical stability of \textsuperscript{1}m was higher than that of \textsuperscript{1}p, although the \tau\textsubscript{S} of \textsuperscript{1}p was shorter than that of \textsuperscript{1}m. This is understandable as the complete suppression of the reaction pathway via \textsuperscript{1}Pn* is due to the extremely short \tau\textsubscript{S} value for \textsuperscript{1}m and \textsuperscript{1}p, although the dominant decomposition pathway of pentacene is known to occur via \textsuperscript{1}Pn*.\textsuperscript{28} Thus, the remaining effective decomposition pathways occur in \textsuperscript{3}Pn*.

### Conclusions

A remarkable improvement in photochemical stability of \textsuperscript{1}m (\textsuperscript{1}p) was achieved, which was 187 (139), 242 (179), and 11.6 (8.6) times higher than that of TIPS-Pn, 2, and 4, respectively. It is also worthy of notice that the intersystem crossing of the purely organic compounds without heavy atoms is realized in the sub-femtosecond region. The trA spectroscopy clarified that the ultrafast enhanced/accelerated ISC was realized owing to the
effective π-conjugation between the radical and the pentacene moieties. In contrast, no enhanced/accelerated ISC and no photochemical stability improvement were reported for the Pn derivative attached to the TEMPO radical.\textsuperscript{19,29} The strong conjugation of the π-radical with the Pn moiety is essential for the enormous photochemical stabilization of 1m and 1p. In addition, π-topological control of the excited-state dynamics was realized and applied to the enhancement of photochemical stability.
