## An effective potential for Frenkel excitons†

Bartosz Błasiak, \* Wojciech Bartkowiak and Robert W. Góra \*

Excitation energy transfer (EET) is a ubiquitous process in life and materials sciences. Here, a new and computationally efficient method of evaluating the electronic EET couplings between interacting chromophores is introduced that is valid in a wide range of intermolecular distances. The proposed approach is based on the effective elimination of electron repulsion integrals from the excitonic Hamiltonian matrix elements *via* the density-fitting approach and distributed multipole approximation. The excitonic Hamiltonian represented in a basis including charge transfer (CT) states is re-cast in terms of the effective one-electron potential functions (EOPs) and adapted into the effective fragment parameter (EFP) framework. Calculations for model systems indicate that the speedup of at least three orders of magnitude, as compared to the state-of-the-art methods, can be achieved while maintaining the accuracy of the EET couplings even at short intermolecular distances.

### 1 Introduction

Excitation energy transfer (EET) is a nonadiabatic phenomenon governing the nonradiative transfer of excitation energy between two chromophores characterized by overlapping spectral features which enable their resonance coupling. It is of fundamental importance for understanding the early stages of photosynthesis or functioning of light-harvesting complexes in general. Thus EET is of central importance to many branches of materials and life sciences. Its strong dependence on the distance and orientation of the coupled chromophores led to the development of several time-resolved spectroscopic techniques, in particular the single-molecule Förster resonance energy transfer, allowing the determination of the mechanisms of biomolecular processes.<sup>1,2</sup>

Since the EET phenomenon and the theoretical framework for its description were recently reviewed thoroughly,<sup>3–8</sup> here we provide only a brief outline of the recent developments. At large intermolecular distances EET coupling can be adequately described by the Förster model<sup>9</sup> which assumes the purely Coulombic interaction between the transition densities of chromophores, and computationally efficient schemes have been developed over recent years that take into account the spatial extent and shape of transition densities.<sup>10–12</sup> However, an accurate description of EET coupling constants become

more difficult at short intermolecular distances due to wavefunction overlap and exchange interactions.<sup>13–15</sup> A robust description of EET coupling in such cases is provided by the Frenkel exciton model<sup>16</sup> in which the excitons are localized on individual chromophores. Such an approach is quite reliable in the weak-coupling limit<sup>17</sup> and can be extended to account for intermolecular charge transfer states.<sup>18–21</sup>

To accurately account for short-range effects, fragment density approaches (FDAs) were developed,<sup>13,22,23</sup> in which the analysis of the Hamiltonian is performed in the eigenstate basis for the initial and final EET states of interest. In particular, the fragment excitation difference (FED) approach,<sup>13</sup> which is a generalization of the energy splitting in dimer (ESD) method<sup>24</sup> for nonsymmetric systems, provides reasonably accurate values of EET at all physically meaningful intermolecular distances. A different strategy was adopted within the so-called transfer-integral (TI) approach.<sup>24,25</sup> This technique stems from a standard two-state diabatic Landau–Zener model in which the off-diagonal Hamiltonian matrix element, called the transfer integral,<sup>24</sup> couples the initial and final states in a nonadiabatic process of electron or excitation energy transfer. This approach can be generalized to interactions among many-level systems, which introduces the so-called indirect coupling matrix elements *via* intermediate (bridge) states in addition to the direct interaction between initial and final states.<sup>25,26</sup> In the context of electronic EET this approach was proposed by Scholes and Harcourt as the superexchange coupling (SEC) method<sup>26,27</sup> and was recently reintroduced by Fujimoto as the transition-density-fragment interaction transfer-integral (TDFI-TI) model.<sup>28–31</sup>

The main advantage of the TI approach is that the EET coupling can be directly expressed *via* the donor and acceptor transition densities by means of perturbation theory which

† Electronic supplementary information (ESI) available: Diagonal Hamiltonian matrix elements, timings of various variants of TI/CIS EET coupling calculations, discussion of basis set extension effects, and Cartesian coordinates of the studied model systems. See DOI: 10.1039/d0cp04636a

allows time-consuming calculations in the eigenstate space of an entire system to be avoided. Unfortunately, from the perspective of *ab initio* electronic structure calculations all the above techniques require the evaluation of the four-center electron repulsion integrals (ERIs) and excited state properties for a given instantaneous orientation of interacting chromophores. Even though nonadiabatic dynamics simulations of interacting chromophores are nowadays possible due to growing computational power and introduction of efficient computational protocols,<sup>18–20</sup> the time-consuming contractions involving 4-index tensors are still a serious bottleneck which generally prohibits systematic studies of large aggregates.

In this paper we introduce a new efficient method to calculate the electronic EET couplings within the TI approach that is valid in both the long- and short-range regimes and is based on the recently introduced effective one-electron potential (EOP) operators technique to eliminate ERIs from fragment-based models.<sup>32</sup> Although we focus here on the singlet–singlet (SS) EET, extension to the triplet–triplet (TT) EET can be readily achieved from the corresponding TI model.

To test the proposed technique we assume the configuration interaction singles<sup>33</sup> (CIS) wavefunction of interacting molecules. For clarity of demonstration, we consider a simple model case in which only the non-degenerate frontier orbitals of the coupled chromophores are kept active to construct the excitonic Hamiltonian.<sup>26,27</sup> An example of the thus formulated variant of the transfer-integral CIS (TI/CIS) method, proposed by Fujimoto,<sup>31</sup> is a starting point for the introduction of the effective one-electron potential transfer-integral (EOP-TI) approach, which is the main purpose of this paper. Although in a general case more orbitals might be required to describe the bridging composite states in the SEC model, we believe that the application of the EOP method would then be straightforward. In the following sections we outline the relevant theoretical framework and discuss the results obtained for model systems, focusing on the accuracy and efficiency of the introduced approximations. Finally, we show that the proposed EOP-TI method *de facto* introduces a way to construct an effective fragment potential for EET couplings.

## 2 Theoretical methodology

### 2.1 Transfer-integral model of EET coupling

In the simplest version of the TI/CIS approach, the Hamiltonian of an aggregate of molecules A and B is constructed assuming the weak-coupling exciton model approximation involving the following four configurations:

$$|\Phi_1\rangle = |\Psi_A^{(e)} \otimes \Psi_B^{(g)}\rangle, \quad (1a)$$

$$|\Phi_2\rangle = |\Psi_A^{(g)} \otimes \Psi_B^{(e)}\rangle, \quad (1b)$$

$$|\Phi_3\rangle = |\Psi_A^{(+)} \otimes \Psi_B^{(-)}\rangle, \quad (1c)$$

$$|\Phi_4\rangle = |\Psi_A^{(-)} \otimes \Psi_B^{(+)}\rangle, \quad (1d)$$

where superscripts g and e denote the ground and excited states of a molecule, and ‘+’ and ‘–’ label the cationic and anionic states, respectively, whereas

$$|\Psi_X \otimes \Psi_Y\rangle \equiv \mathcal{A}\{|\Psi_X\rangle \otimes |\Psi_Y\rangle\} \quad (2)$$

denotes the antisymmetrized Hartree product of the monomer wavefunctions with  $\mathcal{A}$  being the standard antisymmetrization operator and ‘ $\otimes$ ’ denoting the outer product. Instead of diagonalizing the excitonic Hamiltonian in such a basis, one may adopt the perturbation theory to obtain the approximate expression for the EET coupling constant:<sup>26,31</sup>

$$V \approx \langle \Phi_1 | \mathcal{H} | \Phi_2 \rangle - \sum_{n=3,4} \frac{\langle \Phi_1 | \mathcal{H} | \Phi_n \rangle \langle \Phi_n | \mathcal{H} | \Phi_2 \rangle}{E_n - E_1} + \sum_{m,n=3,4} \frac{\langle \Phi_1 | \mathcal{H} | \Phi_m \rangle \langle \Phi_m | \mathcal{H} | \Phi_n \rangle \langle \Phi_n | \mathcal{H} | \Phi_2 \rangle}{(E_m - E_1)(E_n - E_1)}, \quad (3)$$

where  $E_n \equiv \langle \Phi_n | \mathcal{H} - E_0 | \Phi_n \rangle$  and  $E_0$  is the ground state energy of the aggregate. The first two site energies are given by<sup>31</sup>

$$E_1 \equiv \langle \Phi_1 | \mathcal{H} - E_0 | \Phi_1 \rangle = E_{e \rightarrow g}^A + \Delta E_{e \rightarrow g}^A(B), \quad (4a)$$

$$E_2 \equiv \langle \Phi_2 | \mathcal{H} - E_0 | \Phi_2 \rangle = E_{e \rightarrow g}^B + \Delta E_{e \rightarrow g}^B(A), \quad (4b)$$

where  $E_{e \rightarrow g}^X$  is the excitation energy of isolated molecule X and  $\Delta E_{e \rightarrow g}^X(Y)$  accounts for the mean-field environmental effect due to the other molecule, which is given by

$$\Delta E_{e \rightarrow g}^X(Y) \cong \int [\rho_{\text{el},(e)}^X(\mathbf{r}) - \rho_{\text{el},(g)}^X(\mathbf{r})] v^{\text{eff},Y}(\mathbf{r}) d\mathbf{r} \quad (5)$$

with the effective one-electron potential given by

$$v^{\text{eff},Y}(\mathbf{r}_1) \equiv v_{\text{nuc}}^Y(\mathbf{r}_1) + \sum_{ij}^{\text{Occ}} \int d\mathbf{r}_2 \times \left\{ \frac{\phi_i^*(\mathbf{r}_1) \phi_i(\mathbf{r}_1) \phi_j^*(\mathbf{r}_2) \phi_j(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} - \frac{1}{2} \frac{\phi_i^*(\mathbf{r}_1) \phi_j(\mathbf{r}_1) \phi_j^*(\mathbf{r}_2) \phi_i(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} \right\}. \quad (6)$$

If basis functions 3 and 4 are approximated as the HOMO and LUMO of monomers (*i.e.*, the frontier orbital approximation), the remaining two site energies are given by

$$E_3 \equiv \langle \Phi_3 | \mathcal{H} - E_0 | \Phi_3 \rangle \approx -\varepsilon_H^A + \varepsilon_L^B - (\phi_H^A \phi_H^A | \phi_L^B \phi_L^B), \quad (7a)$$

$$E_4 \equiv \langle \Phi_4 | \mathcal{H} - E_0 | \Phi_4 \rangle \approx \varepsilon_L^A - \varepsilon_H^B - (\phi_L^A \phi_L^A | \phi_H^B \phi_H^B), \quad (7b)$$

where  $\varepsilon_j^X$  is the energy of the *j*th Hartree–Fock orbital  $\phi_j^X$  associated with molecule X, and the two-electron integral (ERI) is defined by

$$(\alpha\beta|\gamma\delta) \equiv \iint \frac{\phi_\alpha^*(\mathbf{r}_1) \phi_\beta(\mathbf{r}_1) \phi_\gamma^*(\mathbf{r}_2) \phi_\delta(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2. \quad (8)$$

The first term in eqn (3) is the, so-called, direct coupling, which is composed of two contributions as follows:

$$\langle \Phi_1 | \mathcal{H} | \Phi_2 \rangle = V_{\text{Coul}}^0 + V_{\text{Exch}}^0 \quad (9)$$

where the Förster (or Coulomb) coupling is given by

$$V_{\text{Coul}}^0 = \sum_{\mu\nu \in A} \sum_{\lambda\sigma \in B} P_{e \rightarrow g; \nu\mu}^A P_{g \rightarrow e; \lambda\sigma}^B (\mu\nu | \sigma\lambda), \quad (10)$$

whereas the Dexter (or pure exchange) coupling is

$$V_{\text{Exch}}^0 = -\frac{1}{2} \sum_{\mu\nu \in A} \sum_{\lambda\sigma \in B} P_{e \rightarrow g; \nu\mu}^A P_{g \rightarrow e; \lambda\sigma}^B (\mu\lambda | \sigma\nu). \quad (11)$$

In the above equations,  $\mathbf{P}_{g \rightarrow e}^X$  is the transition one-particle density matrix of molecule X in AO representation.  $V_{\text{Coul}}^0$ , which is usually a leading term for SS EET (but vanishes for TT EET), can be efficiently evaluated by various multipole expansion or electrostatic potential fitting models published to date.<sup>10–12</sup>  $V_{\text{Exch}}^0$  was reported to be rather negligible for SS EET even for close intermolecular contacts,<sup>12,31</sup> but is known to be non-negligible for TT EET.<sup>13,34,35</sup> However, unlike the direct Coulombic coupling, the second- and third-order terms in eqn (3), which are collectively referred to by Fujimoto as the indirect coupling,<sup>31</sup> as well as direct exchange coupling for TT EET, become increasingly important at short intermolecular distances. Unfortunately, the evaluation of such couplings is computationally quite demanding, even if the frontier orbital approximation of eqn (7) is assumed, since it requires evaluation of the ERIs.

Since the TI/CIS model was found to provide quite reliable estimates of EET coupling constants for many organic molecules,<sup>15,31,36</sup> we consider this model as a starting point to develop a computationally more efficient scheme that does not require time-consuming calculations of ERIs at all. First, in Section 2.2 we derive the EOP model based on the TI/CIS approach proposed earlier by Scholes and Ghiggino<sup>26</sup> and Fujimoto<sup>31</sup> (hereonin referred to as the EOP-TI/CIS or, in short, EOP-TI model). Next, we validate it against the various formulations of the TI/CIS method with increasing accuracy for a few selected model complexes in Section 3. Finally, we conclude our findings in Section 4. The auxiliary derivations are outlined in the appendices.

## 2.2 EOP-based model

In this section, we derive the approximation of the TI/CIS model that is completely free from ERIs. This is possible due to effective elimination of ERIs according to the general prescription:<sup>32</sup>

$$\begin{aligned} & \sum_t \mathcal{F}_t[(\mathbf{B}\mathbf{X}|\mathbf{A}\mathbf{A})] + \sum_s (\mathbf{B}|\hat{\delta}_s^A|\mathbf{X}) \\ &= \sum_{ij \in A} (\mathbf{B}|\hat{v}_i^{\text{eff},A}|i^A) [\mathbf{S}^{-1}]_{ij}(j^A|\mathbf{X}), \end{aligned} \quad (12)$$

where the capital italic letters denote subsets of orbitals associated with a particular fragment and  $\mathbf{X} = \mathbf{A}$  or  $\mathbf{B}$ ,  $\mathcal{F}_t$  is an arbitrary linear functional of ERIs, and  $\hat{\delta}_s^A$  and  $\hat{v}_i^{\text{eff},A}$  represent an arbitrary one-electron operator and an EOP operator associated with a molecule or fragment A, respectively. First of all, the coulombic EET coupling can be approximated by the distributed multipole expansion of the transition densities of interacting monomers in a dimer using the distributed transition-density cumulative

atomic multipole moments (TrCAMM) approach, developed by some of us previously:<sup>12</sup>

$$V_{\text{Coul}}^0 \approx \rho_{e \rightarrow g}^A \odot \rho_{g \rightarrow e}^B, \quad (13)$$

where the symbol ‘ $\odot$ ’ denotes the tensor contractions involved in the multipole expansion of the interaction energy between the generalized one-electron densities and the superscript ‘0’ indicates that the matrix elements are not affected by the overlap between molecular wavefunctions (this issue shall be addressed later in Section 2.2.4).

The diagonal elements for the first two basis states that are necessary for the overlapping corrections and also for the evaluation of the indirect EET couplings can be approximated (see the ESI†) by neglecting the environmental correction  $\Delta E_{e \rightarrow g}^X$ , *i.e.*,

$$E_1 \approx E_{e \rightarrow g}^A, \quad (14a)$$

$$E_2 \approx E_{e \rightarrow g}^B. \quad (14b)$$

Although this correction was found to be negligible in all the systems studied in this work (Tables S1 and S2, ESI†), this assumption should be tested for other chromophores and electronic transitions. All the other components of the model involve ERIs between the HOMO and LUMO of monomers A and B. These can be grouped into the following three categories:<sup>32</sup>

1. Integrals of type  $(\phi_i^X \phi_j^X | \phi_k^Y \phi_l^Y)$ , or Coulomb-like integrals. These involve HOMO–LUMO interactions in the expressions for  $E_3$  and  $E_4$  from eqn (7). These shall be treated in this work by the distributed multipole expansion of the form:

$$(\phi_i^X \phi_j^X | \phi_k^Y \phi_l^Y) \approx \rho_{ij}^X \odot \rho_{kl}^Y, \quad (15)$$

where

$$\rho_{ij}^X \equiv \sum_{\alpha\beta} P_{ij;\alpha\beta}^X \varphi_\alpha(\mathbf{r}) \varphi_\beta^*(\mathbf{r}) \quad (16)$$

and  $\mathbf{P}_{ij}^X$  is the associated effective one-particle density matrix in the AO basis given by

$$P_{ij;\alpha\beta}^X = C_{\alpha i}^X (C_{\beta j}^X)^*. \quad (17)$$

In this work, the CAMM method is used to generate the distributed multipole moments from such density matrices, as discussed in ref. 32.

2. Integrals of type  $(\phi_i^X \phi_j^X | \phi_k^X \phi_l^Y)$ , or overlap-like integrals. Matrix elements needed to evaluate EET coupling due to electron and hole transfer processes involve overlap-like ERIs. These shall be treated by the extended density fitting (EDF) technique,<sup>32</sup> *i.e.*,

$$(\phi_i^X \phi_j^X | \phi_k^X \phi_l^Y) \equiv -(\phi_k^X | \hat{v}_{ij}^X | \phi_l^Y) \quad (18)$$

where

$$\hat{v}_{ij}^X | \phi_k^X) = \sum_{\xi \in X}^{DF} V_{\xi;ijk}^X | \xi). \quad (19)$$

In the above, the ‘DF’ label indicates the auxiliary AO basis set used for density fitting, and the effective potential operator is

defined by<sup>32</sup>

$$\hat{v}_{ij}^X = \int d\mathbf{r} |\mathbf{r}\rangle v_{ij}^X(\mathbf{r}) \langle \mathbf{r}| \quad (20)$$

with its spatial form given as

$$v_{ij}^X(\mathbf{r}) \equiv - \int d\mathbf{r}' \frac{\phi_i^*(\mathbf{r}') \phi_j(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \quad (21)$$

(here, note that  $\phi_j(\mathbf{r}) \equiv \langle \mathbf{r} | \phi_j \rangle$ ).

3. Integrals of type  $\langle \phi_i^X \phi_j^Y | \phi_k^X \phi_l^Y \rangle$ , or exchange-like integrals. These cannot be treated by means of the effective one-electron operators, but nonetheless constitute the  $V_{\text{Exch}}^0$  matrix element and also contribute to the indirect coupling. Such integrals can be treated by a number of approximations, which allow one to express ERIs in terms of the one-electron overlap and other ERIs.<sup>37</sup> In this work, the Mulliken approximation is assumed where only two-electron Coulomb-like integrals are necessary, *i.e.*,

$$(ij|kl) \approx \frac{1}{4} S_{ij} S_{kl} [(ii|kk) + (ii|ll) + (jj|kk) + (jj|ll)]. \quad (22)$$

Thus, one can find that the remaining diagonal matrix elements are

$$E_3 \approx -\varepsilon_{\text{H}}^{\text{A}} + \varepsilon_{\text{L}}^{\text{B}} - \rho_{\text{HH}}^{\text{A}} \odot \rho_{\text{LL}}^{\text{B}}, \quad (23a)$$

$$E_4 \approx \varepsilon_{\text{L}}^{\text{A}} - \varepsilon_{\text{H}}^{\text{B}} - \rho_{\text{LL}}^{\text{A}} \odot \rho_{\text{HH}}^{\text{B}}. \quad (23b)$$

In the following subsections, the off-diagonal Hamiltonian matrix elements shall be discussed in detail in order to effectively remove all ERIs from the formulation.

**2.2.1 Indirect coupling *via* electron and hole transfer.** The indirect coupling terms can be intuitively decomposed into electron, hole and charge transfer terms.<sup>26,31</sup> The electron transfer (ET) matrix elements are

$$V_{\text{ET1}}^0 \equiv \langle \Phi_1 | \mathcal{H} | \Phi_3 \rangle \approx \frac{t_{\text{H} \rightarrow \text{L}}^{\text{A}}}{\sqrt{2}} \{ (\phi_{\text{L}}^{\text{A}} | \mathcal{F} | \phi_{\text{L}}^{\text{B}}) + 2(\phi_{\text{L}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{H}}^{\text{A}} \phi_{\text{L}}^{\text{B}}) - (\phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{B}} | \phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}}) \}, \quad (24)$$

along with the twin term,  $V_{\text{ET2}}^0 \equiv \langle \Phi_2 | \mathcal{H} | \Phi_4 \rangle$ , which were introduced earlier by Fujimoto.<sup>31</sup> In the above,  $\mathcal{F}$  is the Fock operator of the entire molecular aggregate. Note that here  $t_{\text{H} \rightarrow \text{L}}^{\text{A}}$  are the CIS amplitudes of isolated monomer A, whereas  $t_{\text{H} \rightarrow \text{L}}^{\text{A}}/\sqrt{2}$  reflects the approximate amplitude in a dimer with monomer B being in its ground state. Here, we also approximate the Fock operator by neglecting the interchromophore relaxation:

$$\mathcal{F}_0 \approx \hat{T} + \sum_{\text{X}}^{\text{A,B}} \left\{ \hat{V}_{\text{nuc}}^{\text{X}} + \hat{J}(\mathbf{P}_{\text{g}}^{\text{X}}) - \frac{1}{2} \hat{K}(\mathbf{P}_{\text{g}}^{\text{X}}) \right\}, \quad (25)$$

where  $\hat{T} \equiv -\frac{1}{2} \nabla^2$  is the one-electron kinetic energy operator,  $\hat{V}_{\text{nuc}}^{\text{X}}$  is the operator associated with the electrostatic potential energy between nuclei and electrons in molecule X, and the Coulomb and exchange operators are defined by

$$\hat{J}(\mathbf{P}_{\text{g}}^{\text{X}}) \equiv \sum_{\lambda\sigma} P_{\lambda\sigma}^{\text{X}(\text{g})} \iint \frac{\phi_{\lambda}(\mathbf{r}_1) \phi_{\sigma}^*(\mathbf{r}_1)}{|\mathbf{r}_1 - \mathbf{r}_2|} |\mathbf{r}_2\rangle \langle \mathbf{r}_1| d\mathbf{r}_1 d\mathbf{r}_2, \quad (26a)$$

$$\hat{K}(\mathbf{P}_{\text{g}}^{\text{X}}) \equiv \sum_{\lambda\sigma} P_{\lambda\sigma}^{\text{X}(\text{g})} \iint \frac{\phi_{\lambda}(\mathbf{r}_1) \phi_{\sigma}^*(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|} |\mathbf{r}_1\rangle \langle \mathbf{r}_2| d\mathbf{r}_1 d\mathbf{r}_2. \quad (26b)$$

Note that the decomposition of the kinetic energy operator into particular molecular contributions is arbitrary. However, consider the following partitioning of the total Fock operator:

$$\mathcal{F}_0 \approx \mathcal{G}_0^{\text{A}} + \mathcal{G}_0^{\text{B}}, \quad (27)$$

in which the auxiliary operator is defined as

$$\mathcal{G}_0^{\text{X}} = \mathcal{F}_0^{\text{X}} - \frac{1}{2} \hat{T} \quad (28)$$

and  $\mathcal{F}_0^{\text{X}} \equiv \hat{T} + \hat{V}_{\text{nuc}}^{\text{X}} + \hat{J}(\mathbf{P}_{\text{g}}^{\text{X}}) - \frac{1}{2} \hat{K}(\mathbf{P}_{\text{g}}^{\text{X}})$  is the Fock operator of isolated molecule X. Here, the contribution from the one-electron kinetic energy operator was symmetrically partitioned in between the two interacting molecules. Thus one can rewrite eqn (24) as

$$V_{\text{ET1}}^0 \approx \frac{t_{\text{H} \rightarrow \text{L}}^{\text{A}}}{\sqrt{2}} \{ (\phi_{\text{L}}^{\text{A}} | (\mathcal{G}_0^{\text{A}} + \mathcal{G}_0^{\text{B}}) | \phi_{\text{L}}^{\text{B}}) - 2(\phi_{\text{H}}^{\text{A}} | \hat{v}_{\text{LH}}^{\text{A}} | \phi_{\text{L}}^{\text{B}}) + (\phi_{\text{L}}^{\text{A}} | \hat{v}_{\text{HH}}^{\text{A}} | \phi_{\text{L}}^{\text{B}}) \}. \quad (29)$$

Now, by using the EOP technique<sup>32</sup> for overlap-like effective-potential operator matrix elements of type (AA|AB) one can collect operators associated to a particular molecule and group them into one effective one-electron operator as

$$(\phi_{\text{L}}^{\text{A}} | \{ \mathcal{G}_0^{\text{A}} + \hat{v}_{\text{HH}}^{\text{A}} \} - (\phi_{\text{L}}^{\text{A}} | 2\hat{v}_{\text{LH}}^{\text{A}} \approx \sum_{\xi \in \text{A}}^{\text{DF}} (\xi | V_{\xi;\text{HL}}^{\text{A:ET}} \quad (30)$$

and

$$\mathcal{G}_0^{\text{B}} | \phi_{\text{L}}^{\text{B}} \approx \sum_{\eta \in \text{B}}^{\text{DF}} V_{\eta;\text{L}}^{\text{B:ET}} | \eta \rangle. \quad (31)$$

In the above transformations that involve the EDF in an auxiliary basis set space,  $V_{\xi;\text{HL}}^{\text{A:ET}}$  and  $V_{\eta;\text{L}}^{\text{B:ET}}$  are the EOP matrix elements associated with the above effective potentials, separately defined for molecules A and B. This allows one to further recast  $V_{\text{ET1}}^0$  into

$$V_{\text{ET1}}^0 \approx \frac{t_{\text{H} \rightarrow \text{L}}^{\text{A}}}{\sqrt{2}} \left\{ \sum_{\xi \in \text{A}}^{\text{DF}} S_{\xi\text{L}}^{\text{AB}} V_{\xi;\text{HL}}^{\text{A:ET}} + \sum_{\eta \in \text{B}}^{\text{DF}} S_{\eta\text{L}}^{\text{BA}} V_{\eta;\text{L}}^{\text{B:ET}} \right\}, \quad (32)$$

which has a particularly simple form as compared to the original expression in eqn (24) that involves four-center electron repulsion integrals. Note that, if the EOP matrices are considered as effective fragment parameters (EFPs), only overlap integrals between auxiliary basis functions and the LUMOs of molecules A and B are necessary, *i.e.*,

$$S_{\xi\text{U}}^{\text{XY}} = \sum_{\beta \in \text{Y}} S_{\xi\beta}^{\text{XY}} C_{\beta\text{U}}^{\text{Y}} \text{ for } \xi \in \text{X}, \quad (33)$$

where

$$S_{\xi\beta}^{\text{XY}} = \int d\mathbf{r} \phi_{\xi}^*(\mathbf{r}) \phi_{\beta}(\mathbf{r}) \quad (34)$$

and  $C_{\beta\text{U}}^{\text{X}}$  is the SCF LCAO-MO matrix element for isolated molecule X associated with the *U*th MO. It is straightforward

to show that the twin term ET2 is

$$V_{\text{ET2}}^0 \cong \frac{t_{\text{H} \rightarrow \text{L}}^{\text{B}}}{\sqrt{2}} \left\{ \sum_{\eta \in \text{B}}^{\text{DF}} S_{\eta \text{L}}^{\text{BA}} V_{\eta; \text{HL}}^{\text{B:ET}} + \sum_{\xi \in \text{A}}^{\text{DF}} S_{\xi \text{L}}^{\text{AB}} V_{\xi; \text{L}}^{\text{A:ET}} \right\}. \quad (35)$$

Note that EOP matrices for ET1 and ET2 terms share a similar structure. Therefore a joint superscript 'ET' is used here to label the EOP matrices and additional subscripts L and HL denote the dependence on only the LUMO or on both the HOMO and LUMO, respectively.

Similar considerations apply to the hole transfer (HT) matrix elements. The corresponding expression

$$V_{\text{HT1}}^0 \equiv \langle \Phi_1 | \mathcal{H} | \Phi_4 \rangle \approx \frac{t_{\text{H} \rightarrow \text{L}}^{\text{A}}}{\sqrt{2}} \left\{ -(\phi_{\text{H}}^{\text{A}} | \mathcal{F} | \phi_{\text{H}}^{\text{B}}) + 2(\phi_{\text{H}}^{\text{A}} \phi_{\text{L}}^{\text{A}} | \phi_{\text{L}}^{\text{A}} \phi_{\text{H}}^{\text{B}}) - (\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{B}} | \phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{A}}) \right\} \quad (36)$$

can be recast as

$$V_{\text{HT1}}^0 \cong \frac{t_{\text{H} \rightarrow \text{L}}^{\text{A}}}{\sqrt{2}} \left\{ \sum_{\xi \in \text{A}}^{\text{DF}} S_{\xi \text{H}}^{\text{AB}} V_{\xi; \text{HL}}^{\text{A:HT}} + \sum_{\eta \in \text{B}}^{\text{DF}} S_{\eta \text{H}}^{\text{BA}} V_{\eta; \text{H}}^{\text{B:HT}} \right\}, \quad (37)$$

with the effective potential matrices given by

$$(\phi_{\text{H}}^{\text{A}} | \{ -\mathcal{G}_0^{\text{A}} + \hat{v}_{\text{LL}}^{\text{A}} \} - (\phi_{\text{L}}^{\text{A}} | 2\hat{v}_{\text{HL}}^{\text{A}} \cong \sum_{\xi \in \text{A}}^{\text{DF}} (\xi | V_{\xi; \text{HL}}^{\text{A:HT}}, \quad (38a)$$

$$-\mathcal{G}_0^{\text{B}} | \phi_{\text{H}}^{\text{B}}) \cong \sum_{\eta \in \text{B}}^{\text{DF}} V_{\eta; \text{H}}^{\text{B:HT}} | \eta). \quad (38b)$$

The twin term HT2 is accordingly

$$V_{\text{HT2}}^0 \cong \frac{t_{\text{H} \rightarrow \text{L}}^{\text{B}}}{\sqrt{2}} \left\{ \sum_{\eta \in \text{B}}^{\text{DF}} S_{\eta \text{H}}^{\text{BA}} V_{\eta; \text{HL}}^{\text{B:HT}} + \sum_{\xi \in \text{A}}^{\text{DF}} S_{\xi \text{H}}^{\text{AB}} V_{\xi; \text{H}}^{\text{A:HT}} \right\}. \quad (39)$$

As it was shown, to compute the Hamiltonian matrix elements associated with the electron and hole transfer, in total eight different EOP matrices need to be precomputed and stored in a file. Note that each of these matrices is actually just a vector of length equal to the size of the auxiliary basis set chosen. Therefore, it can be predicted that the computational cost of the evaluation of the EOP-based Hamiltonian matrix elements is negligible as compared to the original formulation of the TI/CIS method. In Appendix A, the explicit and convenient to implement working formulae for the EOP matrix elements are given in terms of the AOs.

**2.2.2 Indirect coupling via charge transfer.** The Hamiltonian matrix element that is associated with the charge transfer process is

$$V_{\text{CT}}^0 = 2(\phi_{\text{H}}^{\text{A}} \phi_{\text{L}}^{\text{B}} | \phi_{\text{L}}^{\text{A}} \phi_{\text{H}}^{\text{B}}) - (\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{B}} | \phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{B}}). \quad (40)$$

Since it involves ERIs of type (AB|AB), EOPs cannot be readily defined here. However, the application of the Mulliken

approximation from eqn (22) to eqn (40) yields

$$V_{\text{CT}}^0 \approx \frac{1}{2} S_{\text{HL}}^{\text{AB}} S_{\text{LH}}^{\text{AB}} [r_{\text{HL}}^{\text{A}} + r_{\text{HL}}^{\text{B}} + (\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{H}}^{\text{B}} \phi_{\text{H}}^{\text{B}}) + (\phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{A}} | \phi_{\text{L}}^{\text{B}} \phi_{\text{L}}^{\text{B}})] - \frac{1}{4} S_{\text{HH}}^{\text{AB}} S_{\text{LL}}^{\text{AB}} [r_{\text{HL}}^{\text{A}} + r_{\text{HL}}^{\text{B}} + (\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{L}}^{\text{B}} \phi_{\text{L}}^{\text{B}}) + (\phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{A}} | \phi_{\text{H}}^{\text{B}} \phi_{\text{H}}^{\text{B}})], \quad (41)$$

where

$$r_{\text{HL}}^{\text{X}} \equiv (\phi_{\text{H}}^{\text{X}} \phi_{\text{H}}^{\text{X}} | \phi_{\text{L}}^{\text{X}} \phi_{\text{L}}^{\text{X}}). \quad (42)$$

First of all, note that  $r_{\text{HL}}^{\text{A}}$  and  $r_{\text{HL}}^{\text{B}}$  are just constant numbers associated with the isolated monomers and independent of the molecular aggregate. Also, the remaining four ERIs can be considered as Coulombic interactions between the HOMO and LUMO of unperturbed molecular wavefunctions:

$$(\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{H}}^{\text{B}} \phi_{\text{H}}^{\text{B}}) \approx \rho_{\text{HH}}^{\text{A}} \odot \rho_{\text{HH}}^{\text{B}}, \quad (43a)$$

$$(\phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{A}} | \phi_{\text{L}}^{\text{B}} \phi_{\text{L}}^{\text{B}}) \approx \rho_{\text{LL}}^{\text{A}} \odot \rho_{\text{LL}}^{\text{B}}, \quad (43b)$$

$$(\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{L}}^{\text{B}} \phi_{\text{L}}^{\text{B}}) \approx \rho_{\text{HH}}^{\text{A}} \odot \rho_{\text{LL}}^{\text{B}}, \quad (43c)$$

$$(\phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{A}} | \phi_{\text{H}}^{\text{B}} \phi_{\text{H}}^{\text{B}}) \approx \rho_{\text{LL}}^{\text{A}} \odot \rho_{\text{HH}}^{\text{B}}. \quad (43d)$$

In the limiting case when multipole expansion is truncated on the monopole terms, one finds that

$$(\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{H}}^{\text{B}} \phi_{\text{H}}^{\text{B}}) \approx \frac{1}{|\mathbf{r}_{\text{H}}^{\text{A}} - \mathbf{r}_{\text{H}}^{\text{B}}|}, \quad (44)$$

where the charge centroids of the HOMOs are given by

$$\mathbf{r}_{\text{H}}^{\text{X}} \equiv (\phi_{\text{H}}^{\text{X}} | \hat{\mathbf{r}} | \phi_{\text{H}}^{\text{X}}). \quad (45)$$

Note that, once occupied molecular orbitals are localized, the above approximation should yield the correct description. However, the LUMOs are usually quite delocalized. Here, we use the distributed cumulative atomic charges to represent these:<sup>38</sup>

$$q_{x; \text{L}}^{\text{X}} = - \sum_{\alpha \in x} \sum_{\beta} S_{\alpha\beta} C_{\alpha \text{L}}^{\text{X}} C_{\beta \text{L}}^{\text{X}} \quad (46)$$

and one can find that assuming this one obtains

$$(\phi_{\text{L}}^{\text{A}} \phi_{\text{L}}^{\text{A}} | \phi_{\text{L}}^{\text{B}} \phi_{\text{L}}^{\text{B}}) \approx \sum_{x \in \text{A}}^{\text{At}} \sum_{y \in \text{B}}^{\text{At}} \frac{q_{x; \text{L}}^{\text{A}} q_{y; \text{L}}^{\text{B}}}{|\mathbf{r}_x - \mathbf{r}_y|}. \quad (47)$$

The two remaining ERIs can then be approximated as follows:

$$(\phi_{\text{H}}^{\text{A}} \phi_{\text{H}}^{\text{A}} | \phi_{\text{L}}^{\text{B}} \phi_{\text{L}}^{\text{B}}) \approx - \sum_{y \in \text{B}}^{\text{At}} \frac{q_{y; \text{L}}^{\text{B}}}{|\mathbf{r}_{\text{H}}^{\text{A}} - \mathbf{r}_y|}, \quad (48)$$

and similarly for the twin ERIs. To summarize the derivation, the CT matrix element is approximately given by

$$V_{\text{CT}}^0 \approx \frac{1}{2} S_{\text{HL}}^{\text{AB}} S_{\text{LH}}^{\text{AB}} \times \left[ r_{\text{HL}}^{\text{A}} + r_{\text{HL}}^{\text{B}} + \frac{1}{|\mathbf{r}_{\text{H}}^{\text{A}} - \mathbf{r}_{\text{H}}^{\text{B}}|} + \sum_{x \in \text{A}}^{\text{At}} \sum_{y \in \text{B}}^{\text{At}} \frac{q_{x; \text{L}}^{\text{A}} q_{y; \text{L}}^{\text{B}}}{|\mathbf{r}_x - \mathbf{r}_y|} \right] - \frac{1}{4} S_{\text{HH}}^{\text{AB}} S_{\text{LL}}^{\text{AB}} \times \left[ r_{\text{HL}}^{\text{A}} + r_{\text{HL}}^{\text{B}} - \sum_{y \in \text{B}}^{\text{At}} \frac{q_{y; \text{L}}^{\text{B}}}{|\mathbf{r}_{\text{H}}^{\text{A}} - \mathbf{r}_y|} - \sum_{x \in \text{A}}^{\text{At}} \frac{q_{x; \text{L}}^{\text{A}}}{|\mathbf{r}_x - \mathbf{r}_{\text{H}}^{\text{B}}|} \right]. \quad (49)$$

Thus, the computational cost of the above expression is negligible as compared to the original formula in eqn (40).

**2.2.3 Approximate pure exchange coupling.** The Mulliken approximation can also be used to treat the pure exchange coupling (eqn (11)) which leads to

$$V_{\text{Exch}}^0 \approx -\frac{1}{8} \sum_{\mu\nu \in A} \sum_{\lambda\sigma \in B} P_{\nu\mu;e \rightarrow g}^A P_{\lambda\sigma;g \rightarrow e}^B S_{\mu\lambda} S_{\sigma\nu} \times [(\mu\mu|\sigma\sigma) + (\lambda\lambda|\nu\nu) + (\mu\mu|\nu\nu) + (\lambda\lambda|\sigma\sigma)]. \quad (50)$$

Here, such ERIs that involve AOs in two different molecules are approximated by

$$(\mu\mu|\sigma\sigma) \approx \frac{S_{\mu\mu} S_{\sigma\sigma}}{r_{\mu\sigma}}, \quad (51)$$

where  $r_{\mu\sigma}$  is the distance between the centers of the  $\mu$ th and  $\sigma$ th AOs. That leads to the following approximate expression:

$$V_{\text{Exch}}^0 \approx -\frac{1}{8} \left\{ \sum_{\mu\nu \in A} P_{\nu\mu;e \rightarrow g}^A Q_{\mu\nu}^A [S^{AB} P_{g \rightarrow e}^B S^{BA}]_{\mu\nu} + \sum_{\sigma\lambda \in B} P_{\lambda\sigma;g \rightarrow e}^B Q_{\lambda\sigma}^B [S^{BA} P_{e \rightarrow g}^A S^{AB}]_{\sigma\lambda} + \sum_{\mu \in A} \sum_{\sigma \in B} \frac{S_{\mu\mu} S_{\sigma\sigma}}{r_{\mu\sigma}} \left( [S^{BA} P_{e \rightarrow g}^A]_{\sigma\mu} [S^{AB} P_{g \rightarrow e}^B]_{\mu\sigma} + [P_{e \rightarrow g}^A S^{AB}]_{\mu\sigma} [P_{g \rightarrow e}^B S^{BA}]_{\sigma\mu} \right) \right\} \quad (52)$$

with  $Q_{\mu\nu} \equiv (\mu\mu|\nu\nu)$ . Note that  $Q_{\mu\nu}^A$  and  $Q_{\lambda\sigma}^B$  are just matrix elements of constant matrices. Although these are not second-rank tensors (*i.e.*, they do not transform under Euclidean rotations as other AO matrices), they can be easily computed from a small set of proper fourth-rank tensors, which is shown in Appendix B. Therefore, the EFP methodology can still be used to calculate pure exchange Dexter contribution to the EET coupling and the computational cost of the overall procedure is negligible as compared to the evaluation of eqn (11) involving ERIs in the AO space directly.

**2.2.4 Complete model of EET coupling.** To summarize, the overall form of the EOP-TI/CIS model is still given as in the original TI/CIS model<sup>26,31</sup> by

$$V \approx V_{\text{Direct}} + V_{\text{Indirect}}, \quad (53)$$

where the direct and indirect coupling constants are, respectively,

$$V_{\text{Direct}} \equiv V_{\text{Coul}} + V_{\text{Exch}} + V_{\text{Ovlp}}, \quad (54a)$$

$$V_{\text{Indirect}} \equiv V^{\text{TI}(2)} + V^{\text{TI}(3)}, \quad (54b)$$

with

$$V^{\text{TI}(2)} \equiv -\frac{V_{\text{ET1}} V_{\text{HT2}}}{E_3 - E_1} - \frac{V_{\text{ET2}} V_{\text{HT1}}}{E_4 - E_1}, \quad (55a)$$

$$V^{\text{TI}(3)} \equiv \frac{V_{\text{CT}}(V_{\text{ET1}} V_{\text{ET2}} + V_{\text{HT1}} V_{\text{HT2}})}{(E_3 - E_1)(E_4 - E_1)}. \quad (55b)$$

In the above, the direct EET coupling contributions are

$$V_{\text{Coul}} = \frac{V_{\text{Coul}}^0}{1 - S_{12}^2}, \quad (56a)$$

$$V_{\text{Exch}} = \frac{V_{\text{Exch}}^0}{1 - S_{12}^2}, \quad (56b)$$

$$V_{\text{Ovlp}} = -\frac{(E_1 + E_2)S_{12}}{2(1 - S_{12}^2)}. \quad (56c)$$

whereas the indirect EET coupling is evaluated from the overlap-corrected ET, HT and CT matrix elements that read

$$V_t = [1 - S_t^2]^{-1} \left\{ V_t^0 - \frac{1}{2}(E_1 + E_2)S_t \right\}, \quad (57)$$

where 't' denotes one of the matrix element types (ET1, ET2, HT1, HT2, CT) and  $S_t$  is the appropriate overlap integral between basis states.

Despite the same general form, the differences between the original TI/CIS model and the newly derived EOP-based approach are quite significant. The Hamiltonian matrix elements are evaluated from the effective fragment parameters, for which only the one-electron integrals are needed. Therefore, the computational cost is significantly reduced as compared to the parent TI/CIS model. In particular, the  $V_{\text{Coul}}^0$  term is evaluated by using the TrCamm method developed previously,<sup>12</sup> whereas  $V_{\text{Exch}}^0$  and  $V_{\text{CT}}^0$  are computed using the approximate Mulliken formulae in eqn (52) and (49), respectively. In turn, the electron and hole transfer terms  $V_{\text{ET1}}^0$ ,  $V_{\text{ET2}}^0$ ,  $V_{\text{HT1}}^0$  and  $V_{\text{HT2}}^0$  are treated by the EDF with EOP effective matrices as effective parameters spanned in the auxiliary AO basis set (eqn (32), (35), (37), (39) and (58)–(63)). Note that the evaluation of eqn (56) and (57) is computationally inexpensive because it involves computing only approximate overlap integrals between basis states.<sup>31</sup>

On the other hand, the relaxation effects due to the intermolecular interactions are not included in the current EOP-based model. Note that in the TDFI-TI/CIS model the basis states and all the one-particle density matrices are built from the self-consistently adjusted fragment ground-state densities according to the DFI method.<sup>28</sup> However, as demonstrated in the following section, we do not expect major differences due to the relaxation effects.

### 2.3 Adaptation of the EOP-TI/CIS method as effective fragment potentials

In the previous sections, all interfragment ERIs were effectively eliminated from the original TI/CIS equations by using the EOP technique. Here, note that the following quantities, which are sufficient to evaluate the resulting EOP-TI/CIS EET coupling constant without calculating the interfragment ERIs, are functions of the isolated electronic chromophores:

- TrCamm's of monomers A and B,
- excitation energies  $E_{g \rightarrow e}^A$  and  $E_{g \rightarrow e}^B$ , as well as the corresponding transition density matrices  $\mathbf{P}_{e \rightarrow g}^A$  and  $\mathbf{P}_{e \rightarrow g}^B$ ,
- $(\mathbf{pp}|\mathbf{qq})^A$  and  $(\mathbf{pp}|\mathbf{qq})^B$  tensor elements from Appendix B,

- $V_{\xi;HL}^{A:ET}$ ,  $V_{\eta;L}^{B:ET}$ ,  $V_{\xi;L}^{A:HT}$  and  $V_{\eta;HL}^{B:HT}$  vector elements, each of length equal to the size of the auxiliary EOP basis set,
- CIS HOMO–LUMO amplitudes  $t_{H \rightarrow L}^A$  and  $t_{H \rightarrow L}^B$ ,
- CAMMs of HOMO and LUMO densities from eqn (43), as well as the canonical orbital energies,
- distributed atomic charges  $q_{x,L}^A$  and  $q_{y,L}^B$  from eqn (46),
- localized HOMO centroids  $r_H^A$  and  $r_H^B$  from eqn (45), as well as intrafragment (and invariant with respect to the Euclidean rotations of chromophores) Coulomb-type ERIs  $r_{HL}^A$  and  $r_{HL}^B$  from eqn (42), and finally,
- primary and auxiliary basis sets.

Therefore, only one preparative calculation per chromophore is required to obtain all of the above quantities that constitute the EFPs, much like obtaining the EFPs for calculating the interaction energy by means of the second generation of the effective fragment potential (EFP2) method.<sup>39</sup> The rate-determining step in computing the EFPs is the calculation of the CIS amplitudes which can be nowadays performed efficiently even for large molecules.

Such EOP-TI/CIS EFPs can be subsequently used in routine calculations of EET coupling constants in conjunction with the molecular dynamics and rigid molecule algorithm as developed previously in the context of calculations of the solvatochromic vibrational frequency shifts of infrared probes in condensed phases (SolEFP).<sup>40–45</sup> Note that, once EFPs are computed, the evaluation of the EOP-TI/CIS equations requires only one-electron overlap integrals which are relatively inexpensive to calculate.

### 3 Results and discussion

All the models and approximations that were discussed so far were implemented in our inhouse plugin EOPDev<sup>46</sup> to the Psi4 quantum chemistry package,<sup>47</sup> along with the direct CIS method utilizing the Davidson–Liu simultaneous expansion approach.<sup>48–50</sup> In this work, the tested levels of the TI/CIS theory are characterized by the treatment of the Fock operator in the expressions for the off-diagonal ET and HT Hamiltonian matrix elements. For example, in the case of  $V_{ET1}^{(0)}$ , the approximations denoted here as  $V^{TI}(\mathcal{F})$  and  $V^{TI}(\mathcal{F}_0)$  collectively refer to using eqn (24) and (29), respectively.  $V^{TI}(\mathcal{F}_0^{DFI})$  indicates that the approximate Fock matrix was used as in eqn (29) but including the interfragment interactions in a self-consistent manner through the DFI process.<sup>28</sup> The EOP-based model is denoted as  $V^{TI}(\mathcal{F}_0^{EOP})$  and additionally utilizes the TrCAMM approximation for  $V_{Coul}^{(0)}$ , as well as the Mulliken approximation for  $V_{Exch}^{(0)}$  (eqn (52)) and  $V_{CT}^{(0)}$  (two variants are tested: the CAMM-based variant from eqn (41) with eqn (43) or the distributed charge-based variant from eqn (49)). Environmental correction terms from eqn (5) were included in all models except the  $V^{TI}(\mathcal{F}_0^{EOP})$  model. In order to test the EOP-TI/CIS model we chose the EET coupling between the lowest-lying bright  $1\pi\pi^*$  states of ethylene ( $1^1B_{1u}$ ) and 7-aminocoumarin ( $1^1A'$ ) in stacked molecular dimers, having  $D_{2h}$  and  $C_s$  symmetry, respectively. To test the performance and applicability of the proposed

methodology we also performed preliminary calculations on the “special pair” in the reaction center of photosystem I (PS-I).<sup>10,14,51</sup> To improve the convergence of the distributed multipole expansion of the Coulombic EET coupling constants, the transition densities used to compute the TrCAMMs were symmetrized as suggested by Belov *et al.*<sup>52</sup> Occupied core orbitals were included in the CIS calculations except from the PS-I model for which the frozen-core approximation was utilized.

All the reported results were obtained assuming the 6-31G(d) basis set<sup>53</sup> and, when required, the cc-pVDZ-JKFIT density-fitting basis set.<sup>54</sup> To obtain EOP matrices for ET and HT Hamiltonian matrix elements, the EDF scheme<sup>32</sup> was utilized with aug-cc-pVDZ-JKFIT<sup>54</sup> as the auxiliary EOP basis set. Further details of calculations and the selected geometries of the studied complexes are provided in the ESI.†

#### 3.1 Accuracy of transfer integral approximations

The total magnitudes of EET couplings between stacked ethylene molecules in the  $1^1B_{1u}$  states and 7-aminocoumarin in the  $1^1A'$  states, obtained for the selected geometries, are compiled in Table 1. The equilibrium geometry of the ethylene dimer was optimized using the MP2/6-31G(d) method assuming  $D_{2h}$  symmetry of the complex and EET couplings were then computed for the selected intermolecular distances ( $R_{AB}$ ) by translation of the molecules along the intermolecular axis. The  $R_{AB}$  distance between the neighboring carbon atoms of 4.169 Å corresponds to the minimum energy structure. At a distance of 6.0 Å the  $V_{Exch}^0$  term drops below 0.002  $cm^{-1}$  and the total coupling is virtually identical to Coulomb contribution, whereas the structure for  $R_{AB} = 3.0$  Å represents the region of large overlap of molecular wavefunctions where  $V_{Exch}^0$  exceeds 1700  $cm^{-1}$ . The 7-aminocoumarin (7AC) dimer was prepared as reported in our previous study.<sup>12</sup> The structures of two flat 7AC molecules optimized at the MP2/6-31g(d) level were superimposed and shifted with respect to the intermolecular axis. Such a rigid potential energy (PE) scan shows a minimum at  $R_{AB} = 3.6$  Å, while the regions of large and negligible overlap, identified analogously as in the ethylene dimer (*i.e.* based on the magnitudes of  $V_{Exch}^0$ ), occur at intermolecular distances of roughly 2.6 and 4.6 Å, respectively.

The reference values of the total EET coupling  $V^{ESD}$  were calculated using the energy splitting in dimer (ESD) method,<sup>24,55</sup> in which the coupling is calculated as half of the

**Table 1** EET couplings (in  $cm^{-1}$ ) computed between the lowest-lying bright  $1\pi\pi^*$  states in the studied ethylene and 7-aminocoumarin stacked dimers at various levels of approximation (indicated in parentheses by the corresponding Fock matrix estimate) to the CIS reference values. All the results were computed for the selected intermolecular distances  $R_{AB}$  (given in Å) assuming the 6-31G(d) basis set

$R_{AB}$	(Ethylene) <sub>2</sub>			(7AC) <sub>2</sub>		
	3.0	4.169	6.0	2.6	3.6	4.6
$V^{ESD}$	9893	1973	495	12 291	2433	868
$V^{TI}(\mathcal{F})$	7990	1744	495	14 576	1782	840
$V^{TI}(\mathcal{F}_0^{DFI})$	10 156	1762	495	21 241	1942	835
$V^{TI}(\mathcal{F}_0)$	9953	1766	495	21 135	1949	842
$V^{TI}(\mathcal{F}_0^{EOP})$	10 481	1772	494	19 617	2175	837

splitting between the corresponding adiabatic excited state energies in a dimer. In the case of the studied symmetric complexes this method provides the accurate electronic coupling. The transfer-integral  $V^{\text{TI}}(\mathcal{F})$  values, computed assuming the exact Fock matrix of the dimer, are very close to the ESD reference at large and intermediate intermolecular separations and become more approximate at shorter distances. The  $V^{\text{TI}}(\mathcal{F})$  results represent the limiting accuracy of the TI/CIS frontier-orbitals model which is semi-quantitative at equilibrium geometries and becomes only qualitatively correct at shorter distances. Their calculations for the ethylene dimer took 9.2 s of CPU time on one core of the 1.2 GHz AMD EPYC 7301 16-core processor. The  $V^{\text{TI}}(\mathcal{F}_0^{\text{DFI}})$  values correspond to the original transition-density-fragment interaction method (TDFI-TI) of Fujimoto,<sup>31</sup> because the density-fragment interaction (DFI) method<sup>28,29</sup> is used to take into account molecular surroundings in the Fock matrix of the chromophores in a self-consistent fashion. These are overestimated at short distances and underestimated at the equilibrium geometry by roughly 10–20% (depending on the system). As expected, all the tested models predict virtually identical results at large intermolecular separations.

The effect of mutual polarization taken into account in the TDFI-TI method *via* the block-localized self-consistent density-fragment interaction procedure<sup>28</sup> seems to be rather small. This may be inferred from Table 1 by a comparison of  $V^{\text{TI}}(\mathcal{F}_0^{\text{DFI}})$  and  $V^{\text{TI}}(\mathcal{F}_0)$  magnitudes, the relative differences of which are below 2% even at short intermolecular distances. In the latter approach the dimer Fock matrix was constructed from the Fock matrices of monomers assuming the symmetric partitioning introduced in eqn (27) and (28), and thus the interacting monomer ground-state densities were not relaxed in this case. Both calculations took about 3.2 s in the same CPU (*cf.* Table S3 in the ESI†) which shows about 20% speedup with respect to the calculations of  $V^{\text{TI}}(\mathcal{F})$  using the exact Fock matrix of the ethylene dimer. Note, however, that the reported timings do not include the time to solve the SCF and CIS problems for the monomers –  $V^{\text{TI}}(\mathcal{F}_0^{\text{DFI}})$  calculations are obviously longer than  $V^{\text{TI}}(\mathcal{F}_0)$  ones in terms of the elapsed time since the Hartree–Fock problem for the monomers is solved in a block-localized self-consistent fashion for the whole complex.

It is interesting to note that the corresponding EOP-TI calculations took only a few milliseconds of CPU time, which is nearly three orders of magnitude faster (*cf.* Table S3, ESI†), while showing virtually no signs of loss in the accuracy, as the  $V^{\text{TI}}(\mathcal{F}_0^{\text{EOP}})$  values obtained for the ethylene dimer reproduce consistently the  $V^{\text{TI}}(\mathcal{F}_0)$  estimates with a 1–2% accuracy even at short distances. In the case of the 7AC complex the speedup is more spectacular, since  $V^{\text{TI}}(\mathcal{F}_0)$  calculations took about 25 minutes while  $V^{\text{TI}}(\mathcal{F}_0^{\text{EOP}})$  only 79 milliseconds (nearly 20 000 times faster). The speedup is even larger for PS-I, for which the respective timings are about 137 hours *vs.* 6 seconds. The relative differences of total couplings are larger in this system (within about  $\pm 7\%$ ) but one could argue that at short distances the EOP-TI values are, in fact, consistently closer to the reference values. This, however, is entirely due to the cancellation of errors. The fact is that essentially all the discussed TI models

show quite similar accuracy, but the EOP-TI approach is simply much more efficient.

The same conclusions arise from the analysis of the PE cuts shown in Fig. 1, where in panels (a) and (c) the total TI( $\mathcal{F}$ )/CIS couplings and their components are plotted along with the reference ESD values for the model systems in the vicinity of their equilibrium geometries. The total TI( $\mathcal{F}$ ) coupling (marked with gray lines and asterisks) underestimates slightly the ESD values (shown as black lines with circles) at equilibrium and shorter distances. The agreement is at least semi-quantitative unless the region of very large overlap is considered, which would however be hardly accessible in any real physical situation (note the corresponding interaction energies plotted as gray dashed lines *vs.* the right axis). For instance, in the 7AC dimer this occurs for  $\Delta R_{\text{AB}}$  below  $-0.9 \text{ \AA}$  (*cf.* Fig. 1c), where the TI( $\mathcal{F}$ ) estimates start to diverge from the ESD coupling, but the intermolecular repulsion in this region exceeds  $190 \text{ kJ mol}^{-1}$ .

### 3.2 Partitioning of EET couplings

In Tables 2 and 3 the detailed partitioning of EET couplings in ethylene and 7AC dimers, respectively, is shown for the selected intermolecular separations. At large distances the total coupling  $V^{\text{TI}}$  is determined solely by the direct electrostatic contribution which can be accurately approximated from TrCamm expansion. At the equilibrium geometry the exchange, overlap and third-order  $V^{\text{TI}(3)}$  terms are still negligible. However, the total indirect coupling is already significant and almost exclusively due to the second-order terms  $V^{\text{TI}(2)}$ . The same applies also to the special pair of photosystem I (*cf.* Table S4 of the ESI†), which was chosen to test the performance of the EOP-TI scheme. The vanishingly small values of  $V_{\text{Ovip}}$  terms indicate that the relevant adiabatic states of monomers in the studied model systems are virtually orthogonal. Only in the case of the ethylene dimer in the large-overlap region do they rise slightly. Even though the studied ethylene dimer is very weakly bound, having an interaction energy of less than  $1 \text{ kJ mol}^{-1}$  in the MP2/6-31G(d) minimum energy structure, the corresponding interaction energy in the 7AC dimer amounts to about  $20 \text{ kJ mol}^{-1}$ . Thus, it appears that the above conclusions could be general for interacting systems in the vicinity of equilibrium geometry. In the region of large overlap the exchange and third-order terms become significant. In fact, the indirect coupling becomes the leading component with a dominant contribution from the second-order terms. In general the  $V^{\text{TI}}(\mathcal{F}_0)$  partitioning, being a starting point for the introduction of EOP approximation, agrees quantitatively with the corresponding TDFI estimates. The differences between these two methods are essentially due to the lack of relaxation effects in the former. The largest differences are in the magnitudes of second-order terms, which still fall within a few percent margin, unless the Mulliken approximation is utilized. It is interesting to note that in the case of the special pair of PS-I (Table S4, ESI†) at the experimental geometry the agreement is virtually quantitative, for both the total coupling ( $171 \text{ vs. } 178 \text{ cm}^{-1}$ ) and its components. The latter being mostly due to the direct electrostatic coupling  $V_{\text{Coul}}$  ( $157 \text{ vs. } 161 \text{ cm}^{-1}$ ) and the second-order indirect contribution  $V^{\text{TI}(2)}$  ( $15.8 \text{ vs. } 17.6 \text{ cm}^{-1}$ ).

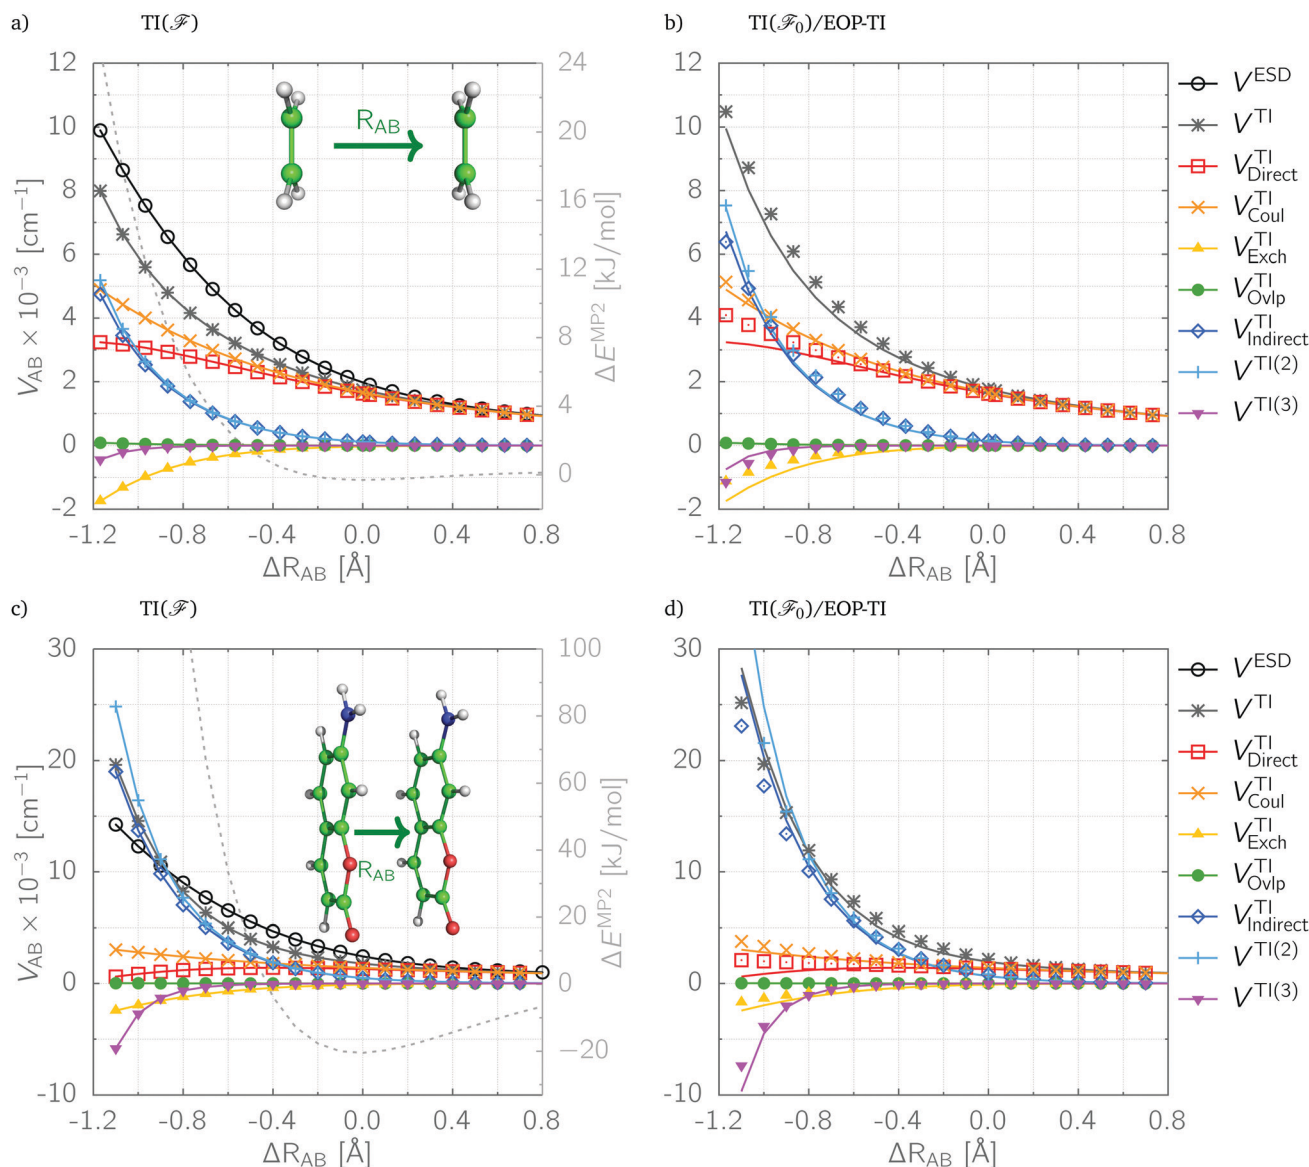

Fig. 1 EET couplings and their partitioning in symmetric ethylene (a and b) and 7AC dimers (c and d) as a function of intermolecular separation.  $\Delta R_{AB}$  is the translation with respect to the equilibrium distance. In the left panels (a and c) the reference ESD values are plotted along with the best TI/CIS estimates obtained for the exact dimeric Fock matrix. In the right panels (b and d) the  $\text{TI}(\mathcal{F}_0)$  results plotted as solid lines are compared with their EOP-TI( $\mathcal{F}_0$ ) estimates shown as points.

The excellent agreement of EOP-TI estimates with  $\text{TI}(\mathcal{F}_0)$  results is demonstrated for a broader range of intermolecular distances in Fig. 1. In panels (b) and (d) the latter are plotted as solid lines while the former as points. In the vicinity of equilibrium geometry the agreement is nearly quantitative and starts deteriorating in the hardly accessible region of very large overlap. However, since the EOP-TI couplings start to underestimate the  $\text{TI}(\mathcal{F}_0)$  values, which in turn overestimate the reference ESD values, the EOP-TI results are consistently closer to the reference. In fact, this is true also at larger intermolecular separations, since the major difference in EOP-TI components is found for the second-order terms being overestimated at large distances and underestimated at short distances.

The basis set extension effects are discussed thoroughly in the  $\text{ESI}^\dagger$  (see Fig. S1). Generally, the choice of aug-cc-pVDZ-

JKFIT as the auxiliary EOP basis set is sufficient even for more flexible orbital basis sets, at least for the first-row atom molecules studied here. The choice of the orbital basis set is more critical, particularly for the calculations of indirect couplings. However, the latter constitute only about 20–30% of the total TI/CIS coupling at minimum energy geometries of the studied model systems. The direct contribution, on the other hand, is sufficiently saturated already in the split-valence polarized double-zeta basis set. Interestingly, the TI/CIS values converge quickly to the exact ESD coupling with basis set extension.

### 3.3 Accuracy of Mulliken and multipolar expansion approximations

The accuracy of the Mulliken approximation for the estimation of pure exchange coupling  $V_{\text{Exch}}$  appears to be semi-quantitative

**Table 2** Partitioning of EET couplings computed between the lowest-lying bright  ${}^1\pi\pi^*$  states of ethylene molecules in stacked alignment at various levels of approximation to the TI/CIS method. Indentation indicates constituents of a given term or its approximation. All the results, given in  $\text{cm}^{-1}$ , were computed for the selected intermolecular distances  $R_{\text{AB}}$  (given in Å) assuming the 6-31G(d) basis set. The superscript 'M' indicates the values estimated using the Mulliken approximation: eqn (52) for the EOP-TI model and eqn (50) for the remaining models. The  $V^{\text{TI}(3)}$  values in the EOP-TI results were computed assuming either the distributed multipolar expansion truncated on  $|R|^{-5}$  terms or on atomic monopoles (values in parentheses) in  $V_{\text{CT}}$  calculations

at the equilibrium geometry and becomes qualitative at shorter intermolecular distances, as the  $V_{\text{Exch}}^{\text{M}}$  term underestimates significantly the magnitude of exchange coupling (*cf.* Tables 2 and 3). It is interesting to note here that the simplified model of  $V_{\text{Exch}}$  in the EOP-TI model from eqn (52) works qualitatively well for both studied systems, as the coupling strength is systematically underestimated. In the case of indirect coupling terms, the Mulliken approximation can be utilized to estimate the magnitude of  $V_{\text{CT}}$  matrix elements and, hence, the third-order  $V^{\text{TI}(3)}$  terms. In fact, this approximation is necessary in the EOP-TI model. However, it works very well and provides the quantitative accuracy of  $V_{\text{CT}}^{\text{M}}$  terms at equilibrium geometry but becomes more approximate in the region of large overlap of

molecular wavefunctions (*cf.* Table 4). It is also interesting to note that the magnitudes of  $V_{\text{CT}}^{\text{M}}$  terms, calculated in the EOP-TI method assuming the distributed multipolar expansion truncated either on  $|R|^{-5}$  terms or on atomic monopoles (values in parentheses), are virtually identical at equilibrium geometry and remain very close even at shorter distances.

In Table 4 the relevant Hamiltonian matrix elements necessary for calculating indirect coupling terms are reported for the studied model systems at selected geometries and levels of TI approximation. The magnitudes of  $V_{\text{ET1}}$  and  $V_{\text{ET2}}$  terms are identical due to the symmetry of the studied complexes and the same applies to the corresponding HT terms. It should be noted that the signs of these terms depend on the arbitrary

**Table 4** Electron, hole and charge transfer (ET, HT and CT, respectively) Hamiltonian matrix elements calculated at various levels of approximation for EET couplings between the lowest-lying bright  ${}^1\pi\pi^*$  states in ethylene and 7AC dimers in stacked alignment. All the results, given in  $\text{cm}^{-1}$ , were computed for the selected intermolecular distances  $R_{\text{AB}}$  (given in Å) assuming the 6-31G(d) basis set. The superscript 'M' indicates the values estimated using the Mulliken approximation: eqn (52) for the EOP-TI model and eqn (50) for the remaining models. The  $V_{\text{CT}}$  values in the EOP-TI results were computed assuming the distributed multipole expansion truncated either on  $|R|^{-5}$  terms or on atomic monopoles (values in parentheses)

phases of frontier orbitals (this is true for all the TI components). However, this does not affect the total magnitude of EET coupling. In this work we adhere to certain convention for which the total coupling is positive. Unfortunately, we have found certain discrepancies between our results and those reported by Fujimoto.<sup>31</sup> A careful analysis of the formula for the CT term given in eqn (40) shows that it should always be negative. A similar inspection of the formulas for ET and HT terms (eqn (24) and (36)) shows that, even though their signs may vary, the resultant  $V^{\text{TI}(2)}$  and  $V^{\text{TI}(3)}$  terms, defined in eqn (55), should have opposite signs. Fujimoto, however, reported both terms as having the same positive sign. We were also unable to reproduce the total magnitudes of  $V^{\text{TI}(\mathcal{F}_0^{\text{DFI}})}$ , which, as shown in Fig. 3 of Fujimoto's paper,<sup>31</sup> seem to be virtually identical to  $V^{\text{ESD}}$ . This is quite surprising considering the crudeness of approximation (frontier orbitals and block-localized Fock matrix). For instance our TDFI-TI results, reported in Table 1, show a relative error of about 3% at a distance of 3 Å.

## 4 Summary and a few concluding remarks

In this work, the effective one-electron potential operators technique of electron-repulsion integral elimination was used to introduce a new efficient variant of the transfer integral approach to calculate excitation energy transfer couplings. The EOP technique was adopted to estimate the EET couplings between singlet bright states in ethylene and 7-aminocoumarine dimers assuming the TI/CIS super-exchange model of Scholes and Harcourt within the frontier orbital approximation introduced earlier by Fujimoto.

It was shown that the EOP-TI/CIS method provides semi-quantitative results even at short distances and the computational cost is reduced by at least 3 orders of magnitude, as compared to the TDFI-TI/CIS calculations. This speedup is expected to increase with the system size as in the 7-aminocoumarine dimer the EOP-TI/CIS calculations were nearly 20 000 times faster than the most efficient variant of the TDFI-TI/CIS approach.

In fact, the EOP-TI/CIS method was found to be so efficient that it is readily applicable in molecular dynamics simulations. This is due to its EOP-based formulation which defines the EET coupling in terms of effective fragment potential parameters which could be determined prior to the simulation in a fully automated fashion for a given excited state of each of the interacting molecules. We note here that the computational costs can be further reduced by applying much smaller tailored density fitting auxiliary EOP basis sets.<sup>32</sup>

It is anticipated here that the EOP-TI/CIS method can be extended to a general multi-state model with multiple electron-hole pairs and bridging CT states,<sup>19,20</sup> because the mathematical form of ERIs within the TIs remains the same as that in the current EOP-TI/CIS model. In other words the extended density fitting EOP method is in principle applicable to any ET- and HT-like matrix elements, whereas the Mulliken approximation and distributed multipole expansion are applicable to any CT-like matrix element.

## Appendices

### A Explicit formulae for ET and HT EOP matrix elements

As developed in ref. 32, the matrix elements of the EOP operators are computed from the EDF scheme, according to which (in general the TI/CIS case)

$$V_{\xi;N}^{\text{X;M}} \approx \sum_{\xi\xi' \in \text{a}} [\mathbf{R}_{\text{ma}}^{\text{X;M;N}}]_{\xi\xi'} [\mathbf{S}_{\text{aa}}^{-1}]_{\xi\xi'} \mathcal{J}_{\xi\xi';N}^{\text{X;M}}, \quad (58)$$

where

$$\mathbf{R}_{\text{ma}}^{\text{X;M;N}} = \mathbf{T}_{\text{mX}}^{\text{X;M;N}} \mathbf{S}_{\text{XX}}^{-1} \left\{ \mathbf{T}_{\text{mX}}^{\text{X;M;N}} \right\}^{\dagger} \mathbf{S}_{\text{ma}}. \quad (59)$$

In the above equations, the auxiliary matrices are defined by

$$\mathbf{T}_{\text{mX}}^{\text{X;M;N}} = \mathbf{S}_{\text{mm}}^{-1} \mathbf{S}_{\text{ma}} \mathbf{T}_{\text{aX}}^{\text{X;M;N}} \mathbf{S}_{\text{XX}}^{-1}, \quad (60a)$$

$$\mathbf{S}_{\text{XX}}^{-1} = (\{\mathbf{T}_{\text{aX}}^{\text{X};\text{M};\text{N}}\}^\dagger \mathbf{S}_{\text{am}} \mathbf{S}_{\text{mm}}^{-1} \mathbf{S}_{\text{ma}} \mathbf{T}_{\text{aX}}^{\text{X};\text{M};\text{N}})^{\frac{1}{2}}, \quad (60b)$$

$$\mathbf{T}_{\text{aX}}^{\text{X};\text{M};\text{N}} = \mathbf{S}_{\text{aa}}^{-1} \mathcal{Q} \mathbf{U}_{\text{aX}}^{\text{X};\text{M};\text{N}}, \quad (60c)$$

where the overlap matrix block corresponding to two AO basis sets 'x' and 'y' is

$$[\mathbf{S}_{\text{xy}}]_{\eta\xi} \equiv \int \varphi_{\eta \in x}^*(\mathbf{r}) \varphi_{\xi \in y}(\mathbf{r}) d\mathbf{r}, \quad (61)$$

and the symbol 'm' denotes the (generally incomplete) auxiliary EOP AO basis set, whereas the symbol 'a' denotes the intermediate AO basis set that approximately fulfills the resolution of identity. The similarity transformation matrix  $\mathbf{T}_{\text{aX}}^{\text{X};\text{M};\text{N}}$  is obtained from the eigenvectors of the co-variance matrix,  $\mathbf{W}_{\text{aa}}^{\text{X};\text{M};\text{N}}$ :

$$\begin{aligned} \mathbf{W}_{\text{aa}}^{\text{X};\text{M};\text{N}} &= \mathbf{S}_{\text{aa}}^{-\frac{1}{2}} \mathbf{f}_{\text{a};\text{N}}^{\text{X};\text{M}} \left\{ \mathbf{f}_{\text{a};\text{N}}^{\text{X};\text{M}} \right\}^\dagger \mathbf{S}_{\text{aa}}^{-\frac{1}{2}} \\ &= \mathbf{U}_{\text{aX}}^{\text{X};\text{M};\text{N}} \mathbf{g}_{\text{XX}}^{\text{X};\text{M};\text{N}} \left\{ \mathbf{U}_{\text{aX}}^{\text{X};\text{M};\text{N}} \right\}^\dagger \end{aligned} \quad (62)$$

The operator  $\mathcal{Q}$  in eqn (60c) selects only eigenvectors (columns of)  $\mathbf{U}_{\text{aX}}^{\text{X};\text{M};\text{N}}$  associated with the non-vanishing eigenvalues stored in the diagonal matrix  $\mathbf{g}_{\text{XX}}^{\text{X};\text{M};\text{N}}$ . The elements of vector  $\mathbf{f}_{\text{a};\text{N}}^{\text{X};\text{M}}$  for M = ET1, ET2, HT1 and HT2 and N = H, L and HL are given by

$$f_{\alpha;\text{L}}^{\text{X};\text{ET}} = \sum_{\beta} C_{\beta\text{L}}^{\text{X}} G_{\alpha\beta}^{\text{X}}, \quad (63a)$$

$$f_{\alpha;\text{HL}}^{\text{X};\text{ET}} = f_{\alpha;\text{L}}^{\text{X};\text{ET}} + \sum_{\beta\gamma\delta} (\alpha\beta|\gamma\delta) \left\{ 2C_{\beta\text{H}}^{\text{X}} C_{\gamma\text{L}}^{\text{X}} - C_{\beta\text{L}}^{\text{X}} C_{\gamma\text{H}}^{\text{X}} \right\} C_{\delta\text{H}}^{\text{X}}, \quad (63b)$$

$$f_{\alpha;\text{H}}^{\text{X};\text{HT}} = - \sum_{\beta} C_{\beta\text{H}}^{\text{X}} G_{\alpha\beta}^{\text{X}}, \quad (63c)$$

$$f_{\alpha;\text{HL}}^{\text{X};\text{HT}} = f_{\alpha;\text{H}}^{\text{X};\text{HT}} + \sum_{\beta\gamma\delta} (\alpha\beta|\gamma\delta) \left\{ 2C_{\beta\text{L}}^{\text{X}} C_{\gamma\text{H}}^{\text{X}} - C_{\beta\text{H}}^{\text{X}} C_{\gamma\text{L}}^{\text{X}} \right\} C_{\delta\text{L}}^{\text{X}}. \quad (63d)$$

Here, the auxiliary one-electron operator  $\mathcal{G}_0^{\text{X}}$  represented in space spanned by the intermediate and primary AO basis sets needs to be computed. This can be done by inverting the following matrix equation to obtain  $G_{\alpha\beta}^{\text{X}}$ :

$$\begin{aligned} \sum_{\beta} C_{\beta\text{U}}^{\text{X}} G_{\alpha\beta}^{\text{X}} &= \sum_{\beta} C_{\beta\text{U}}^{\text{X}} \left( \frac{1}{2} t_{\alpha\beta} + V_{\text{nuc};\alpha\beta}^{\text{X}} \right) \\ &+ \sum_{\beta\gamma\delta} (\alpha\beta|\gamma\delta) \left[ P_{\delta\gamma}^{\text{X}(\text{g})} C_{\beta\text{U}}^{\text{X}} - \frac{1}{2} P_{\beta\gamma}^{\text{X}(\text{g})} C_{\delta\text{U}}^{\text{X}} \right], \end{aligned} \quad (64)$$

where

$$t_{\alpha\beta} = -\frac{1}{2} \int \varphi_{\alpha}^*(\mathbf{r}) \nabla_{\mathbf{r}}^2 \varphi_{\beta}(\mathbf{r}) d\mathbf{r} \quad (65a)$$

and

$$V_{\text{nuc};\alpha\beta}^{\text{X}} = - \sum_{x \in \text{X}} Z_x \int \frac{\varphi_{\alpha}^*(\mathbf{r}) \varphi_{\beta}(\mathbf{r})}{|\mathbf{r} - \mathbf{r}_x|} d\mathbf{r}. \quad (65b)$$

In the above,  $Z_x$  is the atomic number of the  $x$ th atom and  $\nabla_{\mathbf{r}}^2 \equiv \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$ . In this work, the auxiliary EOP basis set was assumed to be identical to the intermediate basis set, *i.e.*, conventional density fitting was used with  $[\mathbf{R}_{\text{ma}}^{\text{X};\text{M};\text{N}}]_{\xi\epsilon} = \delta_{\xi\epsilon}$ .

However, by utilizing the general EDF scheme from eqn (58), additional reduction of computational cost is possible through optimization of the auxiliary EOP basis set.

## B Effective parameters for Dexter coupling

The Euclidean rotation of a shell of  $n_p$  atomic orbitals with angular momentum  $p$  is given by

$$|\mathbf{p}'\rangle = \mathbf{R}^{(p)} |\mathbf{p}\rangle, \quad (66)$$

in which the shell  $|\mathbf{p}\rangle \equiv \{\dots, \varphi_{\mu}(\mathbf{r}), \dots\}$  and  $\mathbf{R}^{(p)}$  is the  $n_p \times n_p$  rotation matrix. Consider now the integrals of type  $(\mathbf{pp}|\mathbf{qq})$ . It immediately follows that

$$(\mathbf{p}'\mathbf{p}'|\mathbf{q}'\mathbf{q}') = \mathbf{R}^{(p)} \otimes \mathbf{R}^{(p)} \otimes \mathbf{R}^{(q)} \otimes \mathbf{R}^{(q)} :: (\mathbf{pp}|\mathbf{qq}) \quad (67)$$

and the  $\mathbf{Q}$  matrix from eqn (52) can be readily constructed by using

$$\mathbf{Q} \equiv (\text{diag}[\mathbf{pp}] | \text{diag}[\mathbf{qq}]), \quad (68)$$

where 'diag' denotes taking the diagonal of a matrix. The symbol '::' denotes the fourfold tensor contraction  $[\mathbf{a} \otimes \mathbf{b} \otimes \mathbf{c} \otimes \mathbf{d} :: \mathbf{B}]_{i'j'k'l'} \equiv \sum_{ijkl} a_{i'} b_{j'} c_{k'} d_{l'} B_{ijkl}$  for arbitrary matrices  $\mathbf{a}$ ,  $\mathbf{b}$ ,  $\mathbf{c}$ ,  $\mathbf{d}$  and a fourth-rank tensor  $\mathbf{B}$ . Note that the number of  $(\mathbf{pp}|\mathbf{qq})$  integrals scales quadratically with the size of the basis set which means that memory requirements to store them on a disk or in a file are relatively small and comparable to sizes of typical AO matrices. Therefore, all the  $(\mathbf{pp}|\mathbf{qq})$  integrals can be treated as effective fragment parameters and the computational cost of superimposition onto a target geometry, which is described by eqn (68) and (67), is relatively small.
