# Characterization of two photon excited fragment spectroscopy (TPEFS) for $\text{HNO}_3$ detection in gas-phase kinetic experiments<sup>†</sup>

Damien Amedro, Arne J. C. Bunkan, Terry J. Dillon and John N. Crowley  \*

We have developed and tested two-photon excited fragment spectroscopy (TPEFS) for detecting  $\text{HNO}_3$  in pulsed laser photolysis kinetic experiments. Dispersed (220–330 nm) and time-dependent emission at  $(310 \pm 5)$  nm following the 193 nm excitation of  $\text{HNO}_3$  in  $\text{N}_2$ , air and He was recorded and analysed to characterise the  $\text{OH}(\text{A}^2\Sigma)$  and  $\text{NO}(\text{A}^2\Sigma^+)$  electronic excited states involved. The limit of detection for  $\text{HNO}_3$  using TPEFS was  $\sim 5 \times 10^9$  molecule  $\text{cm}^{-3}$  (at 60 torr  $\text{N}_2$  and 180  $\mu\text{s}$  integration time). Detection of  $\text{HNO}_3$  using the emission at  $(310 \pm 5)$  nm was orders of magnitude more sensitive than detection of NO and  $\text{NO}_2$ , especially in the presence of  $\text{O}_2$  which quenches  $\text{NO}(\text{A}^2\Sigma^+)$  more efficiently than  $\text{OH}(\text{A}^2\Sigma)$ . While  $\text{H}_2\text{O}_2$  (and possibly  $\text{HO}_2$ ) could also be detected by 193 nm TPEFS, the relative sensitivity (compared to  $\text{HNO}_3$ ) was very low. The viability of real-time TPEFS detection of  $\text{HNO}_3$  using emission at  $(310 \pm 5)$  nm was demonstrated by monitoring  $\text{HNO}_3$  formation in the reaction of  $\text{OH} + \text{NO}_2$  and deriving the rate coefficient,  $k_2$ . The value of  $k_2$  obtained at 293 K and pressures of 50–200 torr is entirely consistent with that obtained by simultaneously measuring the OH decay and is in very good agreement with the most recent literature values.

## 1. Introduction

$\text{HNO}_3$  is an important atmospheric trace gas and its ultra-violet photo-dissociation has been the subject of numerous studies.<sup>1</sup> The photo-dissociation of  $\text{HNO}_3$  can be divided into three channels, leading to formation of OH, O-atoms or H-atoms, the relative importance of which depends on the wavelength.

At wavelengths ( $\lambda$ ) greater than 250 nm, the  $n-\pi^*$  transition (to the  $1^1\text{A}''$  electronic excited state) in  $\text{HNO}_3$  leads to photo-dissociation into predominantly OH +  $\text{NO}_2$  ( $\Phi_{250\text{nm}}^{\text{I}} > 0.97$ ) with a weak contribution from O-atom formation ( $\Phi_{250\text{nm}}^{\text{II}} = 0.03$ ). The formation of  $\text{NO}_3$  and H photo-fragments (Channel III)

at these wavelengths has been assigned an upper limit of  $\Phi_{250\text{nm}}^{\text{III}} < 0.012$ .<sup>2</sup>

At  $\lambda < 250$  nm,  $\text{HNO}_3$  is excited to the  $2^1\text{A}'$  electronic excited through an  $\pi-\pi^*$  transition. At 193 nm, channel II becomes the main photo-dissociation channel with quantum yields of  $\Phi_{193\text{nm}}^{\text{II}} = 0.67$  and  $\Phi_{193\text{nm}}^{\text{I}} = 0.33$ .<sup>2-5</sup> OH fragments formed in channel I are produced in their vibrational ground state with little rotational excitation,<sup>6-9</sup> whereas the  $\text{NO}_2$  co-fragment is formed either in its ground state, or in its  $1^2\text{B}_2$  electronically excited state (yield < 1.0%). The ground state  $\text{NO}_2$  thus formed is sufficiently energy rich to decompose to NO and  $\text{O}(\text{3}^{\text{P}})$ . Experimental determinations of the yield of  $\text{O}(\text{1}^{\text{D}})$  in channel II vary between 0.54 and 0.28.<sup>2,5</sup> At shorter wavelengths,  $\lambda < 155$  nm, OH can be formed in an electronically excited state<sup>10,11</sup> in a single photon process.

In a series of papers by Stuhl and co-workers studying the excitation of  $\text{HNO}_3$  at 193 nm,<sup>12-14</sup> it was shown that electronically excited OH,  $\text{OH}(\text{A})$ , was produced in a sequential, two-photon process. From experimental observations, spin conservation and energy considerations the authors were able to demonstrate that  $\text{OH}(\text{A})$  was not formed directly but *via* the photolysis of electronically excited HONO, probably in its metastable lower triplet state ( $\text{a}^3\text{A}''$ ). They used these findings to develop a new method (laser-photolysis fragment-fluorescence, LPFF) for the measurement of  $\text{HNO}_3$  in the atmosphere.<sup>15,16</sup> Recently, Winiberg *et al.*<sup>17</sup> reported results

Division of Atmospheric Chemistry, Max Planck-Institut für Chemie, 55128, Mainz, Germany. E-mail: john.crowley@mpic.de

† Electronic supplementary information (ESI) available. See DOI: 10.1039/d1cp00297j

from the multi-photon photolysis of  $\text{HNO}_3$  at 193 and 248 nm and reported dispersed OH and NO fluorescence spectra. They demonstrated that OH emission from a 2-photon excitation of  $\text{HNO}_3$  was not only observed upon excitation at 193 nm but also at 248 nm. In a previous study<sup>18</sup> from our group (on the reaction between OH and  $\text{HNO}_3$ ), the TPEFS method was used to check for  $\text{HNO}_3$  concentration gradients across the reactor at low temperature ( $220 \text{ K} < T < 250 \text{ K}$ ).

In this paper, we investigate the two-photon photodissociation of  $\text{HNO}_3$  at 193 nm and demonstrate the application of two-photon excited fragment spectroscopy (TPEFS) detection of  $\text{HNO}_3$  in real-time (flash photolysis) kinetic studies. For the latter we re-measured the well-known rate coefficient<sup>19,20</sup> of the reaction between OH and  $\text{NO}_2$  (R2) by monitoring the  $\text{HNO}_3$  product by TPEFS and also by near-simultaneous detection of OH *via* Laser Induced Fluorescence (LIF):

The three-body association reaction of OH with  $\text{NO}_2$  is known to proceed *via* two product channels ((R2a) and (R2b)) forming mainly nitric acid ( $\text{HNO}_3$ ) but with a contribution from peroxy nitrous acid (HOONO).<sup>21,22</sup> At room temperature and a pressure of 100 mbar the rate coefficients of the two reactions have been evaluated as:  $k_{2a} = 3.0 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  and  $k_{2b} = 2.0 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ .<sup>23</sup> HOONO is thermally unstable with a room-temperature lifetime w.r.t. decomposition to OH +  $\text{NO}_2$  of  $\approx 10 \text{ s}$ . However, on the milli-second timescale of our experiments it can be considered a stable product. As the application of TPEFS in kinetic studies of  $\text{HNO}_3$  will depend on its selectivity, we characterised the sensitivity of TPEFS at 193 nm for detection of several other trace gases, including NO and  $\text{NO}_2$  which are often present (as impurities or products) in reaction systems involving  $\text{HNO}_3$ .

## 2. Experimental

All measurements were performed at 293 K on the PLP-LIF apparatus shown in Fig. 1. Several features of the setup have been described in detail elsewhere.<sup>24</sup> The main modifications to the present set-up are (1) the incorporation of a gated CCD camera for dispersed fluorescence measurement and (2) an additional (193 nm) excimer laser.

### 2.1 Radical generation, fluorescence excitation and detection

Laser-light is coupled in/out of the thermostatted, multi-axis reaction cell (volume  $\sim 500 \text{ cm}^3$ ) *via* Brewster-angle quartz windows. Pulsed ( $\sim 20 \text{ ns}$ ) 248 nm light from a KrF-excimer laser (Coherent COMPex 205F) provided a source of OH radicals (*e.g.* *via*  $\text{H}_2\text{O}_2$  photolysis, see later).

$\text{HNO}_3$  was detected following excitation/dissociation at 193 nm using an ArF excimer laser (Coherent COMPex Pro 201F). A focal lens ( $f = 50 \text{ cm}$ ) was used to mildly focus the laser in the middle of the reactor to enhance the  $\text{HNO}_3$  detection sensitivity. Typical photon fluxes at 193 nm varied from

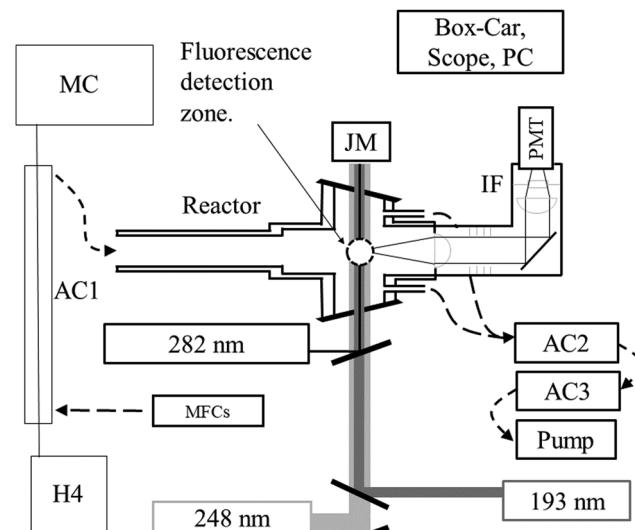

Fig. 1 Schematic of the combined PLP-LIF and PLP-TPEFS set-up. PMT: photomultiplier, IF: interference filter, AC1: absorption cell with  $l = 110 \text{ cm}$  (240–400 nm), AC2: absorption cell with  $l = 34.8 \text{ cm}$  (213.86 nm); AC3: absorption cell with  $l = 43.8 \text{ cm}$  (184.95 nm). MC: monochromator with diode-array detector. H4: Halogen lamp. 193, 248 and 282 nm pulses were provided by excimer lasers and a YAG-pumped dye-laser, respectively. Dispersed fluorescence was collected on an axis orthogonal to the page using a lens/optical-fibre set-up. Dashed lines indicate direction of gas-flow.

30 to 50 mJ  $\text{cm}^{-2}$  (measured at the exit of the photolysis cell). OH was excited at 282 nm using a YAG-pumped Dye-Laser (Quantel Brilliant B/Lambda-Physik ScanMate II). All three lasers operated at 10 Hz. The PMT signal was accumulated using either a box-car integrator (Stanford Research Systems, SR 250) for kinetic measurements or a digital oscilloscope (Tektronix TDS 3014C, 100 MHz) for recording time-resolved fluorescence signals.

The fluorescing volume at the reactor centre was imaged *via* a 5 cm diameter quartz lens on the major axis of the cell onto a photomultiplier tube screened with a 280 nm long-pass filter (BG26) and a  $(310 \pm 5) \text{ nm}$  interference filter. A lens/optical fibre set up on an orthogonal axis transmitted fluorescence from the same volume to the entrance slit of a 0.5 m monochromator (Acton Research 500) equipped with a gated, intensified CCD camera (Roper Scientific, PMax) for measurement of dispersed fluorescence. Spectra were recorded using gratings with either 300 or 1200 lines  $\text{mm}^{-1}$  resulting in spectral ranges of  $\sim 80 \text{ nm}$  (at  $\sim 1.2 \text{ nm}$  resolution) or  $\sim 20 \text{ nm}$  (at  $\sim 0.4 \text{ nm}$  resolution), respectively. Spectral resolution determination and wavelength calibration was carried out using a low pressure Hg-lamp.

### 2.2 Reagent gas concentrations

The concentrations of reagent gases were monitored using three different, on-line optical absorption set-ups. Absorption by  $\text{NO}_2$  (400–450 nm) was measured in an absorption cell ( $l = 110 \text{ cm}$ ) using a halogen lamp as light source and a 0.5 m monochromator/diode array camera as detector.  $\text{NO}_2$  concentrations

were derived by least-squares fitting to a literature reference spectrum degraded to the same resolution.<sup>25</sup> The concentration of  $\text{H}_2\text{O}_2$  was determined from its optical absorption at 213.86 nm (low pressure Zn-lamp,  $l = 34.8$  cm) using an absorption cross-section of  $\sigma_{213.9}(\text{H}_2\text{O}_2) = 3.3 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ .<sup>26</sup> The concentrations of  $\text{HNO}_3$  and  $\text{H}_2\text{O}$  were determined from their optical absorption at 184.95 nm (low pressure Hg-lamp,  $l = 43.8$  cm) using  $\sigma_{184.95}(\text{HNO}_3) = 1.63 \times 10^{-17} \text{ cm}^2 \text{ molecule}^{-1}$ ,<sup>18,27,28</sup> and  $\sigma_{184.95}(\text{H}_2\text{O}) = 7.14 \times 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ .<sup>29</sup> In the same set-up, the ozone concentration was measured at 253.65 nm using a cross-section of  $1.1 \times 10^{-17} \text{ cm}^2 \text{ molecule}^{-1}$ .<sup>23</sup>

### 2.3 Chemicals

Bottled  $\text{N}_2$  (Westfalen, 5.0) was used without further purification.  $\text{H}_2\text{O}_2$  (AppliChem, 50 wt%) was concentrated by vacuum distillation.  $\text{NO}_2$  was prepared by reacting  $\sim 50$  torr of  $\text{NO}$  with a large excess of  $\text{O}_2$  in a dried glass bulb. The  $\text{NO}_2$  was then condensed at liquid  $\text{N}_2$  temperature and excess  $\text{O}_2$  and  $\text{NO}$  were removed by pumping. The resulting  $\text{NO}_2$  was stored as a mixture of 5%  $\text{NO}_2$ , 10%  $\text{O}_2$  and 85%  $\text{N}_2$ . Anhydrous nitric acid was prepared by mixing  $\text{KNO}_3$  (Sigma Aldrich, 99%) and  $\text{H}_2\text{SO}_4$  (Roth, 98%), and condensing the  $\text{HNO}_3$  vapour into a liquid nitrogen trap. Anhydrous nitric acid was kept at 252 K between experiments.

## 3. Results and discussion

### 3.1 Fluorescence from $\text{HNO}_3$ at $(310 \pm 5)$ nm in $\text{N}_2$

Our TPEFS measurement of  $\text{HNO}_3$  monitors a fluorescence signal that is transmitted through an interference filter  $(310 \pm 5)$  nm) that biases detection to the strong  $\text{OH}$  (0,0) emission lines. Fig. 2 (upper panel) displays the averaged (500 laser pulses), time-resolved signal due to three different concentrations of  $\text{HNO}_3$  (in a flow of  $\text{N}_2$  at a total pressure of 100 torr) which were quantified by absorption at 184.95 nm. The integrated fluorescence signals are plotted against  $\text{HNO}_3$  concentration in the lower panel of Fig. 2 which indicates that, for  $[\text{HNO}_3]$  up to  $2 \times 10^{14} \text{ molecule cm}^{-3}$  and under these experimental settings (PMT voltage, focused 193 nm laser light), the fluorescence signal is proportional to  $[\text{HNO}_3]$ . At 60 torr  $\text{N}_2$ , we achieved a limit of detection for  $\text{HNO}_3$  of  $5 \times 10^9 \text{ molecule cm}^{-3}$  at  $1\sigma$  for 2 min of signal accumulation, which results (at 10 Hz) in a total signal integration time of 180  $\mu\text{s}$ .

The dependence of the TPEFS signal on the 193 nm laser energy ( $E_{193\text{nm}}$ , varied by changing the high-voltage of the excimer laser or placing fine metal mesh in the beam at the exit of the laser) is displayed in Fig. 3. The relative change in energy was measured by splitting part of the laser-beam to a photo-diode with a linear response in the range measured.

The signal does not follow the expected quadratic dependence on laser energy for a two-photon process, but varies linearly, with a negative offset. This is a result of saturation of the first electronic transition due to the focused 193 nm radiation and the large absorption cross-section of  $\text{HNO}_3$ . The apparent, negative offset is

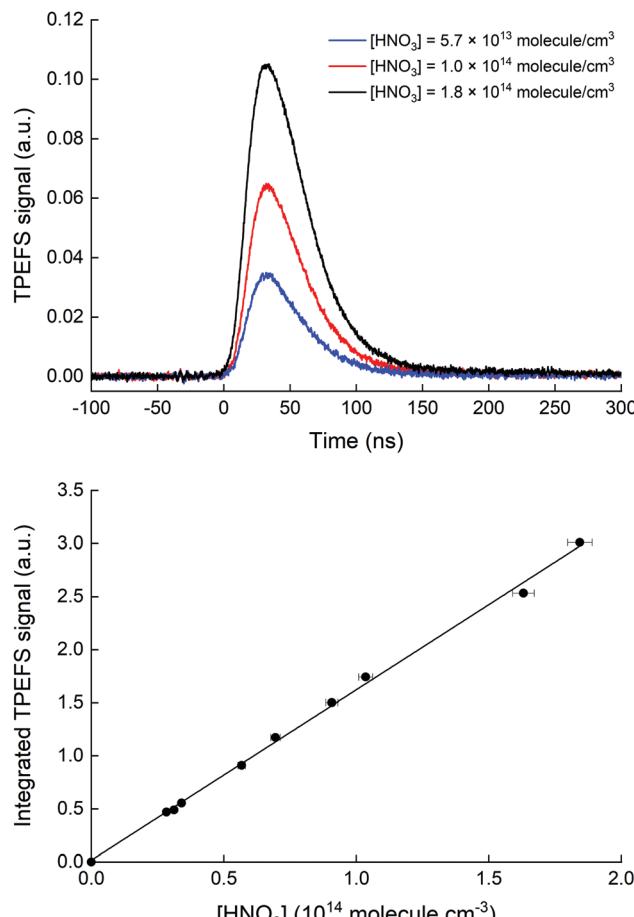

Fig. 2 Upper panel: Time resolved fluorescence signal detected by the PMT and  $(310 \pm 5)$  nm interference filter at 100 torr  $\text{N}_2$  and room temperature  $(298 \pm 2 \text{ K})$ . Lower panel: TPEFS signal  $(0\text{--}150 \text{ ns})$  versus  $\text{HNO}_3$  concentration. The straight line is a linear regression to the data.

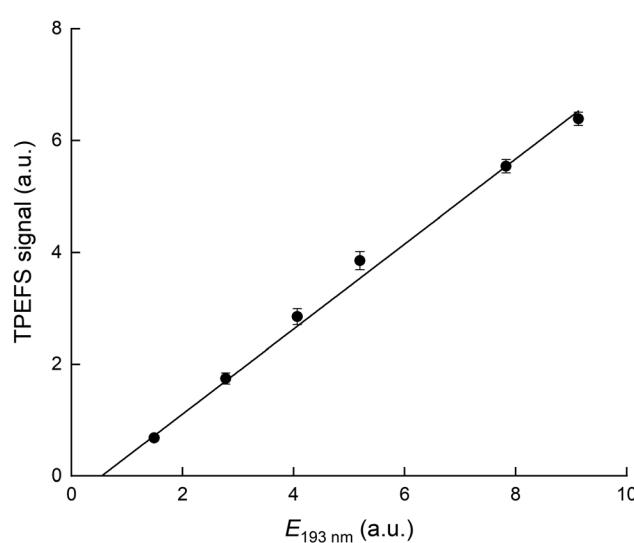

Fig. 3 TPEFS signal as a function of 193 nm laser energy. The solid line is a linear regression. The experimental conditions were: 100 torr  $[\text{N}_2]$  and  $[\text{HNO}_3] = 1.1 \times 10^{13} \text{ molecule cm}^{-3}$ .

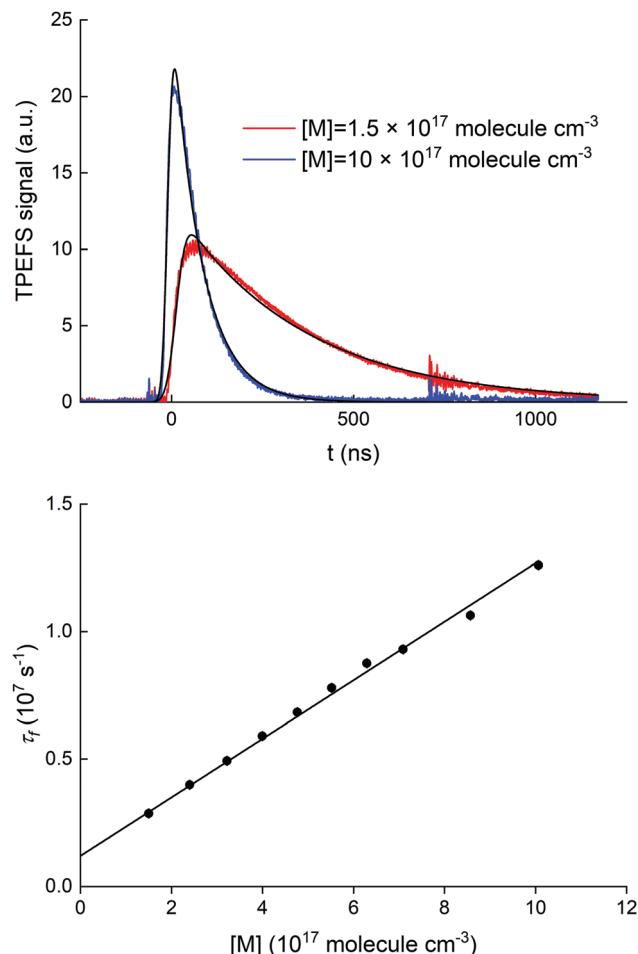

Fig. 4 Upper panel: Time resolved fluorescence signal detected by the PMT through the  $(310 \pm 5)$  nm interference filter following the 193 nm excitation of  $\text{HNO}_3$ . The black, solid lines correspond to fits using (E2). Lower panel: Fluorescence decay constant ( $\tau_f$ ) versus bath gas ( $\text{N}_2$ ) concentration. The black solid line corresponds to a linear regression used for fitting  $\tau_f$ . Error bars are  $2\sigma$  statistical only.

a manifestation of non-linearity at low laser energy where the first transition is not yet saturated. Our energy dependence contrasts that reported by Winiberg *et al.*<sup>17</sup> who observed a quadratic dependence on laser fluence. This difference is likely related to their use of much lower laser fluences (factor  $\sim 15$ ) and (potentially) a less focused laser beam.

A series of auxiliary experiments was conducted to examine the quenching of the fluorescence by  $\text{N}_2$ . The fluorescence signals, recorded for  $[\text{HNO}_3] = 5.0 \times 10^{12}$  molecule  $\text{cm}^{-3}$ , at  $\text{N}_2$  densities between  $1.5$  and  $10 \times 10^{17}$  molecule  $\text{cm}^{-3}$  ( $\sim 4$  and  $\sim 30$  torr at  $293\text{ K}$ ), are displayed in the upper panel of Fig. 4.

Assuming that the fluorescence corresponds to the  $(0,0)$  transition from the  $\text{OH}(\text{A})$  state we can write:

$$d[\text{OH}(\text{A})]/dt = k_f + k_q(\text{N}_2)[\text{N}_2] + k_q(\text{HNO}_3)[\text{HNO}_3] \quad (1)$$

where  $k_f$  is the fluorescence decay rate constant ( $\text{s}^{-1}$ ) and is the inverse of the radiative lifetime,  $\tau_f$ .  $k_q(\text{N}_2)$  is the quenching rate constant for  $\text{N}_2$  bath gas,  $k_q(\text{HNO}_3)$  is the quenching rate constant for  $\text{HNO}_3$  ( $k_q$  in units of  $\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ ),

$[\text{HNO}_3]$  and  $[\text{N}_2]$  are the concentrations of  $\text{HNO}_3$  and  $\text{N}_2$  (both in molecule  $\text{cm}^{-3}$ ). The fluorescence profiles in Fig. 4 were fitted to eqn (E2), which is a convolution of a Gaussian function and a simple exponential decay:

$$S = S_0 \exp\left(\left(\frac{\alpha^2}{\beta^2}\right) - \frac{(t - t_0)}{\beta}\right) \times \left(1 - \text{erf}\left(\alpha^2 - \frac{\beta \times (t - t_0)}{\sqrt{2} \times \alpha \times t}\right)\right) \quad (2)$$

where  $S_0$  is the signal intensity,  $\alpha$  (s) is the width of the Gaussian function,  $\beta$  is the fluorescence decay lifetime in s and thus the reciprocal of the decay constant ( $\tau_f$ ),  $t_0$  is the time (s) at the onset of the signal rise and erf is the error function. This equation allows us to account for the finite pulse width of the 193 nm excimer laser ( $\sim 20$  ns), the response time for the PMT ( $\sim 20$  ns) and the oscilloscope bandwidth (100 MHz) which result in non-instantaneous build-up of signal. The slope of the plot of  $\tau_f$  versus  $[\text{N}_2]$  (lower panel of Fig. 4), is the quenching rate constant, here determined as  $k_q(\text{N}_2) = (1.1 \pm 0.1) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ . This is in good agreement with the value of  $(1.3 \pm 0.4) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  reported by Kenner *et al.*<sup>14</sup> for collisional deactivation of rotational levels  $N' = 1\text{--}16$  of the  $v' = 0$  state of  $\text{OH}(\text{A})$  generated by the 193 nm excitation of  $\text{HNO}_3$ . It is approximately 3 times smaller than those derived from experiments in which  $\text{OH}(\text{A}, v' = 0)$  was formed rotationally cold ( $N' < 4$ )<sup>30,31</sup> and thus in qualitative agreement with previous observations that the electronic quenching rate coefficient decreases as the rotational level increases.<sup>32,33</sup>

At an  $\text{HNO}_3$  concentration of  $5 \times 10^{12}$  molecule  $\text{cm}^{-3}$  and using the quenching rate constant reported by Kenner *et al.*<sup>14</sup> of  $k_q(\text{HNO}_3) = 5.9 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ , we calculate  $k_q(\text{HNO}_3)[\text{HNO}_3] \approx 3000 \text{ s}^{-1}$  which thus represents a negligible contribution ( $< 1\%$ ) to the intercept of  $(1.2 \pm 0.1) \times 10^6 \text{ s}^{-1}$ . The intercept can thus be equated to  $k_f$  and results in a radiative lifetime of about  $(840 \pm 90)$  ns (errors are  $2\sigma$  statistical). This value is somewhat larger than the natural fluorescence lifetime of  $(688 \pm 21)$  ns<sup>34</sup> for the  $\text{A}^2\Sigma(v' = 0) \rightarrow \text{X}^2\Pi(v'' = 0)$  transition, indicating that the nascent  $\text{OH}(\text{A}^2\Sigma(v' = 1,2))$  formed from 193 nm, two-photo excitation of  $\text{HNO}_3$  undergoes vibrational energy transfer down to  $\text{A}^2\Sigma(v' = 0)$  on the same timescale as the fluorescence emission and the electronic quenching. This was confirmed by the observation of an increase in the signal intensity as the pressure was increased although  $[\text{HNO}_3]$  was kept constant.

### 3.2 Dispersed fluorescence spectrum of $\text{HNO}_3$

In Fig. 5 we display the emission spectrum (220 to 330 nm) obtained in the excitation of  $\text{HNO}_3$  at 193 nm in He bath gas at 90 torr. The individual spectra for each  $\sim 20$  nm wide spectral region are the average of 2000 single spectra (obtained at 10 Hz) with a gate width (*i.e.* CCD exposure time) of 1  $\mu\text{s}$  and were recorded 45 ns after the 193 nm laser pulse. The features are assigned to emission from excited OH and NO. Note that the final spectrum is not corrected for the wavelength dependent sensitivity of the detector or wavelength dependent transmission

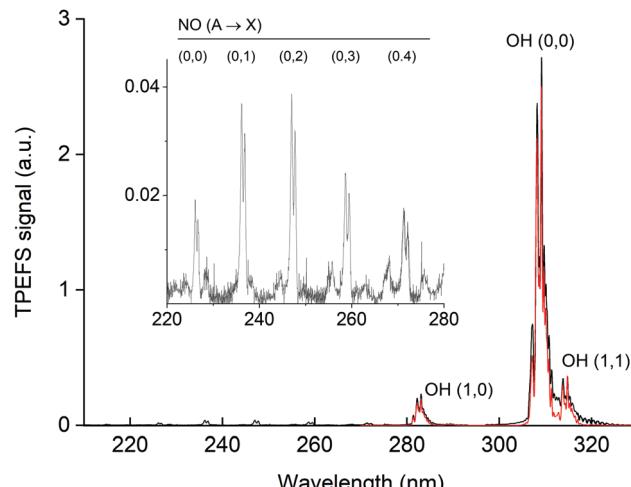

Fig. 5 Fluorescence emission spectrum (black line) following excitation of  $7 \times 10^{13}$  molecule  $\text{cm}^{-3}$   $\text{HNO}_3$  in 90 torr He at 193 nm. The inset has an expanded y-scale showing NO fluorescence emission lines from 220 to 280 nm. The red line is a simulation (LIFBASE<sup>35</sup>) of the relative line intensities for the  $\text{OH} \text{A}^2\Sigma(v' = 0,1,2) \rightarrow \text{X}^2\Pi(v'' = 0,1,2)$  transition using  $T_{\text{vib}} = 3200$  K and  $T_{\text{rot}} = 700$  K.

of either the monochromator or the optical fibre used. This will result in a positive bias to longer wavelength fluorescence and thus features such as the NO emission lines between 225 and 280 nm are stronger (relative to the OH(A) lines) than depicted in this figure. Under these experimental conditions, we were able to observe the OH(0,0) emission centred at 310 nm and emissions of vibrationally excited OH at  $\sim 282$  nm OH(1,0),  $\sim 287$  nm OH(2,1) and  $\sim 315$  nm OH(1,1).

Using LIFBASE<sup>35</sup> we could approximately reproduce the measured OH fluorescence spectra with a vibrational temperature ( $T_{\text{vib}}$ ) of  $\sim 3200$  K and a rotational temperature ( $T_{\text{rot}}$ ) of  $\sim 700$  K. The former value is in qualitative agreement with Kenner *et al.*<sup>14</sup> who also observed a high degree of vibrational excitation in OH and reported a vibrational temperature of 375 K.

The NO emission lines have been observed previously in the 193 nm excitation of  $\text{HNO}_3$  and were thought to be the result of the excitation of  $\text{NO}_2$ , which was present as an impurity in the experiments of Papenbrock *et al.*<sup>12</sup> However, our measurement of the  $\text{NO}^*$  fluorescence emission resulting from the excitation of  $\text{NO}_2$  at 193 nm (see Fig. 6) showed that the intensities of the NO emission lines are much smaller than those observed in the excitation of similar amounts of  $\text{HNO}_3$ , which leads us to conclude that  $\text{NO}^*$  is formed *via* 193 nm excitation of  $\text{HNO}_3$  and not from  $\text{NO}_2$  impurity.

Indeed, this additional channel, in which the co-product would be OH in its electronic ground state, is energetically feasible and has been proposed previously.<sup>36</sup> Recent work by Winiberg *et al.*<sup>17</sup> also showed that NO(A) was observed from the two photon photolysis of  $\text{HNO}_3$  at 248 nm.

### 3.3 TPEFS detection of selected $\text{NO}_x$ and $\text{HO}_x$ trace gases

In this section we discuss the relative detection sensitivity of TPEFS to  $\text{HNO}_3$ , NO and  $\text{NO}_2$ . The results are summarised in

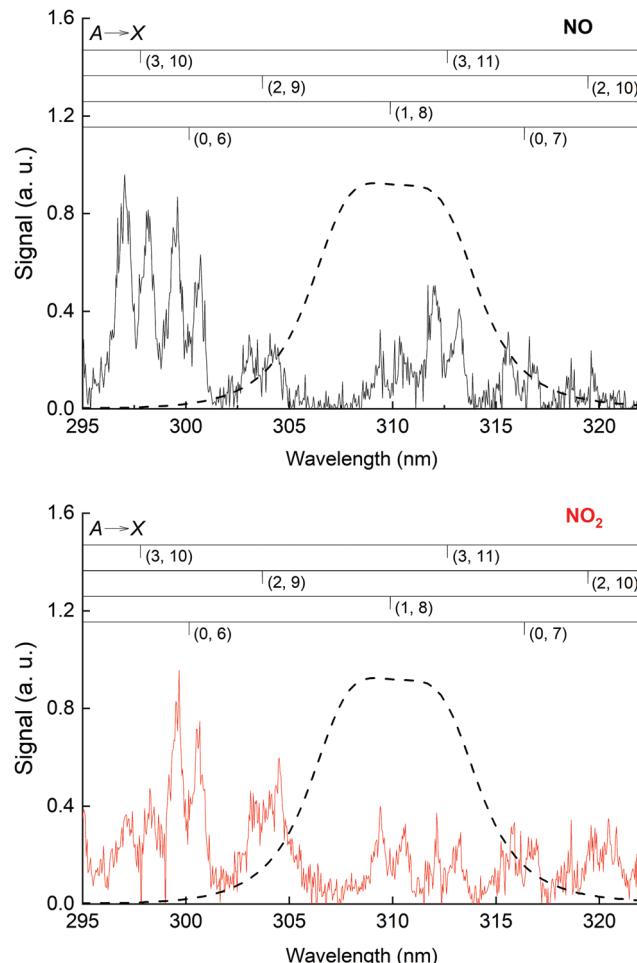

Fig. 6 Upper panel: NO fluorescence emission spectrum following 193 nm excitation of NO with assignment to vibrational transitions from the A to X electronic states. Lower panel: As upper panel but following 193 nm  $\text{NO}_2$  excitation. Experiments were carried out at  $\sim 298$  K and a bath gas-pressure of 60 torr ( $\text{N}_2$ ) with  $[\text{NO}] = 3.0 \times 10^{15}$  molecule  $\text{cm}^{-3}$  or  $[\text{NO}_2] = 2.4 \times 10^{15}$  molecule  $\text{cm}^{-3}$ . The 310 nm interference filter transmission curve (used for selective detection of emission from OH(A)) is represented by the dashed line.

Table 1. As described above, the NO(A) emission lines seen when exciting  $\text{HNO}_3$  samples at 193 nm may arise from the presence of impurities such as NO or  $\text{NO}_2$ . Here, we examine the relative detection sensitivity for NO and  $\text{NO}_2$ , identify the origin of these lines and assess the potential interference of NO and  $\text{NO}_2$  whilst monitoring  $\text{HNO}_3$  as OH(A).

Table 1 TPEFS sensitivity ( $S$ ) to NO,  $\text{NO}_2$ ,  $\text{HO}_2$  and  $\text{H}_2\text{O}_2$

	$\text{HNO}_3$	NO	$\text{NO}_2$	$\text{H}_2\text{O}_2$	$\text{HO}_2$
$\sigma^a$	$1100^{23}$	$<0.001$	$29^{37}$	$61^{23}$	$390^{38}$
$S(\text{N}_2)$	10 000	$(30 \pm 10)$	$(50 \pm 20)$	—	$<(3 \pm 1)$
$S(\text{air})$	10 000	$(5 \pm 1)$	—	$(0.6 \pm 0.2)$	
$S(\text{He})$	10 000	$<1$	—	—	

<sup>a</sup>  $\sigma$  is the single-photon absorption cross-section at 193 nm (units of  $10^{-20}$   $\text{cm}^2$  molecule $^{-1}$ ). Detection sensitivity is relative to  $\text{HNO}_3$ . Uncertainties are  $2\sigma$  statistical only.

For both NO and NO<sub>2</sub>, we performed a series of experiments in different bath gases (N<sub>2</sub> and He) and with and without O<sub>2</sub> in order to assess the excitation mechanism at the origin of emission around 310 nm. To minimize HNO<sub>3</sub> interference from NO and NO<sub>2</sub> excitation spectra, we coated the gas line leading to the reactor with NaHCO<sub>3</sub>. The removal of HNO<sub>3</sub> was confirmed by the non-observation of OH emission lines.

In experiments designed to investigate the kinetics of HNO<sub>3</sub> formation *via* the reaction between OH and NO<sub>2</sub> (Section 3.4) we used H<sub>2</sub>O<sub>2</sub> as the photolytic source of OH. In these experiments, HO<sub>2</sub> was also formed and we therefore report the sensitivity (relative to HNO<sub>3</sub>) of TPEFS to both HO<sub>2</sub> and H<sub>2</sub>O<sub>2</sub>.

The experiments on NO, NO<sub>2</sub>, HO<sub>2</sub> and H<sub>2</sub>O<sub>2</sub> are described in Sections 3.3.1–3.3.4, the results are summarized in Table 1.

**3.3.1 NO emission spectrum.** In Fig. 6 (upper panel), we present the dispersed NO fluorescence emission (recorded 45 ns after the 193 nm laser pulse) observed upon 193 nm excitation of NO in N<sub>2</sub>. Vibronic transitions were assigned using LIFBASE.<sup>35</sup> In Fig. S1 (ESI<sup>†</sup>) we present absorption cross-sections (185–230 nm) of NO obtained at a spectral resolution of 0.16 nm (as derived from the measured full width (at half maximum) of the 253.65 nm line from a low-pressure Hg lamp). The spectrum was recorded at 19 torr of N<sub>2</sub> with [NO] = 3.1 × 10<sup>16</sup> molecule cm<sup>-3</sup> using a 10 cm absorption cell. In this wavelength range, the NO spectrum shows discrete transitions from the ground state to the A, B, C and D electronic states which were assigned using LIFBASE.<sup>35</sup> In Fig. S1 (ESI<sup>†</sup>), we also indicate the position of the 193 nm ArF laser pulse which lies between the NO absorption features centered around ∼191 nm and ∼195 nm, thus highlighting the lack of NO absorption at the excitation wavelength. At 193 nm, the single-photon absorption cross-section of NO is very low (see Table 1).

Shibuya and Stuhl<sup>39</sup> and Hack *et al.*<sup>40</sup> measured the dispersed fluorescence from a few mTorr of pure NO upon excitation with an ArF laser and reported that the emission (in the 200 to 300 nm range) arose mainly from the B<sup>2</sup>Π(v' = 7) state, but identified weaker features from the adjacent A(v' = 3) and C(v' = 0) states. Shibuya and Stuhl hypothesized that at 193 nm the absorption arose from the transition from high rotational states (R<sub>11</sub>, P<sub>11</sub>, Q<sub>11</sub>, R<sub>22</sub> and P<sub>22</sub>) of the ground state (X<sup>2</sup>Π, v'' = 0) to the B<sub>2</sub>Π(v' = 7) state.

Additionally, we measured the dependence of the NO fluorescence signal (as measured through the (310 ± 5) nm interference filter and PMT) as a function of the 193 nm laser energy, which is displayed in Fig. S2 (ESI<sup>†</sup>). There is a strictly proportional dependence of the NO fluorescence signal as a function of E<sub>193nm</sub>, which (given the weak absorption of NO at this wavelength) may indicate that the process leading to NO fluorescence involves one photon.

In Fig. S3 (ESI<sup>†</sup>), we display a series of spectra showing the effect of changing bath gas (He to N<sub>2</sub>) and of adding O<sub>2</sub> on the distribution of the NO emission lines upon 193 nm excitation of either NO or NO<sub>2</sub>. All spectra were recorded at a total pressure of 65 torr with similar concentrations of either NO or NO<sub>2</sub> ([NO] = 2.6 × 10<sup>15</sup> molecule cm<sup>-3</sup>, [NO<sub>2</sub>] = 2.1 × 10<sup>15</sup> molecule cm<sup>-3</sup>) and [O<sub>2</sub>] = 4.0 × 10<sup>16</sup> molecule cm<sup>-3</sup>.

In Fig. S3a (ESI<sup>†</sup>) (NO<sub>2</sub> excitation) we observed that the fluorescence emission is ∼5 times more intense in He than in N<sub>2</sub> for the A(v' = 0) → X vibrational series. For NO (Fig. S3b, ESI<sup>†</sup>), we also observed a stronger quenching effect of He relative to N<sub>2</sub> but observed that in He fluorescence was mainly from the A(v' = 3) electronic state while in N<sub>2</sub> it was from the A(v' = 0) state.

The relative intensity of the emission lines indicates that 85% of the vibrational population was located in the A(v' = 3) state. The replacement of He with N<sub>2</sub> leads to the depopulation, through vibrational energy transfer, of the A(v' = 3) electronic state to form A(v' = 0, 1, 2). We did not observe any evidence of emission down from the B<sup>2</sup>Π(v' = 7) state as reported previously<sup>39,40</sup> however it appears that under our pressure and bath gas conditions that the B<sup>2</sup>Π(v' = 7) is quenched down to the observed A<sup>2</sup>Σ(v' = 3) state in agreement with Hack *et al.*<sup>40</sup> We note that the quenching rate constants were reported to be larger for N<sub>2</sub> (see Settersen *et al.*<sup>41</sup> and references therein) than for He.<sup>42,43</sup>

In Fig. S3c to f (ESI<sup>†</sup>), we present spectra highlighting the strong O<sub>2</sub> quenching effect on NO fluorescence from both NO<sub>2</sub> and NO excitation.

We also examined the quenching of NO fluorescence (as measured by the PMT through the (310 ± 5) nm interference filter) by O<sub>2</sub>. As shown in Fig. 6, in this wavelength window, NO fluorescence arises from NO A(v' = 0, 1, 2, 3) emission to the ground state. In Fig. S4 (ESI<sup>†</sup>) we show the relative change in fluorescence intensity while the concentration of O<sub>2</sub> was varied from 0 to 4 × 10<sup>17</sup> molecule cm<sup>-3</sup> (in N<sub>2</sub> bath gas at a total pressure of 60 torr). From this we derive a quenching rate constant for O<sub>2</sub> of (1.5 ± 0.1) × 10<sup>-10</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup>, where the uncertainty is 2σ statistical only (more details in ESI<sup>†</sup>). This result is in excellent agreement with previous measurements which reported a quenching rate constant for O<sub>2</sub> of 1.5 × 10<sup>-10</sup> cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> (see Nee *et al.*<sup>42</sup> and references therein) for NO (A, v' = 0). Quenching rate constants were reported as being only weakly dependent on the vibrational level of the A state, with values of k<sub>q</sub> within 30% for (A, v' = 0, 1, 2, 3) for N<sub>2</sub> and O<sub>2</sub>.<sup>42</sup> Our experiments indicate that the numerous quenching rate constant determinations reported in the literature can reproduce our observations at 310 nm.

**3.3.2 NO<sub>2</sub> emission spectrum.** At 193 nm, the single-photon absorption cross-section of NO<sub>2</sub> is not accurately known with reported values ranging from 2.7 to 5.4 × 10<sup>-19</sup> cm<sup>2</sup> molecule<sup>-1</sup>,<sup>44</sup> the most recent measurement reported a cross-section of (2.9 ± 1.2) × 10<sup>-19</sup> cm<sup>2</sup> molecule<sup>-1</sup> at this wavelength.<sup>45</sup>

Excitation of NO<sub>2</sub> at 193 nm (6.42 eV) leads to its photo-dissociation to vibrationally excited, electronic ground-state NO(X<sup>2</sup>Π) and both O(<sup>1</sup>D) and O(<sup>3</sup>P)<sup>37,46</sup> as well as N(<sup>4</sup>S) and O<sub>2</sub>.<sup>47</sup> As shown in Fig. 6 (lower panel), upon excitation of NO<sub>2</sub> at 193 nm, we observed fluorescence emission from NO(A<sup>2</sup>Σ<sup>+</sup>), as previously reported.<sup>48</sup>

The energy thresholds for the formation of NO A<sup>2</sup>Σ<sup>+</sup> and NO B<sup>2</sup>Π are 8.60 and 8.75 eV respectively.<sup>49–51</sup> Welge<sup>52</sup> reported the formation of NO(A<sup>2</sup>Σ<sup>+</sup> and B<sup>2</sup>Π) after exciting NO<sub>2</sub> to Rydberg

states at 116.5 nm (10.64 eV), 123.6 nm (10.03 eV) and 129.5 nm (9.57 eV) but not at 147 nm (8.43 eV). This indicates that single-photon processes at 193 nm cannot explain the formation of  $\text{NO}(\text{A}^2\Sigma^+)$ . On the other hand, simultaneous absorption of two-photons at 193 nm (12.84 eV) appears unlikely to be the source of  $\text{NO}(\text{A}^2\Sigma^+)$  as the ionization energy threshold for the formation of  $\text{NO}^+$  is only 12.38 eV.<sup>51</sup> We conclude that a sequential, two-photon absorption mechanism involving a sufficiently long-lived intermediate state (*i.e.* similar to the formation of excited OH in the 2-photon photolysis of  $\text{HNO}_3$ ) might be at the origin of the observed  $\text{NO}(\text{A}^2\Sigma^+)$  in  $\text{NO}_2$  photolysis at 193 nm.

**3.3.3 Relative TPEFS sensitivity of NO,  $\text{NO}_2$  and  $\text{HNO}_3$ .** Initial experiments indicated that the TPEFS detection of  $\text{HNO}_3$  around 310 nm (*i.e.* non-dispersed fluorescence) was orders of magnitude more sensitive than for NO or  $\text{NO}_2$ . In order to extend the dynamic range to measure relative signals from NO,  $\text{NO}_2$  and  $\text{HNO}_3$  under the same settings (*i.e.* PMT voltage) we reduced the sensitivity (by a factor of 5.4) when monitoring signals from  $\text{HNO}_3$  by adding a BG26 optical filter in front of the PMT and using concentrations of  $\text{HNO}_3$  that were roughly 10 times smaller than those of NO and  $\text{NO}_2$ :  $[\text{HNO}_3] = 0.2\text{--}1.2 \times 10^{13} \text{ molecule cm}^{-3}$ ,  $[\text{NO}] = 2.1\text{--}9.9 \times 10^{13} \text{ molecule cm}^{-3}$ ,  $[\text{NO}_2] = 2.1\text{--}8.5 \times 10^{13} \text{ molecule cm}^{-3}$ . Under these conditions, saturation of the signal at the PMT was avoided when using  $\text{HNO}_3$  although the TPEFS signals observed were still roughly 100 times larger for  $\text{HNO}_3$  than for NO and  $\text{NO}_2$ .

In Fig. 7, we present calibration curves in which TPEFS signals are plotted as a function of NO,  $\text{NO}_2$  and  $\text{HNO}_3$  concentrations.

Note that the right y-axis (for NO and  $\text{NO}_2$  detection) is scaled by a factor 0.01 compared to that for  $\text{HNO}_3$  (left y-axis). Concentrations of  $\text{NO}_2$  and  $\text{HNO}_3$  were obtained by *in situ* optical absorption (Section 2.2), whereas the concentration of NO was derived from the mixing ratio in the storage bulb, its

dilution in bath gas and the total pressure. The solid-line fits to the data indicate a sensitivity for detection of NO relative to  $\text{HNO}_3$  of  $(3 \pm 1) \times 10^{-3}$  in  $\text{N}_2$ . The values obtained in air and He were  $(5 \pm 1) \times 10^{-4}$  and  $< 10^{-4}$ , respectively.

The lower relative sensitivity in air compared to  $\text{N}_2$  is readily explained by the more efficient quenching of  $\text{O}_2$  on NO fluorescence than on OH fluorescence. It is also amplified by the very low quenching rate constant of NO fluorescence by  $\text{N}_2$ .<sup>41</sup>

In He, the TPEFS sensitivity to  $\text{HNO}_3$  increased (compared to  $\text{N}_2$ ) much more than it did for NO or  $\text{NO}_2$ . This forced us to reduce the PMT-voltage when monitoring  $\text{HNO}_3$  whereby usable signals from NO and  $\text{NO}_2$  were only obtained by adding much larger concentrations for which fluorescence self-quenching was an issue. In He we were thus unable to extend the dynamic range of the experiment to measure signals from  $\text{HNO}_3$  and NO or  $\text{NO}_2$  under the same conditions and we only report a lower limit of  $10^{-4}$  to the relative sensitivity.

In order to perform similar experiments on  $\text{NO}_2$ , we initially used diluted  $\text{NO}_2$  samples. However, we found that a small but variable fraction (around 0.1–1%) of the  $\text{NO}_2$  was converted to  $\text{HNO}_3$  on the inlet and reactor surfaces. We therefore generated  $\text{NO}_2$  *in situ* in a pre-reactor by reacting NO with  $\text{O}_3$ . The latter, at a concentration of  $1.0 \times 10^{13} \text{ molecule cm}^{-3}$ , was generated by the photolysis of  $\text{O}_2$  at 185 nm using a Hg lamp.

The conversion of NO to  $\text{NO}_2$  was 92 to 95%. We thus obtained a relative detection efficiency (in  $\text{N}_2$ ) of  $\text{NO}_2$  compared to  $\text{HNO}_3$  of  $(5 \pm 3) \times 10^{-3}$ .

**3.3.4 Detection of  $\text{H}_2\text{O}_2$ .** The single-photon cross-section of  $\text{H}_2\text{O}_2$  at 193 nm is  $6.1 \times 10^{-19} \text{ cm}^2 \text{ molecule}^{-1}$ .<sup>23</sup> In a series of experiments in 50 torr  $\text{N}_2$  at  $\sim 298$  K we observed a linear dependence of the TPEFS signal on the  $\text{H}_2\text{O}_2$  concentration (varied from  $0.11$  to  $1.1 \times 10^{16} \text{ molecule cm}^{-3}$ ) as shown in Fig. S5 (ESI†). The TPEFS detection sensitivity of  $\text{H}_2\text{O}_2$  relative to that of  $\text{HNO}_3$  was found to be  $(6 \pm 2) \times 10^{-5}$ , where the uncertainty is  $2\sigma$  statistical only.

Previous studies on the VUV photolysis of  $\text{H}_2\text{O}_2$ <sup>53–56</sup> indicate that OH, H and O-atoms are formed:

At  $\lambda < 198$  nm excitation, the main dissociation pathways lead to two OH (R5a and R5b) and to  $\text{H}(\text{S})$  atom and  $\text{HO}_2$  (R5c). At 193 nm, the yields for the OH + OH channel (R5a) and the H +  $\text{HO}_2$  (R5c) are 0.8 and 0.2, respectively and an upper limit of 0.15 was given for the formation of vibrationally excited OH( $\text{X}^2\Pi, \nu'' > 0$ ) (R5b).<sup>54</sup> The yields of O-atoms are very low with upper limits of 0.001 for  $\text{O}(\text{P}^3) + \text{O}(\text{D}^1)$  and 0.02 for  $\text{O}(\text{S}^1)$  channels. OH(A) is formed at wavelength below 172 nm.<sup>57</sup>

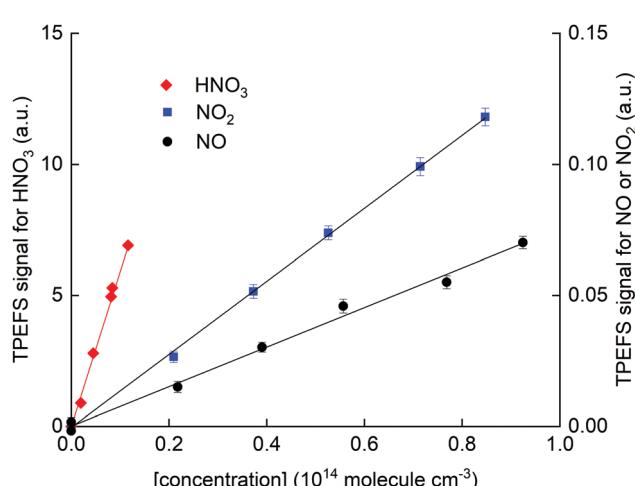

Fig. 7  $\text{HNO}_3$  TPEFS signal (left y-axis) and NO and  $\text{NO}_2$  TPEFS signal (right y-axis) as a function of concentration. These results were obtained in  $\text{N}_2$  (62 torr) and at room temperature ( $298 \pm 2$  K).

Formation of OH(A), has however been observed in the two-photon excitation of  $\text{H}_2\text{O}_2$  at 193 nm<sup>58,59</sup> which, *via* analysis of the state resolved internal distribution of OH(A), was demonstrated to originate from a resonant, 2-photon sequential absorption process.

**3.3.5 Detection of  $\text{HO}_2$ .**  $\text{HO}_2$  was formed in the 248 nm photolysis of  $\text{H}_2\text{O}_2$  whereby the initially formed OH radicals were converted to  $\text{HO}_2$  in (R4).

The sensitivity for detection of  $\text{HO}_2$  at 193 nm was examined in 60 torr of  $\text{N}_2$  with  $[\text{H}_2\text{O}_2] = 2.4 \times 10^{15}$  molecule  $\text{cm}^{-3}$ . The photon density at 248 nm was measured using a calibrated Joulemeter as  $6.8 \times 10^{16}$  photon  $\text{cm}^{-2}$ . Under these conditions,  $\sim 1.6 \times 10^{13}$  molecule  $\text{cm}^{-3}$  of  $\text{HO}_2$  were generated. The observed TPEFS signal was modelled as the sum of the signals originating directly from  $\text{H}_2\text{O}_2$  and from  $\text{HO}_2$  formed in R4. The kinetic model included R4 and R5 with diffusion coefficients for OH and  $\text{HO}_2$  set to  $30 \text{ s}^{-1}$ . In Fig. S6 (ESI†), we show the signal expected when assuming that  $\text{HO}_2$  was not detected. The slight depletion in signal at time = zero is explained by the loss of  $\text{H}_2\text{O}_2$  by photolysis ( $\sim 1.5\%$ ) and in the subsequent OH +  $\text{H}_2\text{O}_2$  reaction. From this data we were only able to report an upper limit  $\text{HO}_2$  detection sensitivity (relative to  $\text{HNO}_3$ ) of  $(3.2 \pm 1.2) \times 10^{-4}$  ( $2\sigma$  statistical only, including a 15% uncertainty on the photon density).

### 3.4 Rate coefficient for the OH + $\text{NO}_2$ reaction

Rate coefficients for OH +  $\text{NO}_2$  were measured by both conventional pulsed laser photolytic formation of OH with its detection in real time by laser induced fluorescence (PLP-LIF, with 282 nm excitation of OH and PLP-TPEFS with 193 nm excitation for detection of the  $\text{HNO}_3$  product).

OH radicals were generated either in the 248 nm photolysis of  $\text{H}_2\text{O}_2$  (R5) or by the 248 nm photolysis of  $\text{O}_3$  in the presence of  $\text{H}_2\text{O}$  (R6 and R7).

The concentrations used were  $[\text{H}_2\text{O}_2] \sim 1 \times 10^{14}$  molecule  $\text{cm}^{-3}$ ,  $[\text{O}_3] = (2-7) \times 10^{13}$  molecule  $\text{cm}^{-3}$  and  $[\text{H}_2\text{O}] = (1.5-6.0) \times 10^{16}$  molecule  $\text{cm}^{-3}$  (corresponding to a mixing ratio of  $\sim 4.2\%$  at the total pressure of 50 to 200 torr, see Table 2). Using a laser-fluence of  $\sim 50 \text{ mJ cm}^{-2}$ ,  $1-3 \times 10^{12}$  molecule  $\text{cm}^{-3}$  [OH] were generated per pulse such that the experiments were conducted under pseudo-first order conditions (*i.e.*  $[\text{NO}_2] \gg [\text{OH}]$ ).

We observed that small amounts of  $\text{NO}_2$  ( $< 0.1\%$ ) were converted into  $\text{HNO}_3$  on the surfaces of the reactor adding a background signal to the kinetics profile. The effect became more pronounced when water vapour was added to the reactor where as much as a few percent of  $\text{NO}_2$  were converted to  $\text{HNO}_3$ . We note that the build-up of background  $\text{HNO}_3$  occurred on a longer time scale ( $\sim 2-3$  hours) than the time

Table 2 Determination of  $k_2$  in air

Pressure (torr)	$\text{H}_2\text{O} (\%)$	$k_2 (10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1})$
$\text{O}_3/\text{H}_2\text{O}$ as OH precursor		
50	4.5	$(3.2 \pm 0.7)$
100	4.1	$(4.5 \pm 0.4)$
150	3.8	$(5.7 \pm 0.8)$
200	4.5	$(6.6 \pm 0.3)$
$\text{H}_2\text{O}_2$ as OH precursor		
50	0	$(2.3 \pm 0.3)$
100	0	$(3.9 \pm 0.3)$
100	0	$(4.0 \pm 0.1)^a$

<sup>a</sup> OH LIF measurement. Errors are  $2\sigma$  statistical only.

necessary to gather the data necessary to derive a rate constant for one particular set of conditions. However, it did prevent conducting a long-time series of measurements (*e.g.* over the course of a day) as the background became too large and the reactor cell needed to be flushed with dry  $\text{N}_2$  for several hours to return to favourable conditions. The use of  $\text{NaHCO}_3$  to coat the surface was impractical in these experiments as its efficiency to remove  $\text{HNO}_3$  also changed over time.

In both schemes, OH is generated quasi-instantaneously compared to its loss rate and the time profiles for OH loss and  $\text{HNO}_3/\text{HOONO}$  production in the cell are then given by:

$$[\text{OH}]_t = [\text{OH}]_0 \exp(-[k_2[\text{NO}_2] + d_{\text{OH}}]t) \quad (3)$$

$$[\text{HNO}_3]_t = \alpha C(\exp(-d_{\text{HNO}_3}t) - \exp(-[k_2[\text{NO}_2] + d_{\text{OH}}]t)) \quad (4)$$

$$[\text{HOONO}]_t = (1 - \alpha)C(\exp(-d_{\text{HOONO}}t) - \exp(-[k_2[\text{NO}_2] + d_{\text{OH}}]t)) \quad (5)$$

where  $k_2$  is the rate coefficient for reaction (R2),  $d_{\text{OH}}$  and  $d_{\text{HNO}_3}$  are first-order rate constants ( $\text{s}^{-1}$ ) for the diffusive loss of OH and  $\text{HNO}_3$  from the reaction volume, respectively and  $C$  is equal to  $[\text{OH}]_0(k_2[\text{NO}_2] + d_{\text{OH}})/(k_2[\text{NO}_2] + d_{\text{OH}} + d_{\text{HNO}_3})$ . We do not know if TPEFS detects HOONO but note that, to a very good approximation, the first-order constant for formation of HOONO will be the same as for  $\text{HNO}_3$  as both are very long-lived compared to the time-scale of the decay of OH. Only the absolute concentrations of  $\text{HNO}_3$  and HOONO are defined by the branching ratio and thus the kinetic parameters would not be impacted whether HOONO is detected or not.

The pseudo-first-order loss rate coefficient for OH is:

$$k_2' = k_2[\text{NO}_2] + d_{\text{OH}} \quad (6)$$

Experiments to derive  $k_2$  were carried out at room temperature and at a number of different pressures of air (50–200 torr) using the two different OH precursors described above. We worked in air rather than in  $\text{N}_2$  as this improves the relative sensitivity to  $\text{HNO}_3$  compared to  $\text{NO}_2$ .

Fig. 8 shows time profiles for both OH decay (upper panel) and  $\text{HNO}_3$  production (lower panel) obtained for the same chemical system using  $\text{H}_2\text{O}_2$  as a precursor. The  $\text{HNO}_3$  TPEFS signals displayed were accumulated for 40 scans ( $\sim 10$  min) while OH LIF signal were accumulated for 25 scans ( $\sim 5$  min). The profiles were obtained by computer-controlled variation of

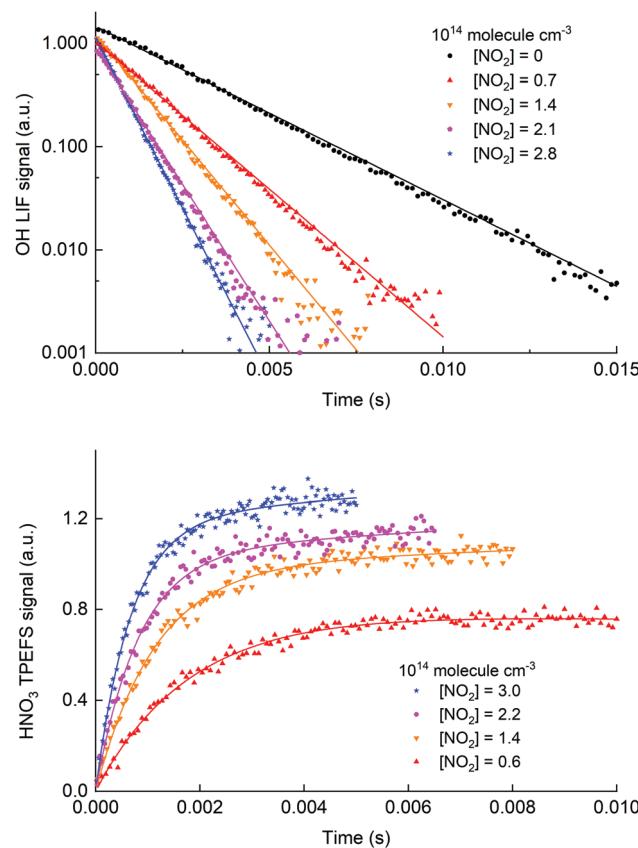

Fig. 8 Time dependent signals from OH (upper panel, LIF) and  $\text{HNO}_3$  (lower panel, TPEFS) obtained in measurements at 100 torr of air using  $\text{H}_2\text{O}_2$  as a OH precursor. The solid lines are fits to the OH (eqn (3)) and  $\text{HNO}_3$  signals (eqn (4)). The reaction time for the  $\text{HNO}_3$  formation datasets was adjusted (i.e. shorter at high  $[\text{NO}_2]$ ) to get sufficient datapoints in the early part of the profile.

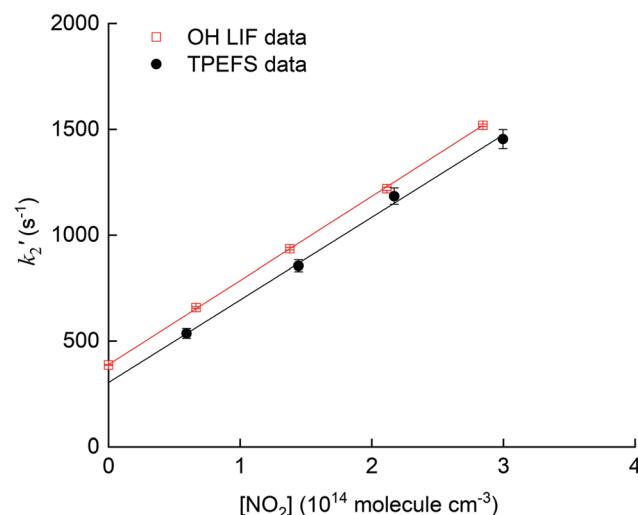

Fig. 9 Plot of  $k'_2$  versus  $[\text{NO}_2]$  for the reaction (R2) of OH with  $\text{NO}_2$  at 100 torr of air using  $\text{H}_2\text{O}_2$  as OH precursor. The solid lines represent a linear regression returning  $k'_2 = (4.0 \pm 0.1) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  using OH detection by LIF (red line) and  $k'_2 = (3.9 \pm 0.3) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  using  $\text{HNO}_3$  detection by TPEFS (black line). Error bars are  $2\sigma$  statistical only.

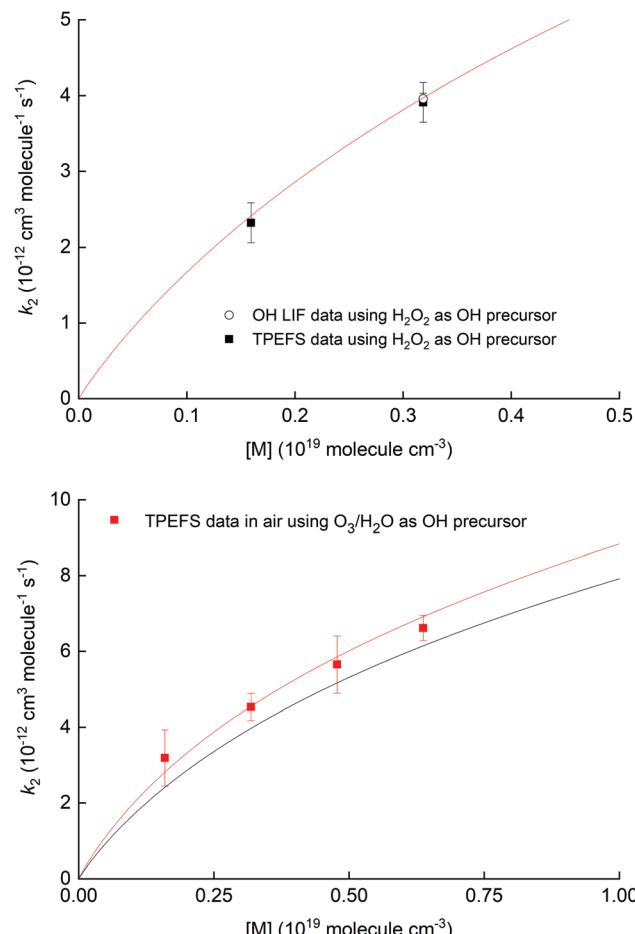

Fig. 10 Upper panel: Measurement of  $k_2$  for the OH reaction with  $\text{NO}_2$  in air using 248 nm photolysis of  $\text{H}_2\text{O}_2$  as a OH precursor and either TPEFS detection of  $\text{HNO}_3$  or conventional LIF detection of OH. The solid red line is a fall-off parameterisation (see ESI†). Lower panel: Measurement of  $k_2$  for the OH reaction with  $\text{NO}_2$  in air using 248 nm photolysis of  $\text{O}_3\text{--H}_2\text{O}$  to generate OH. The solid red line is a fall-off parameterization (see the ESI†) using a mixing ratio for  $\text{H}_2\text{O}$  of 4.2% while the solid black line corresponds to the same parameterisation in dry air.

the delay-time between the 248 nm excimer laser pulse (generating OH at time zero) and either the 282 nm laser exciting OH or the 193 nm excimer-laser exciting  $\text{HNO}_3$ .

The pseudo first-order rate coefficients,  $k'_2$ , were obtained by fitting the observed time profiles to eqn (3) and (4) for OH loss and  $\text{HNO}_3$  production, respectively. The bimolecular rate coefficients were then obtained by plotting  $k'_2$  against  $[\text{NO}_2]$  as shown in Fig. 9, which displays data from an experiment at a total pressure of 100 torr of air whereby  $[\text{NO}_2]$  was varied between 0.5 and  $3 \times 10^{14} \text{ molecule cm}^{-3}$ .

The values of  $k_2$  obtained from the slopes of least-squares fits to these datasets are  $(4.0 \pm 0.1) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  and  $(3.9 \pm 0.3) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ , respectively.

Fig. 10 shows the measured rate coefficients as a function of pressure along with fall-off expression (see the ESI†) used to parameterize data recently measured in this laboratory.<sup>19,20</sup>

The results displayed in the upper panel of Fig. 10 indicate that the rate coefficients obtained using detection of  $\text{HNO}_3$

using TPEFS are in excellent agreement (better than 10%) with that obtained using OH-LIF and also with the parameterisation presented in our previous, comprehensive study (using OH-LIF). The lower panel indicates that larger rate coefficients are obtained when using  $O_3/H_2O$  as OH-precursor. This observation is entirely consistent with the enhancement of  $k_2$  in the presence of  $H_2O$  described in detail by Amedro *et al.*<sup>19</sup> and the parameterisation of  $k_2$  presented by those authors (red line). Note that the overall aim of the kinetic investigations described in Section 3.4 was not to strengthen the database on the OH +  $NO_2$  reaction, but to show that time resolved detection of  $HNO_3$  by TPEFS can be used to derive accurate rate coefficients. For more details about the OH reaction with  $NO_2$  rate constants measurements, including an extended comparison with previous works and a newly developed parametrization, we invite the interested reader to view our previous studies.<sup>19,20</sup> We are unaware of any reason why TPEFS detection of  $HNO_3$  could not be extended to kinetic studies at *e.g.* different temperatures.

## 4. Conclusions

We have characterized the detection of  $HNO_3$  using TPEFS as part of a study to assess its viability for detection of  $HNO_3$  in real-time (*e.g.* pulsed laser) kinetic studies. We have shown that detection of  $HNO_3$  (*via* OH(A) emission at  $\sim 310$  nm) is orders of magnitude more sensitive than detection NO or  $NO_2$  (*via*  $NO^*$  emission) at the same wavelength, especially in air where the quenching of NO fluorescence is most efficient owing to the presence of  $O_2$ . As a test case, we have used TPEFS for real-time detection of  $HNO_3$  in the reaction between OH and  $NO_2$ . The rate constant obtained (293 K, 50–200 torr) is entirely consistent with that obtained by simultaneously measuring the OH decay and is in very good agreement with the most recent literature values.

## Author contributions

DA, TD and JC set up the apparatus, DA, TD and AB performed the experiments. DA analysed the data. JC conceptualised the experiments and helped DA write the manuscript.

## Conflicts of interest

There are no conflicts to declare.

## Acknowledgements

We thank the Deutsche Forschungsgemeinschaft (DFG) for partial financial support of this research (CR 246/2-1). Open Access funding provided by the Max Planck Society.
