1. Introduction

Bismuth borate glasses constitute a promising family of materials for contemporary technological applications. For more than two decades the majority of such applications involved the field of photonics, while recent investigations recognize that the non-toxic bismuth borate glasses may replace radiation shielding concretes and lead-based commercial glasses for gamma ray and neutron radiation shielding applications.

Early studies suggested that potential alternatives to semiconductor materials with nonlinear optical properties could be transparent glasses with high linear refractive index. Thus, stable glassy systems having a broad forming range and containing highly polarizable metal ions are desirable; one possible candidate is the bismuth-borate system. The pioneering work on the complete phase diagram of the Bi₂O₃–B₂O₃ system by Levin and McDaniel showed that stable glasses can be prepared with up to 76 mol% Bi₂O₃, whereas five crystalline compounds also exist with molar ratios of bismuth oxide to boron oxide of 1:4, 1:3, 3:5, 2:1 and 12:1. Among these
crystals, the monoclinic BiB₂O₅ shows exceptionally large linear and nonlinear optical coefficients.²¹,²² More recent studies on glass formation and properties in the bismuth-borate system extended the glass forming range up to ca. 88.2 mol% Bi₂O₃ by employing the twin roller quenching technique.²³,²⁴

Glasses xBi₂O₃-(1 – x)B₂O₃ continue attracting interest mostly because of their unique linear and nonlinear optical properties which can be tuned by varying the Bi₂O₃ content over a broad composition range.²³–²⁷ For example, the second order non-linear optical susceptibility induced by thermal poling was found to increase with increasing the Bi₂O₃ content,⁸ and the third order optical non-linearity is one order of magnitude larger than that of silica glass and has a response time faster than 200 fs.⁹ In addition, doping bismuth borate glasses with a variety of rare earth ions, like Dy³⁺, Eu³⁺, Tb³⁺ and Nd³⁺ makes them luminescence materials with potential applications in solid-state lasers and optical amplifiers.¹¹,¹²,¹⁵ Recently, bismuth-borate glasses have been used as suitable matrices for the incorporation of gold nanoparticles resulting in materials with high refractive index suitable for photonic applications.¹⁴

Bismuth-borate glasses have also large and positive values of the thermo-optic coefficient (dn/dT), i.e. large changes of the refractive index with temperature, with dn/dT increasing with Bi₂O₃ content.²⁸

The correlation of properties with composition and structure allows for the tuning of the glass response according to specific technological applications. Therefore, the investigation of chemical, physical/optical and structural properties of Bi₂O₃-containing borate glasses is of key importance and several efforts have been made in this direction.²⁹–³⁸ In previous studies, a multitude of characterization techniques have been employed including XPS,²⁹,³⁰ infrared,²⁹,³²,³³,³⁴ Raman,²⁵,³²–³⁵ neutron diffraction,³¹ and ¹¹B MAS NMR.²⁵,³⁷

It is widely documented that the structure of metal oxide-containing borate glasses consists of borate tetrahedral and triangular units; the number of non-bridging oxygen atoms on the latter units depends on the modification level of the borate network.³⁹–⁵⁵ In the absence of metal oxides, i.e. pure B₂O₃ glass, the borate structure contains only neutral BO₃ triangles (O denotes an oxygen atom bridging two boron centers), of which ca. 75% are arranged in planar six-membered boroxol rings.⁵⁶ Upon addition of metal oxide to B₂O₃, BO₃ triangles are converted initially to charged tetrahedral units BO₄⁻.

The further increase of metal oxide content results in the progressive depolymerization of the borate backbone, through the breaking of B–O–B linkages and the creation of non-bridging oxygen atoms (NBO, or O’). The latter are formed mainly on charged triangular borate units which change gradually from BO₃O⁻ to BOO₂²⁻ and to BO₃⁺ i.e. from metaborate to pyroborate and to ortho-borate triangular moieties, respectively.³⁹–⁵⁵

Previous investigations on xBi₂O₃-(1 – x)B₂O₃ glasses revealed the coexistence of borate tetrahedral and triangular units for modification levels up to ca. x = 0.70.²³,³¹,³₄,³⁷ For the quantification of the borate structure, the molar fraction of tetrahedral borate units, N₄, was obtained by NMR²⁵,³⁷ and neutron diffraction³¹ techniques. The NMR results showed that N₄ exhibits a maximum value at about x = 0.42, while neutron diffraction data indicated a gradual increase of N₄ from N₄ = 0.38 at x = 0.30 to N₄ = 0.48 at x = 0.67. However, neither the nature of the borate triangles was unambiguously identified nor their molar fractions were obtained in previous studies,²⁵–³¹,³₄,³⁶–³⁸ due mostly to two reasons. First, the employed NMR and neutron diffraction techniques could not easily distinguish the different types of triangular borate units. Second, when infrared spectroscopy was used, by which the vibrational modes of different triangular borate units can be resolved,³⁴–⁵⁰ the infrared spectra of bismuth-borate glasses were measured using the KBr pellet technique.²⁹,³²–³⁸ While this method allows for the derivation of qualitative information, it leads usually to partial hydrolysis of the dispersed glass, to ion-exchange phenomena and to the mixing of transmission and reflection responses; these factors lead to spectral distortions and to non-reproducible intensities of the infrared absorption bands.⁴⁵,⁵⁷

The literature overview presented above shows that a detailed mapping of the borate network structure as a function of bismuth oxide content is still lacking. We present here for the first time, to the best of our knowledge, a systematic investigation in the bismuth-borate glass system by means of infrared reflectance spectroscopy. This technique has been successfully applied in the past to study different families of glasses, to quantify their network structure and to reveal the nature and distribution of sites hosting the metal ions.⁴⁴–⁵⁰,⁵⁷ Specifically, the analysis of the mid-infrared spectra, i.e. above ca. 650 cm⁻¹, can facilitate the quantitative mapping of the borate structural units; whereas information about the oxide sites hosting the Bi ions can be deduced from the analysis of far-infrared profiles. This will permit to identify the role of Bi₂O₃ in borate glasses either as modifier and/or as glass-former oxide. The quantification of structure allows discussing the evolution of glass transition temperature on the basis of glass rigidity, as viewed in terms of the average number of bridging boron–oxygen bonds per boron center, the average boron–oxygen and bismuth–oxygen single bond energy and the atomic packing density of the bismuth-borate glasses.

2. Experimental

2.1. Glass preparation

Bismuth-borate glasses with the nominal composition xBi₂O₃–(1 – x)B₂O₃ were prepared by mixing appropriate stoichiometric amounts of high purity (>99.5%) reagent-grade anhydrous Bi₂O₃ and B₂O₃ powders. Batches corresponding to approximately 5 g were thoroughly mixed, placed in Pt crucibles and melted for 15 minutes at temperatures between 800 and 1000 °C depending on composition. The use of Pt crucibles and low melting temperatures are crucial factors, because a previous investigation on glasses containing bismuth oxide showed that silica and porcelain crucibles are very strongly corroded when used for melting and this leads to alterations of glass.
composition. The melts of this study were homogenized by frequent stirring, and glass samples were prepared by the conventional splat-quenching technique by quenching the melt between two polished stainless-steel blocks. With this preparation method, nine bismuth-borate compositions were obtained in bulk glass forms in the range 0.2 ≤ x ≤ 0.8 (x = 0.2, 0.3, 0.4, 0.5, 0.6, 0.65, 0.7, 0.75 and 0.80). The glass specimens had thickness of about 1 mm with smooth and flat surfaces, suitable for specular reflectance measurements without any further treatment. The prepared glasses were light yellow to brownish with increasing the Bi₂O₃ content.

2.2. Infrared spectroscopy

Infrared (IR) reflectance spectra were measured on a vacuum Fourier-transform spectrometer (Bruker IFS 113v) at room temperature. A quasi-normal incidence mode (11°) was employed with an aluminum mirror as reference. Different infrared sources (globar and Hg arc lamp) and detectors (DTGS with KBr and polyethylene windows) were used to cover effectively the 30–5000 cm\(^{-1}\) frequency range. Mid-infrared spectra (400–5000 cm\(^{-1}\)) were measured with a KBr beam splitter, whereas far-infrared spectra at frequencies below 700 cm\(^{-1}\) were collected using five different mylar beam splitters with thickness 3.5–50 μm. Each spectrum, measured using a particular optic configuration, is the average of 200 scans with 2 cm\(^{-1}\) resolution. The final reflectance spectrum of each glass composition results from the appropriate merging of the six individual measured spectra to give a continuous spectrum in the 30–5000 cm\(^{-1}\) range.

The measured reflectance spectra were analyzed by the Kramers–Kronig (KK) method to calculate the real, n(ν), and imaginary, k(ν), parts of the complex refractive index n(ν) = n(ν) + ik(ν), where ν is the frequency in wavenumbers (cm\(^{-1}\)). The KK procedure requires extrapolation of the measured reflectance spectrum at the two limits ν → 0 and ν → ∞, as has been described in previous studies. The results of this study are presented and discussed here in terms of the absorption coefficient spectra at(ν) calculated by a(ν) = 4πνk(ν). Then, the absorption coefficient spectra were deconvoluted into Gaussian component bands, G(ν), according to the relationship:

\[
z(\nu) = \sum_{i=1}^{n} G_i(\nu) = \sum_{i=1}^{n} A_i \exp \left[ -\frac{(\nu - \nu_i)^2}{w_i^2} \right]
\]

where the parameters νᵢ, wᵢ, Aᵢ denote the resonance frequency, width and integrated band intensity of each Gaussian component, respectively. The deconvolution procedure relates to the determination of the best values of the adjustable parameters νᵢ, wᵢ, Aᵢ in order to obtain the most accurate description of the calculated z(ν) spectrum. The fitting procedure requires using, as a first step, the simplex algorithm followed by the application of the Levenberg–Marquardt algorithm, with a tolerance of 10\(^{-8}\). In the fitting procedure, the minimum number of component bands is used and, at the same time, the width values of the component bands that are assigned to the same vibrational mode of a particular structural unit are restricted to differ by less than 10% for different glass compositions. By imposing this constraint, it becomes meaningful to extract a quantitative description for the glass speciation.

3. Results

The reflectance spectra of glasses xBi₂O₃–(1 – x)B₂O₃ are depicted in Fig. 1 and 2 for 0.2 ≤ x ≤ 0.5 and 0.6 ≤ x ≤ 0.8 respectively. As the Bi₂O₃ content increases the far-IR activity shifts to higher frequencies and enhances relative to that in the mid-IR range. The far-infrared profiles of the studied glasses should result mainly from vibrational modes of Bi-containing oxide sites, while the mid-infrared activity arises from B–O vibrations in borate entities.

A detailed consideration of the spectral profiles and their composition dependence will be presented next in the absorption coefficient formalism, a(ν). The calculated a(ν) spectra are depicted in Fig. 3 and 4 after being normalized to their band maxima and appropriately shifted for better visualization.

3.1. Mid-infrared spectra

Inspection of Fig. 3 and 4 shows that all mid-infrared spectra exhibit three distinct absorption profiles, situated between ca. 600–750 cm\(^{-1}\), 750–1150 cm\(^{-1}\) and 1150–1600 cm\(^{-1}\), with shape and relative intensity depending strongly on glass composition. According to previous studies, the high-frequency IR envelope at ca. 1150–1600 cm\(^{-1}\) originates from asymmetric B–O stretching vibration modes of borate triangular units, while the corresponding modes of tetrahedral borate units are active at lower frequencies (750–1150 cm\(^{-1}\)). Deformation modes of the borate units give rise to weaker absorption bands in the ca. 600–750 cm\(^{-1}\) range. For example, the relatively narrow peaks at 700 and 710 cm\(^{-1}\) in Fig. 3 and 4 can be attributed to the out-of-plane bend of borate triangular units.

![Fig. 1 Infrared reflectance spectra of glasses xBi₂O₃–(1–x)B₂O₃ with x = 0.2, 0.3, 0.4 and 0.5.](image-url)
It is observed that the high-frequency profile exhibits a red shift upon increasing the Bi$_2$O$_3$ content, the peak maxima shifting from 1375 to 1240 cm$^{-1}$ for 0.2 $\leq x \leq 0.5$ and from 1285 to 1240 cm$^{-1}$ for 0.6 $\leq x \leq 0.8$. In addition, the bandwidth of the high-frequency profile decreases progressively upon increasing the modification level. It is noted that pronounced red shifts of the high-frequency IR absorption envelopes were observed also in recent studies of Sr,Eu borate glasses $^{51}$ and highly modified Sr,Mn borate glasses. $^{61}$ These trends have been attributed to the progressive depolymerization of the borate network as meta-borate triangles, BO$_2$O$^-$, in super-structural units transform progressively to pyroborate dimers, B$_2$O$_5^4-$, and to ortho-borate monomers, BO$_3^{3-}$, upon increasing the degree of modification.

For $x = 0.20$ and 0.30, the high-frequency envelope is characterized by the presence of a peak at 1375–1360 cm$^{-1}$ and a shoulder at ca. 1270 cm$^{-1}$, which signal the presence of meta-borate triangles, BO$_2$O$^-$. In particular, the peak at 1375–1360 cm$^{-1}$ can be attributed to the stretching of B–O$^-$ bonds and the lower-frequency shoulder to the stretching of B–O bonds in BO$_3^-$ triangles. Previous studies of lithium borate $^{45}$ and silver borate $^{47}$ glasses showed that replacement of a bridging oxygen (O) by a non-bridging one (O') in a BO$_3$ triangle of D$_{3h}$ symmetry to form a BO$_3$O$^-$ unit will reduce the symmetry to C$_{2v}$, and this will split the doubly generate $E'$ asymmetric stretching mode under D$_{3h}$ into two IR-active components of A$_1$ and B$_2$ symmetry. This phenomenon is manifested in the infrared absorption spectra of Li- and Ag-borate glasses by the appearance of two component bands in the 1220–1250 cm$^{-1}$ and 1435–1450 cm$^{-1}$ frequency ranges, attributed to the stretching of B–O and B–O$^-$ bonds of BO$_3$O$^-$ units, respectively. Similar results were found in recent studies of highly modified borate glasses. $^{51,52,61}$ The observed decrease in frequency of the B–O$^-$ stretching in BO$_2$O$^-$ units (1375–1360 cm$^{-1}$) in the present study suggests stronger interactions between Bi$^{3+}$ ions and non-bridging oxygens, which consequently weakens the strength in B–O$^-$ bonding and increases the degree of covalence in Bi–O bonding.

For compositions with $x = 0.4$ and 0.5, the progressive downshift of the peak frequency to 1325 and 1310 cm$^{-1}$ is attributed to the formation of pyroborate dimers, B$_2$O$_5^4-$, in accordance with previous findings in highly modified borate glasses. $^{45,51,52,61}$ As shown in Fig. 3, this downshift is accompanied by the presence of a shoulder at ca. 1210 cm$^{-1}$. Such features are typical for the asymmetric stretching of the

**Fig. 3** Calculated absorption coefficient spectra, $\alpha(\nu)$, of glasses xBi$_2$O$_3$–(1–x)B$_2$O$_3$ for x = 0.2, 0.3, 0.4 and 0.5. All spectra are normalized to their maximum intensity value and shifted for better visualization.

**Fig. 4** Calculated absorption coefficient spectra, $\alpha(\nu)$, of glasses xBi$_2$O$_3$–(1–x)B$_2$O$_3$ for x = 0.6, 0.7, 0.75 and 0.8. All spectra are normalized to their maximum intensity value and shifted for better visualization.
terminal B–O\(^{-}\) bonds (1325–1310 cm\(^{-1}\)) and the B–O–B bridges (1210 cm\(^{-1}\)) in pyroborate units.\(^{45,51,52,61}\)

At large Bi\(_2\)O\(_3\) contents \((0.6 \leq x \leq 0.8,\) Fig. 4) the high frequency envelope consists of two distinct features, a peak at 1285–1240 cm\(^{-1}\) and a shoulder at ca. 1190 cm\(^{-1}\). These spectral characteristics signal the formation of \textit{ortho}-borate units, BO\(_3\)\(^{3-}\),\(^{45,51,61}\) as they can be assigned to the splitting of the doubly degenerate \(\nu_1\) asymmetric stretching mode of such units. The presence of BO\(_3\)\(^{3-}\) units is also manifested by the well-defined peak around 710 cm\(^{-1}\) that is due to their out-of-plane bending mode.\(^{45,51,61}\)

The absorption envelope of BO\(_4\) tetrahedral units, between ca. 750 to 1150 cm\(^{-1}\), appears to gain its maximum intensity relative to the high-frequency envelope for the composition \(x = 0.4\) (Fig. 3), indicating a maximum fraction of BO\(_4\) units. At higher Bi\(_2\)O\(_3\) contents, the 750–1150 cm\(^{-1}\) envelope loses gradually indicating the destruction of BO\(_4\) units in favor of other structural entities. For \(x = 0.75\) and 0.80, this mid-frequency absorption profile is substantially narrowed by almost 100 cm\(^{-1}\) and is characterized by the appearance of peaks at around 840, 910 and 980 cm\(^{-1}\). Previous studies of \textit{ortho}-borate crystals YBO\(_3\),\(^{62}\) GdB\(_3\),\(^{63}\) EuB\(_3\), TbB\(_3\) and DyB\(_3\)\(^{64}\) having the vaterite type structure, that consists of BO\(_3\)\(^{3-}\) tetrahedra arranged in B\(_2\)O\(_3\)\(^{3-}\) rings, showed that the strongest infrared activity is in the 800–1150 cm\(^{-1}\) range with sharp peaks at ca. 870, 920 and 1010 cm\(^{-1}\). Along the same lines, previous studies of superionic AgI-containing \textit{ortho}-borate glasses,\(^{45,51,61}\) Sr,Eu \textit{ortho}-borate glasses,\(^{51}\) and highly modified Sr,Mn borate glasses\(^{52}\) supported the existence of BO\(_3\)\(^{3-}\) tetrahedra at very high modification levels. For convenience, the assignments of the infrared bands discussed here are summarized in Table 1 as a function of Bi\(_2\)O\(_3\) content.

A key finding of this study is that the structure of bismuth-borate glasses with modification level higher than \(x = 0.70\) contains \textit{ortho}-borate tetrahedra BO\(_2\)O\(_3\)\(^{3-}\) in coexistence with \textit{ortho}-borate triangles BO\(_3\)\(^{3-}\). These species are present in equilibrium because they are chemically isomeric, \(\text{i.e.} \) BO\(_2\)O\(_3\)\(^{3-}\) \(\rightleftharpoons\) BO\(_3\)\(^{3-}\). It is noted also that the formation of BO\(_2\)O\(_3\)\(^{3-}\) tetrahedral species, which have two bridging (0) and two non-bridging (O\(^{-}\)) oxygen atoms, is compatible with the very broad glass-forming region \(0.2 \leq x \leq 0.8\) in xBi\(_2\)O\(_3\)-(1 \(-\) x)B\(_2\)O\(_3\) glasses. While the nominal \textit{ortho}-borate composition \((O/B = 3/1)\) corresponds to \(x = 0.5\) in such glasses, the glass-forming region extends well-above this limit and reaches \(x = 0.80\) by splat-quenching and even \(x = 0.88\) by twin roller quenching.\(^{21}\) This is in contrast to lithium-borate glasses xLi\(_2\)O-(1 \(-\) x)B\(_2\)O\(_3\) for which glass formation by splat-quenching was possible up to \(x = 0.73\), \(\text{i.e.}\) the pure \textit{ortho}-borate glass composition \((x = 0.75)\) was not achieved due to partial crystallization at \(x = 0.73.\)^\(^{45}\) This can be rationalized in terms of the main structural difference between these two glass systems; while BO\(_3\)\(^{3-}\) triangles are the only borate species present in Li-\textit{ortho}-borate, they coexist with their isomeric tetrahedral \textit{ortho}-borate units BO\(_2\)O\(_3\)\(^{3-}\) in highly-modified Bi-borate glasses and this appears to prevent crystallization.

The above findings are in line with reported structures and infrared spectra of crystalline bismuth-borate compounds of similar stoichiometry. Starting with the low Bi\(_2\)O\(_3\) content \(x = 0.20\), the structure of the Bi\(_2\)B\(_2\)O\(_5\)\(_3\) crystal consists of infinite chains of \textit{meta}-borate rings B\(_3\)O\(_7\)\(^{3-}\) linked together by BiO\(_6\) octahedra, BO\(_3\) triangles and BO\(_4\) tetrahedra.\(^{66}\) The corresponding mid-IR transmittance spectrum\(^{35}\) exhibits the two characteristic bands of BO\(_2\)O\(_3\) units centered at ca. 1250 and 1360 cm\(^{-1}\), and several peaks in the 800–1100 cm\(^{-1}\) range due to BO\(_4\)\(^{-}\) tetrahedra. The Bi\(_2\)O\(_6\) crystal, corresponding to \(x = 0.25\) and having the \textit{meta}-borate stoichiometry \((O/B = 2/1)\), consists of infinite chains of alternating \textit{meta}-borate triangles BO\(_2\)O\(_3\) and \textit{meta}-borate tetrahedra BO\(_4\) in a 1:1 ratio.\(^{67}\) The mid-IR spectrum of BiB\(_5\)O\(_9\) crystal\(^{35}\) resembles that of Bi\(_2\)B\(_2\)O\(_5\)\(_3\), with characteristic absorptions of \textit{meta}-borate triangular and tetrahedral species.

The Bi\(_2\)B\(_2\)O\(_5\)\(_3\) crystal structure, \(x = 0.375\), contains Bi\(_{3+}\) cations, isolated pentaborate type anions B\(_3\)O\(_7\)\(^{-}\) and O\(^{2-}\) anions not bonded to any boron–oxygen group and situated in the centers of isolated OBi\(_3\) triangles.\(^{68}\) The isolated

</table>
pentaborate type anions are formed by two condensed rings sharing a $\text{BO}_4^-$ tetrahedron; one ring consists of this $\text{BO}_4^-$ tetrahedron and two $\text{BO}_3^-$ triangles and the other involves the common $\text{BO}_4^-$ tetrahedron bonded to a $\text{BO}_2^-$ triangle and to a $\text{BO}_2\text{O}_3^-$ tetrahedron.\textsuperscript{58} The mid-IR transmittance spectrum of the $\text{Bi}_2\text{B}_3\text{O}_12$ crystal\textsuperscript{15} exhibits a broad band centered at ca. 1320 cm$^{-1}$ characteristic of $\text{BO}_2\text{O}_3^-$ triangles, bands in the range 1030–1125 cm$^{-1}$ for $\text{BO}_4^-$ tetrahedral units and well defined bands at 840 and 938 cm$^{-1}$ consistent with the existence of $\text{BO}_2\text{O}_3^-$ tetrahedra.

The structures of the crystalline compounds $\text{B}_2\text{O}_3$ (orthoborate, $x = 0.50$) and $\text{Bi}_2\text{B}_2\text{O}_5$ ($x = 0.67$) contain discrete planar ortho-borate triangles, $\text{BO}_3^{3-}$.\textsuperscript{69,70} The mid-IR transmittance spectra\textsuperscript{35} of these two crystals can be fully described in terms of bands attributed to $\text{BO}_3^{3-}$ vibrational modes; these include the $\text{B-O}$ asymmetric stretch (broad envelope in the 1100–1300 cm$^{-1}$ range), and out-of-plane bend at 690 cm$^{-1}$. The presence of multiple bands in the 1100–1300 cm$^{-1}$ envelope arises from the low positional symmetry and the existence of non-equivalent sites for the ortho-borate triangles in the crystal structure, which remove the degeneracy of the asymmetric stretching vibration mode of the $\text{BO}_3^{3-}$ units.

To summarize this section, our mid-IR structural analysis for four-fold coordinated B atoms in Bi-borate glasses suggests the presence of meta-borate tetrahedral units, $\text{BO}_4^-$, for glasses with $0.2 \leq x \leq 0.50$, with ortho-borate tetrahedral units, $\text{BO}_3^{3+}$, prevailing at higher modification levels. Units with three-fold coordinated B atoms include the meta-borate triangles, $\text{BO}_3^-$, dominating in glasses with $x = 0.2$ and $0.3$, and pyroborate dimers, $\text{B}_2\text{O}_5^{4-}$, for $x = 0.3$ to $x = 0.6$, while the ortho-borate monomers, $\text{BO}_3^{3-}$, constitute the majority of triangular borate species for $x \geq 0.50$.

3.2. Far-infrared spectra

Information on the bonding of metal cation in glass can be deduced from the far-IR spectral region, where vibrations of metal ions against their sites in the glass network are active.\textsuperscript{44,45,52,57,61,65} As seen in Fig. 3 and 4, introduction of $\text{Bi}_2\text{O}_3$ in the borate glass causes the progressive evolution of a complex absorption profile which extends up to ca. 670 cm$^{-1}$. The contribution of this profile to the entire infrared response increases with $\text{Bi}_2\text{O}_3$ addition, suggesting that its origin should be traced mainly to vibration modes involving Bi cations.

Inspection of Fig. 3 shows that for the lower modification levels, $x = 0.2$–$0.4$, the far-IR profile appears to consist mainly of a low-frequency band with peak frequency increasing from about 160 cm$^{-1}$ ($x = 0.20$) to 200 cm$^{-1}$ ($x = 0.40$). For the $x = 0.50$ glass, the low-frequency band about 220 cm$^{-1}$ is in co-existence with a higher-frequency component centered at about 510 cm$^{-1}$. These two features dominate the far-infrared region for the rest of glass compositions, $0.60 \leq x \leq 0.80$, as depicted in Fig. 4. In addition, the first peak at about 240 cm$^{-1}$ appears to loss intensity at higher $\text{Bi}_2\text{O}_3$ contents in favor of the peak at about 510 cm$^{-1}$, which at $x = 0.80$ becomes the dominant feature of the entire IR spectrum.

We note that an infrared and Raman study of crystalline $\alpha$-$\text{Bi}_2\text{O}_3$ and bismuth oxide derivatives with sillenite structure showed strong infrared activity in the 400–600 cm$^{-1}$ range, assigned to the stretching of Bi–O bonds in BiO$_2$ polyhedra.\textsuperscript{71} Similarly, studies on multicomponent bismuthate glasses assigned the far-IR absorption centered around 480 cm$^{-1}$ to the Bi–O stretching in strongly distorted BiO$_6$ octahedral moieties.\textsuperscript{32,33,36,72,73} The existence of BiO$_6$ octahedra was proposed also in Raman studies of unconventional lithium-bismuthate glasses\textsuperscript{74} and ternary BiO$_2$-containing phosphate and borate glasses,\textsuperscript{75} in a neutron and X-ray diffraction study of Bi$_2$O$_3$–Ga$_2$O$_3$ glasses,\textsuperscript{76} and in a structural study of Bi$_2$O$_3$–Fe$_2$O$_3$ glasses by X-ray diffraction, IR, EPR and Mossbauer spectroscopies.\textsuperscript{77} On these grounds, we associate the band at ca. 500 cm$^{-1}$ with the formation of BiO$_6$ octahedral units in the bismuth-borate glasses of this study.

The lower-frequency peak in the 160–240 cm$^{-1}$ range can be attributed to vibrations of Bi cations against their ionic sites formed by oxygen atoms of the glass network. This assignment is in line with a plethora of previous investigations on metal oxide-containing borate glasses by both experimental and molecular simulations techniques.\textsuperscript{44–52,57,61,65,78–81}

4. Discussion

4.1. Quantification of the short-range borate structure

The previously described qualitative picture for the evolution of the borate structure with Bi$_2$O$_3$ content can be further elaborated to determine the borate speciation expressed as molar fractions of the various borate entities. To this aim, we proceed by considering the deconvolution of the absorption coefficient spectra $x(\tilde{\nu})$ according to eqn (1). Representative deconvoluted $x(\tilde{\nu})$ spectra are depicted in Fig. 5 for $x = 0.2$ and $x = 0.4$ and in Fig. 6 for the $x = 0.65$ and $x = 0.80$ compositions, whereas the fitting parameters of the component bands are listed in Table 2 for all glass compositions.

In the following, we focus on the bands 1–6 in the 750–1600 cm$^{-1}$ range which originate from the stretching vibration modes of borate units and use the notation $X_i$ for the molar fraction of the unit having $i$ bridging oxygen atoms per boron. Thus, $X_1\text{in}$ denotes the molar fraction of meta-borate tetrahedral unit, $\text{BO}_4^-$, and $X_1$, $X_2$, $X_3$, $X_4$, $X_5$ the molar fractions of $\text{BO}_3$, $\text{BO}_2\text{O}_3^-$, $\text{BO}_2\text{O}_3^{2-}$ and $\text{BO}_3^{3-}$ triangular units, respectively.

For glass compositions $0.20 \leq x \leq 0.40$, mass and charge balance considerations give:

$$\sum_i X_i = 1 \quad (2)$$

$$X_{\text{in}} + 2X_2 + 3X_3 = \frac{3x}{1-x} \quad (3)$$

denoting by $A_j$ the integrated intensity of the $j$-th component band normalized by the total integrated intensity in the 750–1600 cm$^{-1}$ range, the quantities $A_j$ and $X_i$ are related as follows:

$$A_j = \sum_i X_i a_i \quad (4)$$

where $a_i$ is the normalized absorption coefficient of the particular vibration mode of a borate unit involved in the $j$-th
component band. In eqn (4) the summation extends over the different borate units that contribute to the activity of the j-th component band.

Starting with the x = 0.20 glass composition, Fig. 5 shows that the 750–1600 cm⁻¹ range is best fitted with six component bands. According to Section 3.1, the three bands at 1093, 957 and 824 cm⁻¹ are due to BO₃⁻ triangles, whereas the components at ca. 1382 and 1258 cm⁻¹ are due to the stretching of B–O⁻ and B–O bonds in BO₂O⁻ units, respectively. The remaining band at 1482 cm⁻¹ originates from the stretching of B–O bonds in neutral BO₃ triangles. This assignment is consistent with the infrared spectrum of pure B₂O₃ glass that exhibits a similar feature at ca. 1500 cm⁻¹.⁴⁵ Following these assignments, eqn (2) and (3) take the forms:

\[
X_{4\text{m}} + X_1 + X_2 = 1
\]

\[
X_{4\text{m}} + X_2 = \frac{3x}{1-x} = 0.6, \quad X_3 = 0.75
\]

From the above equations, we obtain directly the molar fraction of BO₃ triangles, \(X_3 = 0.23\). Also, it is reasonable to assume that \(a_{\text{B-O}}\) values for B–O bond stretching in either BO₂O⁻ or BO₃ units do not differ appreciably. In that case, eqn (4) for the component bands at 1258 and 1482 cm⁻¹ leads to \(A_{1258} = X_1a_{\text{B-O}}\) and \(A_{1482} = X_3a_{\text{B-O}}\). Then, division of the latter equations by members and substitution of the integrated intensity values from Table 2 gives:

\[
\frac{A_{1258}}{A_{1482}} = 1.68 = \frac{X_1}{X_3} \Rightarrow X_2 = 1.68 \cdot X_3 = 0.42
\]

Using the above result, the \(a_{\text{B-O}}\) value can be estimated:

\[
a_{\text{B-O}} = \frac{A_{1258}}{X_2} = 0.4624 \text{ cm}^{-2}.
\]

The fitting results in Table 2 indicate that for \(x = 0.30\) the 800–1600 cm⁻¹ range is best fitted with five component bands (Fig. 5, bands 2–6). The first three bands at 1079, 957 and 824 cm⁻¹ are due to BO₄⁻ tetrahedra, whereas the components at ca. 1393 and 1263 cm⁻¹ are due to the stretching of B–O⁻ and B–O bonds of BO₂O⁻ and BOO₂²⁻ units, respectively. For the \(x = 0.30\) glass, eqn (2) and (3) give:

\[
X_{4\text{m}} + X_1 + X_4 = 1
\]

\[
X_{4\text{m}} + X_2 + 2X_1 = \frac{3x}{1-x} = 0.9, \quad X_3 = 1.286
\]

Subtracting eqn (8) from eqn (9) gives immediately \(X_1 = 0.286\). Moreover, eqn (4) for the component at 1263 cm⁻¹ takes the form \(A_{1263} = (X_2 + X_1)a_{\text{B-O}}\) and by using the fitting values of Table 2 we obtain: \(A_{1263} = (X_2 + X_1)a_{\text{B-O}} \Rightarrow X_2 + X_1 = A_{1263} / a_{\text{B-O}} = 0.592\). Thus, the calculated molar fractions of the borate units are \(X_1 = 0.286, X_2 = 0.306, X_{4\text{m}} = 0.408\). For the \(x = 0.40\) composition, the 800–1600 cm⁻¹ range is best fitted with five component bands. The first three at 1066, 952 and 842 cm⁻¹ are typical for BO₄⁻ tetrahedra, while the two remaining components at 1331 and 1214 cm⁻¹ originate from the vibrations of both BOO₂²⁻ and BO₃⁻ units. Eqn (2) and (3) take now the following forms:

\[
X_{4\text{m}} + X_1 + X_6 = 1
\]

\[
X_{4\text{m}} + 2X_1 + 3X_6 = \frac{3x}{1-x} = 1.2, \quad X_0 = 2
\]

These equations are easily reduced to: 

---

**Fig. 5** Deconvolution into Gaussian component bands of the infrared absorption coefficient spectra, \(\alpha(\nu)\), of glasses \(x\text{Bi}_2\text{O}_3-(1-x)\text{B}_2\text{O}_3\) with \(x = 0.2\) (a) and 0.4 (b). Black solid lines represent the experimental spectra and circle symbols (○) the simulated spectra. Gaussian component bands are colored as follows; ▼: band 1 attributed to BO₃ triangles (\(x = 0.2\)), ⭑: bands 2 and 3 attributed to BO₂O⁻ (\(x = 0.2\)) or to BO₂O²⁻ and BOO₂⁻ triangles (\(x = 0.4\)), ▲: bands 4–6 attributed to BO₄⁻ tetrahedral units. For assignments of bands 7–11 see text and Table 2.

**Fig. 6** Deconvolution into Gaussian component bands of the infrared absorption coefficient spectra, \(\alpha(\nu)\), of glasses \(0.8\text{Bi}_2\text{O}_3-0.2\text{B}_2\text{O}_3\) (a) and \(0.65\text{Bi}_2\text{O}_3-0.35\text{B}_2\text{O}_3\) (b). Black solid lines represent the experimental spectra and circle symbols (○) the simulated spectra. Gaussian component bands are colored as follows; ▼: bands 2 and 3 attributed to BO₂O⁻ triangles, ▲: bands 4–6 attributed to BO₄⁻ tetrahedral units. For assignments of bands 7–11 see text and Table 2.
The proposed reaction (14) is in agreement with the provision of eqn (12). To proceed further, we note that for compositions with $x \geq 0.65$ the only borate triangles present are the BO$_3$ units. Also, we observe that for the two component bands attributed to BO$_3$ units, due to the splitting of their doubly degenerate $\nu_3$ asymmetric stretching mode, the results of Table 2 indicate that the ratio of the integrated intensities of the low (1155–1170 cm$^{-1}$) vs. the high (1240–1270 cm$^{-1}$) frequency component band attributed to BO$_3$ units is constant and equal to 0.14 for $x \geq 0.65$. This was a constraint imposed in the fitting procedure in order to minimize the residual between experimental and simulated data in the $x = 0.65$ up to $x = 0.80$ composition range. With this constraint in mind, we return to composition $x = 0.40$ for which eqn (4) gives for the two components at 1331 and 1214 cm$^{-1}$ the relations:

$$A_{1331} = (X_1 + X_0) a_{BO} -$$

$$A_{1214} = X_1 a_{BO} + 0.14 X_0 a_{BO} -$$

where $a_{BO}$ is the normalized absorption coefficient for B–O bond stretching in either BO$_2$ units or BO$_3$ units. After substitution of $a_{BO}$ from eqn (15a) and using $X_1 + 2X_0 = 1$ from eqn (13), the eqn (15b) then yields the following trinomial expression:

$$X_1 a_{BO} + X_0 (a_{BO} - 0.14 A_{1331} - A_{1214}) + 0.14 A_{1331} - A_{1214} = 0$$

The positive root of the above equation is $X_1 = 0.139$ and, as follows from eqn (12) and (13), $X_{nm} = X_0 = 0.43$. In addition, for the normalized absorption coefficient for B–O bond stretching in either BO$_2$ units or BO$_3$ units one obtains the value $a_{BO} = 0.785$ cm$^{-2}$. As mentioned in Section 3.1 and shown in Fig. 4, the borate speciation for glasses with $x = 0.50$ and 0.60 involves BO$_2$– and BO$_3$– trigonal units and borate tetrahedra in the form of either BO$_2$O$_2$ or BO$_3$. The evaluation of molar fractions is based now on the mass balance equation, eqn (3), and on eqn (15), by adopting the previously calculated values for
$a_{\text{B-O}} = 0.785 \text{ cm}^{-2}$ and $a_{\text{B-O}} = 0.4624 \text{ cm}^{-2}$ and the results of fitting for the normalized integrated intensities. In fact, a pair of equations similar to eqn (15) applied for the first two component bands, 1290–1315 cm$^{-1}$ and 1185–1199 cm$^{-1}$, can be solved to obtain first the molar fractions $X_1$ and $X_0$ of BOO$_2$ and BO$_3$ units. Then, the remaining molar fraction of borate tetrahedra results from the mass balance equation. With this procedure the calculated molar fractions for $x = 0.50$ are $X_4 = 0.145, X_0 = 0.447$ and $X_4 = 0.408$, whereas for $x = 0.60$ the corresponding values are $X_1 = 0.089, X_0 = 0.576$ and $X_4 = 0.335$. Details for the calculation of molar fraction of borate species for $x = 0.50$ and 0.60 are presented in the ESL.†

For the remaining glass compositions, $x = 0.65–0.80$, the molar fraction of BOO$_2$ species vanishes and the molar fraction of BO$_3$ units can be deduced from the normalized integrated intensity $A_2$ of the highest-frequency component band with center frequency 1242–1270 cm$^{-1}$ (see Table 2), as follows:

$$X_0 = \frac{A_2}{a_{\text{B-O}}} = \frac{A_2}{0.785}$$  \hspace{1cm} (17)

Then, the molar fraction of borate tetrahedra results from the mass balance equation as $X_4 = 1 - X_0$, where $X_4$ includes now the new BO$_2$O$_2$$^2$- ortho-borate tetrahedra and the remaining meta-borate BO$_3$ tetrahedra. The results for the short-range borate structure as a function of the bismuth oxide content are presented in Fig. 7.

The IR-derived molar fraction of borate tetrahedra $X_4$ is compared in Fig. 8a with the reported $N_4$ values from NMR spectroscopy. It is evident that in the common composition range, between $x = 0.2$ and $x = 0.65$, the IR and NMR data are in good agreement. The experimental $X_4$ data are also compared in Fig. 8a with the theoretical $N_4$th value obtained if all oxygen atoms introduced by Bi$_2$O$_3$ are forming BO$_3$ units, $N_{4th} = 3x/(1 - x)$. Clearly, the experimental rate for BO$_3$ formation is considerably lower than $3x/(1 - x)$. For $x = 0.2$ the experimental rate is $1.3x/(1 - x)$, indicating that only 43% of the introduced oxygen forms BO$_3$ units. For $x = 0.3$ the experimental $N_4$ rate reduces to $x/(1 - x)$, indicating that 33% of the available oxygen forms BO$_3$ units. Therefore, the rest of the added oxygen should participate in other structural arrangements, including the non-bridging oxygen containing BO$_2$O$^-$ and BOO$_2$ units with molar fractions $X_0$ and $X_1$ (Fig. 7).

The last demanding task to fully resolve the short-range borate structure is to separate the contributions of the BO$_2$O$_2$$^3$- and BO$_3$ tetrahedral species to the $X_4$ values, as resulted from the analysis of the IR spectra. Unfortunately, the characteristic bands of both tetrahedral borate species lie in the 800–1200 cm$^{-1}$ range and overlap strongly; thus, the deconvolution procedure cannot be adopted in this case. Nevertheless, it is possible to evaluate the contributions of the BO$_2$O$_2$$^3$- and BO$_3$ species by observing that at low Bi$_2$O$_3$ contents $x = 0.2$ and 0.3 only BO$_3$ species are present and at the highest content, $x = 0.80$, BO$_2$O$_2$$^3$- units prevail as shown in Fig. 3 and 4 and discussed in Section 3.1. Based on the results of Table 2 and the calculated $X_4$ values, the normalized absorption coefficients $a_{\text{BO}}$ and $a_{\text{BO}}$ for meta-borate BO$_4$ and ortho-borate BOO$_2$$^3$- species can be evaluated: $a_{\text{BO}} = 0.865 \text{ cm}^{-2}$ and $a_{\text{BO}} = 2.440 \text{ cm}^{-2}$. Then, if we denote by $X_{4m}$ and $X_{4o}$ the contributions to the molar fraction $X_4$ of the meta- and ortho-borate tetrahedra, the following equations result:

$$X_{4m} + X_{4o} = X_4, \quad a_{4m}X_{4m} + a_{4o}X_{4o} = A_{4t}$$  \hspace{1cm} (18)
where $A_{4t}$ is the total normalized integrated intensity of the component bands attributed to borate tetrahedral (bands 4–6). Then, solution of eqn (18) gives the molar fractions $X_{\text{4m}}$ and $X_{\text{4o}}$ as follows:

$$X_{\text{4m}} = \frac{a_{\text{4m}} X_4 - A_{\text{4m}}}{a_{\text{4o}} - a_{\text{4m}}} = \frac{2.440 X_4 - A_{\text{4m}}}{1.575}$$

$$X_{\text{4o}} = \frac{A_{\text{4o}} - a_{\text{4m}} X_4}{a_{\text{4o}} - a_{\text{4m}}} = \frac{A_{\text{4o}} - 0.865 X_4}{1.575}$$

(19)

The fractional contributions of the meta-borate, $X_{\text{4m}}$, and the ortho-borate, $X_{\text{4o}}$, tetrahedra to the total population of borate tetrahedra $X_4$ are presented in Fig. 8b. In the same figure are shown also the best fitted curves to the data, according to the exponential formulae:

$$\frac{X_{\text{4m}}(x)}{X_4(x)} = A + B e^{C x}$$

$$\frac{X_{\text{4o}}(x)}{X_4(x)} = A' + B' e^{C x}$$

(20)

As shown in Fig. 8b, the relative populations of the BØ$_4$ and BO$_2$O$_2$ species are described well by exponential curves with the constant $C$ in the exponent being $C = 11 \pm 1$, the pre-exponential factors are $B = (-10 \pm 1) \times 10^{-5}$ and $B' = (10 \pm 1) \times 10^{-5}$, and $A = 1, A' = 0$.

### 4.2. Bonding of bismuth in borate glasses

As observed in Fig. 5 and 6, the infrared profiles below 650 cm$^{-1}$ can be described by four component bands. Table 2 shows that the frequencies of these components are in the ranges 162–232 cm$^{-1}$ (band 11), 330–365 cm$^{-1}$ (band 10), 475–510 cm$^{-1}$ (band 9) and 597–615 cm$^{-1}$ (band 8). The latter component (band 8) is related to borate species as it can be assigned to the in-plane bending mode of borate triangular units.45

The composition dependence of frequency and relative integrated intensity of bands 9, 10 and 11 are shown in Fig. 9a and b, respectively; relative intensities were obtained by normalizing with the integrated intensity of the entire infrared spectrum. The integrated intensity of band 11 shows an increasing trend up to about $x = 0.60$ and then a tendency for saturation at higher Bi$_2$O$_3$ levels. As noted above, band 11 can be associated to bismuth–oxygen stretching, $\nu$(Bi–O), in ionic sites formed by oxygen atoms provided by the borate network in analogy to previous findings for metal oxide-containing borate glasses.15,47,46,52,78–81

Bands 9 and 10 exhibit similar dependences on composition in terms of both frequency and relative intensity. This suggests that these bands can be associated to vibrations of the same bisumuthate species, like the BiO$_6$ octahedra discussed in Section 3.2. BiO$_6$ octahedra would have two infrared active $T_{1u}$ modes under $O_h$ point group; the asymmetric stretching ($\omega_3$) and the asymmetric bending ($\omega_4$) modes.82 Due to structural distortions, the degeneracy of the $\omega_3$ and $\omega_4$ modes will be removed in the glassy state and contribute to broadening of the corresponding bands. Along these lines, we attribute band 9 to the asymmetric stretch ($\omega_4$) and band 10 to the asymmetric bend ($\omega_3$) of distorted BiO$_6$ octahedra in borate glasses. Using frequency data from Table 2 for the $\omega_3$ ($\nu_{\text{10}}$) and $\omega_4$ ($\nu_{\text{10}}$) modes of BiO$_6$ octahedra we find an average value of 0.71 for the frequency ratio $\omega_4/\omega_3$, in good agreement with the average value $\omega_4/\omega_3 = 0.69$ for octahedral Bi$^{3+}$ complexes.82

We note also that the relatively high-frequency value of the $\omega_3$ mode (average 495 cm$^{-1}$) indicates considerable covalence in the Bi–O bonding. Nevertheless, the corresponding Bi–O bond strength is lower than the average B–O strength as suggested by the large difference in the so-called interaction parameter for the corresponding cation–anion pairs, $A_{\text{Bi}}$, as determined by Dimitrov and Komatsu;83 i.e. $A_{\text{Bi}}$(Bi$_2$O$_3$) = 0.008 and $A_{\text{Bi}}$(B$_2$O$_3$) = 0.244. In addition to this approach, a comparison between the Bi–O and B–O bond strengths can be made by employing experimentally derived values for the weighted average frequency of the $\omega_3$ and $\omega_4$ modes for the BiO$_6$ glass-forming sites, $\nu_{\text{Bi-O(0)}} = 451$ cm$^{-1}$, and the weighted average $\nu_{\text{B-O}}$ frequency in 4-fold, $\nu_{\text{B-O(4)}} = 952$ cm$^{-1}$, and 3-fold, $\nu_{\text{B-O(3)}} = 1292$ cm$^{-1}$, coordinated boron–oxygen sites. For this, we used frequencies $\nu_9$ and $\nu_{\text{10}}$ from Table 2 to calculate the weighted average $\nu_{\text{Bi-O(0)}}$ value, frequencies $\nu_{\text{9}}$, $\nu_{\text{10}}$ and $\nu_{\text{9}}$ for $\nu_{\text{B-O(4)}}$ and frequencies $\nu_{\text{9}}$ and $\nu_{\text{10}}$ for $\nu_{\text{B-O(3)}}$.

The harmonic oscillator model for the frequency of vibration of an M–O bond gives $\nu_{\text{M-O}} = (1/2\pi)(\sqrt{\nu_{\text{M-O}}^2 + \nu_{\text{M-O}}})^{1/2}$ where $\nu$ is the speed of light and $\nu_{\text{M-O}}$ and $\nu_{\text{M-O}}$ are the force constant and reduced mass of vibration; this leading to the following expression for $M = \text{Bi}$ and $M = \text{B}$:

$$\frac{k_{\text{Bi-O}}}{k_{\text{B-O}}} = \frac{\mu_{\text{Bi-O}}}{\mu_{\text{B-O}}} \frac{\nu_{\text{Bi-O}}^2}{\nu_{\text{B-O}}^2}$$

(21)

Approximating the reduced mass by $\mu_{\text{Bi-O}} = (m_\text{O} m_\text{M})/(m_\text{O} + m_\text{M})$ where $m$ is the atomic mass, and considering borate triangular sites with average frequency $\nu_{\text{B-O(0)}} = 1292$ cm$^{-1}$, eqn (21) gives for the glass-forming BiO$_6$ sites $k_{\text{Bi-O}} = 0.28 k_{\text{B-O}}$ using...
$\nu_{\text{Bi-O}}(\text{f}) = 451$ cm$^{-1}$. Application of the same equation to ionic bismuth–oxygen sites, which manifest the glass-modifier role of Bi$_2$O$_3$ with an average frequency $\nu_{\text{Bi-O(m)}} = 210$ cm$^{-1}$, results in $\nu_{\text{Bi-O(m)}} = 0.06\nu_{\text{Bi-O(f)}}$.

In conclusion, infrared spectroscopy gives values for the average Bi–O bond strength reflecting the dual role of Bi$_2$O$_3$ in borate glasses, i.e., as glass-forming and glass-modifying oxide with average Bi–O bond strengths reaching about 28% and 6% of the average B–O bond strength in triangular borate sites.

### 4.3. Property–structure correlations in bismuth-borate glasses

The strong effect of Bi$_2$O$_3$ on the nature and distribution of structural units constituting the glass, as shown in Fig. 7 and 8, can provide insights into the composition dependence of physical properties. Previous studies focused on the optical basicity and electronic polarizability of bismuth-borate glasses. We consider here the glass transition temperature, $T_g$, a property related to the rigidity of the glass network; the latter reflects the interatomic bonding energy and the atomic packing density of the glass.

The composition dependence of $T_g$ is shown in Fig. 10a, based on data reported by Bajaj et al. for Bi$_2$O$_3$ contents up to 66 mol% and by George et al. for higher Bi$_2$O$_3$ contents (Table 3). Clearly, $T_g$ exhibits a decreasing trend upon increasing Bi$_2$O$_3$ content and the rate of decreasing $T_g$ appears to be composition dependent. In particular, three composition regimes can be distinguished where $T_g$ exhibits approximate linear dependencies on the Bi$_2$O$_3$ content: (I) $0.2 \leq x \leq 0.4$, where $T_g$ decreases at a rather mild rate; (II) $0.4 < x \leq 0.6$, with a faster decrease of $T_g$; and (III) $0.6 < x \leq 0.83$, where $T_g$ decreases at a reduced rate in comparison to regime II.

The variation of $T_g$ with Bi$_2$O$_3$ content can be viewed in terms of the molar fractions of the short-range units constituting the borate structure (Fig. 7 and 8). The composition range I is characterized by decreasing fractions $X_b$, $X_z$, and $X_i$, while $X_i$ increases towards its maximum value at $x = 0.4$. The net effect of these structural rearrangements leads apparently to a decreasing connectivity of the borate network as manifested by a slightly decreasing $T_g$. In region II, the combined effect of decreasing $X_b$ and the formation of the completely depolymerized ortho-borate triangular BO$_3$– species ($X_o$) cause a pronounced decrease of $T_g$. It is of interest to note that in region III the decrease of $T_g$ slows down, despite the continuing decrease of $X_o$ and the rise of $X_b$ as observed in Fig. 7. This apparent discrepancy can be resolved by recalling the increasing formation of ortho-borate tetrahedral BO$_2$O$_3$– species in region III ($X_o$ in Fig. 8). This process restores some of the borate connectivity, because BO$_2$O$_3$– provides two bridging boron–oxygen bonds (B-O) per boron in comparison to zero B–O bonds offered by BO$_3$– species.

For alkali-borate glasses M$_2$O–2B$_2$O$_3$ (M = Li–Cs), $T_g$ was found to vary proportionally to the average number of bridging B–O bonds per boron center, $N_b$. Using the molar fraction data of this study, $N_b$ can be calculated for bismuth-borate glasses as follows:

$$N_b = 4X_{4m} + 2X_{4o} + 3X_3 + 2X_2 + X_1$$

(22)

To calculate $N_b$ for glasses not studied in this work, we used interpolated or extrapolated values for the mole fractions of the borate species involved in eqn (22). The obtained $N_b$ values are plotted in Fig. 10b versus Bi$_2$O$_3$ content, and are found to exhibit approximate linear dependencies on composition in the three regimes defined by the $T_g$ response.

As observed in Fig. 10b, the slopes of the $N_b$ variations show differences compared to those of $T_g$; for example, the decrease of $N_b$ in regime II is not as steep as that of $T_g$. This indicates that the proportionality constant between $T_g$ and $N_b$ is composition dependent. Also, although $N_b$ plays a crucial role on $T_g$, there are additional factors which influence $T_g$ as well. They are the strength of the metal cation–oxygen interactions, and the effectiveness in packing of the glass constituents as quantified by the atomic packing density $C_p$. Previous studies on alkali-borate, alkaline-earth borate, and transition metal-borate glasses, having fixed metal oxide contents, demonstrated linear-dependences of $T_g$ on the strength of the M–O interactions, which express the ability of the M$^{+}$ cations to cross-link network segments through M–O
Table 3  Selected properties of glasses $x\text{Bi}_2\text{O}_3-(1-x)\text{B}_2\text{O}_3$; density $d$, molar weight $M_w$; glass transition temperature $T_g$; average number of bridging boron–oxygen bonds per boron center $N_b$; average single bond strength $E_{M-O}$; and atomic packing density $C_g$. Values for $N_b$, $E_{M-O}$, and $C_g$ were calculated using eqn (22), (24) and (26), respectively.

</table>

$^a$ Density and glass transition temperature data are from Bajaj et al. for Bi$_2$O$_3$ contents up to 66 mol% and from George et al. for higher Bi$_2$O$_3$ contents.

The average single bond energy in three-fold borate sites we use $E_{B-O(3)} = 498$ kJ mol$^{-1}$ and apply eqn (24) to calculate the average single bond energy, $E_{M-O}$, in glasses $x\text{Bi}_2\text{O}_3-(1-x)\text{B}_2\text{O}_3$. The results are given in Table 3 and plotted in Fig. 10c as a function of composition. It is found that consideration of both borate and bismuthate constituents leads to a rather smooth decrease in the average single bond energy with Bi$_2$O$_3$ content. Nevertheless, progressive changes in the slope of $E_{M-O}$ versus Bi$_2$O$_3$ content can still be seen in the three composition regimes. In any case, the variation of $E_{M-O}$ with composition is in line with the general trends of both $T_g$ and $N_b$.

Finally, we evaluate the composition dependence of the atomic packing density $C_g$ in bismuth-borate glasses. $C_g$ is defined as the ratio between the theoretical volume occupied by the constituent ions and the real volume of glass. For multicomponent glasses $C_g$ is given by the general equation:

$$C_g = d^3 \sum \frac{N_A}{f_i} (x_A r_A^3 + 3y_i r_i^3)$$

where $d$ is the glass density, $N_A$ is the Avogadro number, and $f_i$ is the molar fraction of the $i$th glass component having chemical formula $A_{x_i}B_{y_i}$, molar mass $M_i$, and ionic radii $r_A$ and $r_B$ for atoms A and B, respectively.

For glasses $x\text{Bi}_2\text{O}_3-(1-x)\text{B}_2\text{O}_3$, eqn (25) reduces to the form:

$$C_g = d^3 \sum \frac{N_A (2x_A r_A^3 + 2(1-x) y_B r_B^3 + 3y_i r_i^3)}{M_w}$$

Values of density ($d$) and molar weight ($M_w$) are given in Table 3, noting that the ratio $d/M_w$ in eqn (26) is the inverse of the glass molar volume, $1/V_m$. For radii we use effective ionic radii of Shannon, taking the values $r_A = 1.35$ Å for oxygen and $r_B = 1.03$ Å for bismuth, the latter corresponding to Bi in six-fold coordination. For the ionic radius of boron we take into consideration the change in coordination number with composition ($x$) and write $r_B = X_B r_{B(4)} + (1-X_B) r_{B(3)}$, where the ionic radius of transition metal radii for 4- and 3-fold coordination are $r_{B(4)} = 0.11$ Å and $r_{B(3)} = 0.01$ Å recognizing that boron has a very small effect on $C_g$ in comparison to oxygen and bismuth.

The calculated $C_g$ values are given in Table 3, while the evolution of the atomic packing density with composition is demonstrated in Fig. 10d. Despite the fact that the $C_g$ values seem to have relatively larger scattering than those for $N_b$ and $E_{M-O}$, all three properties are found to exhibit a general decreasing trend with Bi$_2$O$_3$ content. It is noted though that $C_g$ shows a maximum at $x = 0.25$, which should reflect the minimum in $V_m$ at the same composition as reported by George et al. In any case, it is found that $N_b$, $E_{M-O}$, and $C_g$ all contribute to shaping the overall composition dependence of $T_g$ (Fig. 10a). Considering that the glass structure affects directly $N_b$, $E_{M-O}$, and $C_g$ as expressed by eqn (22), (24) and (26), the present results demonstrate the close correlation between $T_g$ and glass structure in the broad glass-forming region of the bismuth-borate system.
5. Conclusions

Glasses in the system $x$Bi$_2$O$_3$–$(1-x)$B$_2$O$_3$ were synthesized by melting in Pt crucibles and subsequent splat-quenching between two stainless-steel blocks; this technique was found to give homogeneous glasses in the continuous range $0.2 \leq x \leq 0.8$. The evolution of glass structure with composition ($x$) was studied by infrared (IR) reflectance spectroscopy in a broad and continuous spectral range, comprising well-separated far- (30–650 cm$^{-1}$) and mid-IR (650–5000 cm$^{-1}$) responses for bismuth-borate glasses. Absorption coefficient spectra were calculated from the measured reflectance spectra, and were deconvoluted into component bands attributed to vibration modes of specific bismuthate and borate species.

The Bi–O vibrational activity was probed at low frequencies in the far-IR region. It involves a band at 160–230 cm$^{-1}$ due to Bi–O stretch in ionic sites reflecting the glass-modifying role of Bi$_2$O$_3$, and bands at 330–365 cm$^{-1}$ and 475–510 cm$^{-1}$ assigned to the asymmetric bend and asymmetric stretch in distorted BiO$_6$ sites. The relatively high frequency of the latter bands demonstrates considerable covalence in the Bi–O bonding in BiO$_6$ sites and manifests the parallel glass-forming role of Bi$_2$O$_3$. Ionic Bi–O and relatively covalent BiO$_6$ sites were found to coexist in the composition region $0.20 \leq x \leq 0.80$. The latter sites prevail for Bi$_2$O$_3$ contents above 60 mol%, and account for the extended glass-forming range of the bismuth-borate system. Consideration of the corresponding IR frequencies allowed estimating the average Bi–O bond strengths in glass-modifying and glass-forming bismuthate sites; they reach ca. 6% and 28% of the average B–O bond strength in triangular borate sites.

Bands arising from B–O stretching modes were found in the 810–1090 cm$^{-1}$ and 1155–1490 cm$^{-1}$ range for borate units having tetrahedral and triangular B–O coordination, while their bending modes are active in the 595–710 cm$^{-1}$ range. Comparison with previous IR studies on modified borate glasses and bismuth-borate crystalline compounds allowed the borate speciation as a function of composition. Thus, two kinds of borate tetrahedral species were identified having the meta-borate, BO$_4^-$, and ortho-borate, BO$_2$O$_3^-$, stoichiometry where the oxygen atoms are all bridging (O) or two are bridging and two non-bridging (O$^-$), respectively. In addition, all possible types of triangular borate units were identified in bismuth-borate glasses for the first time, i.e. units BO$_3$, BO$_3^-$, BOO$_2$ and BO$_3^{3-}$ with increasing number of non-bridging oxygen atoms per boron. The IR results on the relative integrated intensity of bands characterizing the different borate species were combined with mass and charge balance equations to quantify for the first time all six type of borate species present in the bismuth-borate glass system. The complete mapping of the short-range borate structure as a function of composition was achieved in terms of the molar fractions $X_{4m}$, $X_{4o}$, $X_{3i}$, $X_{3o}$, $X_1$ and $X_0$ of units BO$_3^-$, BO$_2$O$_3^-$, BO$_3$, BO$_2$O, BOO$_2$ and BO$_3^{3-}$, respectively. The present IR results for the total molar fraction $X_4$ of the borate tetrahedral species, $X_4 = X_{4m} + X_{4o}$ were found in excellent agreement with reported $N_4$ data from NMR spectroscopy. In addition to $X_4$ or $N_4$, the present work gives the $X_{4m}$ and $X_{4o}$ fractions as well as the fractions of all types of triangular borate species $X_{3+n}$ where $n = 0, 1, 2$ and 3.

The composition dependence of the glass transition temperature, $T_g$, of bismuth-borate glasses was discussed in terms of three glass properties calculated using the structural results of this work: the average number of bridging boron–oxygen bonds (B–O) per boron center, $N_{BO}$, the average Bi–O and B–O single bond energy, $E_{Bi-O}$, and the atomic packing density, $C_g$. It was found that $N_{BO}$, $E_{Bi-O}$ and $C_g$ all exhibit approximate linear dependencies on the Bi$_2$O$_3$ content in the three composition regimes $0.2 \leq x \leq 0.4$, $0.4 < x \leq 0.6$ and $0.6 < x \leq 0.83$, and contribute to the overall composition dependence of $T_g$. In conclusion, $T_g$–structure correlations are determined by the combined effect of the borate cross-linking ability, the strength of the interatomic bonding energy and the effectiveness of atomic packing in the studied bismuth-borate glasses.
