## Local structuring of diketopyrrolopyrrole (DPP)-based oligomers from molecular dynamics simulations†

Maryam Reisjalali, J. Javier Burgos-Mármol, Rex Manurung and Alessandro Troisi

The microscopic structure of high mobility semiconducting polymers is known to be essential for their performance but it cannot be easily deduced from the available experimental data. A series of short oligomers of diketopyrrolopyrrole (DPP)-based materials that display high charge mobility are studied by molecular dynamics simulations to understand their local structuring at an atomic level. Different analyses are proposed to compare the ability of different oligomers to form large aggregates and their driving force. The simulations show that the tendency for this class of materials to form aggregates is driven by the interaction between DPP fragments, but this is modulated by the other conjugated fragments of the materials which affect the rigidity of the polymer and, ultimately, the size of the aggregates that are formed. The main structural features and the electronic structure of the oligomers are fairly similar above the glass transition temperature and at room temperature.

### Introduction

The use of organic semiconducting polymers (SCPs) in electronic devices is a topic of great interest due to this class of materials displaying properties such as environmental stability, easy solution processability and flexibility<sup>1,2</sup> while exhibiting charge carrier mobilities gradually approaching those of their inorganic counterparts. These materials have applications across fields such as the active layer of field-effect transistors (FETs),<sup>3,4</sup> organic photovoltaics (OPVs)<sup>5,6</sup> and bioelectronics<sup>7–9</sup> with reported mobilities as high as  $\sim 10 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ .<sup>10,11</sup>

Following the analogy with inorganic semiconductors in which crystalline phases have the highest charge mobility, thiophene-based semicrystalline organic semiconductors such as P3HT (poly(3-hexylthiophene)), PQT (poly(3,3'-dialkyl-quaterthiophene)) and PBTTT with a choice of alkyl side chains for solution processability were extensively studied for a long while.<sup>12</sup> The experimentally reported higher charge mobility for PBTTT compared to P3HT in thin-film transistors (TFT) resulted in theoretical and computational studies focusing on the morphology of these materials.<sup>13,14</sup> A review of many different techniques to analyse the structure of these materials was provided by Do *et al.*<sup>15</sup> The larger free volume between alkyl

side chains of PBTTT was shown to facilitate a higher degree of crystallinity by the formation of a lamellar structure of interdigitated side chains as well as the higher degree of planarity of the backbones. Interdigitation of side chains was also experimentally observed using X-ray diffraction (XRD).<sup>16,17</sup> Even though a high volume of research was initially carried out for more crystalline SCPs, it became increasingly apparent by collating the experimental evidence<sup>18</sup> that long-range ordering was not essential for a high charge carrier mobility. The existence of short-range stacked domains was shown to be sufficient enough as long as there existed long chains connecting ordered domains. Experimental techniques such as grazing incidence X-ray diffraction (GIXRD)<sup>19</sup> have provided evidence for the existence of ordered domains in a wide range of different classes of materials from semicrystalline P3HT and regioregular P3HT (Rr-P3HT) to amorphous materials. In understating these materials theoretical approaches have been used as a stand-alone method or in conjunction with experimental data<sup>16,20</sup> to investigate the structural properties such as aggregation, the existence of local ordered domains and segregation of different parts of the polymeric chains. The chemical structure of these materials and the endless list of possible combinations of aromatic rings in the backbone and alkyl side chains make it nearly impossible to study all the variations and their effects on morphological properties and, consequently, the device performance.<sup>21</sup> Some of these variations are changing the size of the side chains, using branched or linear side chains, the length and planarity of the backbone, and the type of

conjugating aromatic rings.<sup>4,22–24</sup> Despite many years of investigation, the relationship between the polymer structure and charge transport properties remains unclear.

In the following, the family of DPP-base semiconducting polymers is selected to be investigated for their morphological and structural properties. The rationale behind choosing this family has been the figure of merit, their reported high charge carrier mobility without having an overall crystalline structure.<sup>18,25–27</sup> These materials' paracrystalline properties, meaning they can form short-range ordered domains without having an overall crystalline structure,<sup>28</sup> and the strong electron-withdrawing nature of the DPP units make them good candidates for use in ambipolar devices such as organic solar cells, OFETs and OLEDs,<sup>29–32</sup> one of the first organic devices to report near-infrared (NIR) light emission.<sup>11</sup> Despite many reports of high mobility when these materials are used in an OFET device it is not yet determined how the varying factors contribute to such performance.<sup>33</sup> Some of these factors are changing the composition of the conjugated backbone, changing the side chain length and whether a linear or branched side chain is used. Huang *et al.*<sup>34</sup> investigated the effect of changes in the length of conjugated backbones by studying the morphology and structural ordering of DPP-4T and DPP-6T. Using UV-vis measurements, they showed that both oligomers, DPP-4T and DPP-6T, exhibit a red-shifted spectra in solution compared to the solid state due to the higher level of aggregation and decreased intermolecular distances in the solid state.<sup>35</sup> Grazing incidence wide-angle X-ray scattering (GIWAXS) and electron diffraction methods were used to study the morphology of crystalline portions of these systems. The  $\pi$ -stacking distance calculated from lattice modelling was reported to be  $\sim 3.2$  Å and  $\sim 3.8$  Å for DPP-4T and DPP-6T, respectively. It was concluded that the higher level of conformational degrees of freedom for the longer conjugated backbone of DPP-6T can result in the introduction of defects in the crystalline portion and therefore shorten the charge-transporting channel and lower charge mobility. Magic-angle spinning NMR, which is suitable to investigate the local structure in the absence of long range ordering, was used to study bulk and thin film DPP-DTT.<sup>36</sup> These measurements in combination with computational quantum and molecular dynamics modelling showed a high level of backbone planarity for DPP-DTT with a donor-on-acceptor stacking arrangement. The preferred conformational stacking was rationalised by the existence of weak hydrogen bonding<sup>37</sup> between the thiophene rings and DPP, with a measured  $\pi$ -stacking of 3.67 Å. The aggregation of the same polymer was also verified in solution using small angle neutron scattering (SANS) and light scattering.<sup>38</sup>

The effect of the chemistry of the backbone was investigated by replacing the T rings with fused aromatic segments such as thienothiophene (TT)<sup>39,40</sup> or furan rings,<sup>41–43</sup> with both changes reported to increase the planarity and therefore improve the chain stacking and aggregation. The effect of using phenyl rings instead of thiophene was also investigated for single molecules by studying their solid-state features.<sup>44</sup> In this

case where stronger hydrogen bonds are present and the phenyl is twisted outside the conjugation plane, a face-to-edge packing was observed hindering the  $\pi$ -stacking and lower charge mobility. Zhang *et al.*<sup>45</sup> reported that increasing the number of thiophene and bithiophene rings between DPP units increases the glass transition temperature but does not change appreciably the mechanical properties. Replacing the sulphur atoms of the thiophene rings with larger heteroatoms such as selenium was reported to result in a higher degree of  $\pi$ -stacking caused by the stronger intermolecular interactions between Se atoms, compared to those of S atoms.<sup>46</sup> The solid state aggregation properties and chain stacking is reported to improve by random terpolymerisation of DPP-4T with a low amount of isoindigo<sup>47</sup> resulting in higher charge mobility due to the enhancements in amorphous features. Wang *et al.*<sup>46,48</sup> measured the changes in the mobility of the DPP-selenophene system where one branched side chain is replaced by a linear side chain.

Different aspects of alkyl side chains can also be studied<sup>48</sup> such as the existence of an extra carbon atom before the branching position in a branched side chain which is reported to increase the  $\pi$ - $\pi$  stacking.<sup>49</sup> UV-vis obtained for DPP-4T showed that changing the side chains from linear to branched had subtle effects on the spectra in solution, while in thin films the linear side chains showed stronger intermolecular interactions.<sup>50</sup> The effects of different end groups were investigated for different end groups such as hydrogen atoms, thiophene rings or pyrene segments.<sup>51–53</sup> Finally, optical spectra have shown evidence of H- and J-aggregates<sup>54</sup> in polymers of the DPP family.

The combination of these studies point to a coherent qualitative picture: DPP polymers form short range aggregates with the size of the aggregate being modulated by changes in the polymer backbone and side chain.<sup>55–57</sup> The conjugated portions in the more ordered phases are co-planar with a measurable  $\pi$ -stacking distance but there is no other information available on the local structure and therefore on the driving force for aggregation and the microscopic effect of chemical changes.

Classical molecular dynamics (MD) simulations have helped to establish a link between experimental observations and microscopic structures since the beginning of organic electronics. A substantial number of studies have focused on P3HT and PBT<sub>TT</sub> for many years due to the earlier assumption of these materials being best for exhibiting crystalline nature.<sup>58–61</sup> More reports on the simulation of polymer melts have appeared for oligomers such as poly(phenylenevinylene) (PPV),<sup>62</sup> Didodecylquaterthiophenes (DDQT),<sup>63</sup> and poly(2-vinyl pyridine) (P2PV)<sup>64</sup> including recent attempts to collectively compare the performance of different materials for different applications.<sup>65–68</sup> A particularly challenging aspect is the generation of equilibrated structures for the melt phase, which requires large computational resources. To overcome this obstacle, different approaches have been followed, such as simulated annealing,<sup>69</sup> coarse-grained models<sup>70</sup> or implicit solvent models.<sup>71</sup> Where possible, the simulation data are checked against the experimental data.<sup>72–75</sup> Recent molecular dynamics studies at an atomic level of DPP systems employed single long chains in explicit solvents to

understand the conformational and morphological properties<sup>71</sup> and small copolymers to investigate the effect of the position of side chain linkers on electronic and optical properties.<sup>76</sup> Simulations are used in conjunction with the experimental techniques to compare, validate or isolate the effect of a single change in the chemistry of a material on other properties. The effect of weak hydrogen bonds of DPP polymers on the  $\pi$ -stacking chain conformations showed good agreement between values obtained from NMR spectroscopy and computational simulations (DFT and MD).<sup>36</sup> The comparison between experimental data and computational calculations was also reported using coarse-grained methods<sup>45</sup> for chain alignments. The effect of changing a bulky branched side chain with a linear chain was studied using MD simulations<sup>48</sup> in agreement with experimental data to show that linear side chains result in higher planarity.

In this work, we present MD simulation analyses of three systems belonging to the DPP family with different backbone segments. All three systems were chosen based on their reported high charge carrier mobilities.<sup>51,77–80</sup> Studying the family of related compounds helps in discriminating between the general feature of polymers containing the DPP fragment and aspects that are more sensitive to the overall chemistry of the polymer. The alkyl side chains are the same for all the systems, a branched alkyl chain at position 2, which are reported to possess the best solubility.<sup>81</sup> Different backbone combinations ranging from 2 thiophene (2T) rings, 4 thiophene rings (4T) and 6 thiophene rings (6T) were studied to analyse the backbone's contribution to the overall morphology of the polymeric systems (see Fig. 1).

## Methods

### Force-field

The molecular model employed in the present work was based on an implementation of All-atom Optimised Potentials for Liquid Simulations<sup>82</sup> (OPLS) force-field. While the OPLS mathematical form has been used in this document, the key parameters were derived from density functional theory (DFT) calculations. All the equilibrium bond distances and angles of

the conjugated part were taken from the optimisation of trimer chains where values of the middle monomer were used to account for intermonomer connections at the B3LYP/6-311G\*\* level of theory, the atomic point charges were calculated *via* CHelpG (charges from electrostatic potentials using a grid-based method)<sup>83</sup> and the torsional potentials between the conjugated fragments were recomputed through scanning the dihedral potential at the MP2/6-311G\*\* level.<sup>84,85</sup> The equilibrium geometry and intermolecular interaction parameters are very similar to those computed by Jiang *et al.*<sup>86</sup> with a force matching procedure and validated through simulations of small molecular crystals. OPLS-AA parameters were used for the alkyl side chains. Non-bonded van der Waals (vdW) parameters based on the 6-12 Lennard-Jones (LJ) potential were taken directly from OPLS-AA for all atom types using the geometric mixing rule as well as long range Coulomb interactions between point charges, as a common practice for the simulation of polymeric semiconductors.<sup>86</sup>

### Simulation details

Attempts have been made to develop a specialised force-field (FF)<sup>86–88</sup> for this class of materials; however, due to the complexity of the systems, some parametrisation is needed for each new polymer. In this work, simulations were performed on oligomers of three repeat units of each of the monomers. The choice of the length of oligomers was made having in mind the computational resources and the need for studying long enough chains to account for interactions of several monomers. While the slow-down in simulation production is obvious for longer chains, the choice was made based on our objective of having equilibrated and highly-reproducible simulations to use as a reference for these systems. All the MD simulations were performed using large-scale atomic/molecular massively parallel simulator (LAMMPS).<sup>89</sup> The Velocity Verlet algorithm was adopted and periodic boundary conditions (PBCs) were applied in all directions with a time step of 2 fs while using the rattle algorithm to constrain H–X bonds. The Nosé–Hoover isothermal-isobaric barostat and a thermostat were used to control the ensemble properties. The particle–particle

Fig. 1 Chemical structure of the three systems used in this study.

particle-mesh (PPPM) summation algorithm was used during production simulations to compute the electrostatic forces with a cut-off of 12 Å.

The oligomers studied here form glassy phases at room temperature that are difficult to equilibrate (and to verify they are equilibrated). The primary focus of this paper is to study the aggregation of DPP polymers in equilibrated and highly reproducible phases above the glass transition temperature ( $T_g$ ). To establish the simulation temperature, simulated annealings were performed on all three systems from 1000 K to 100 K at a rate of 0.02 K ps<sup>-1</sup>. This process was repeated three times to make sure that annealings were performed for long enough and at a plausible rate. The three simulations were all performed at the same rate where the last point of one run is taken to start the next run by instantly heating it up to 1000 K and slowly cooling it down to 100 K at the given rate. Annealing processes have been shown to improve the structural ordering in the films as evidenced by X-ray scattering and atomic force microscopy.<sup>17,90</sup> Fig. 2 represents the inverse density as a function of temperature for the three sets of simulated annealing for each system where each set is presented with a different colour. The average gradient of the three sets is plotted for both the lower range (0 to 300 K) and the higher range (600 to 1000 K) of temperatures in the dashed black line. The intersection of the two lines is considered as  $T_g$ . The exact values of  $T_g$  are reported in red for each system. The production runs were performed at a temperature above the  $T_g$  of all three systems (550 K). Production simulations were performed from the last point of the second set of simulated annealings for the three systems in an NPT ensemble at 550 K for 400 ns with an integration time step of 2 fs. In agreement with ref. 45 the  $T_g$  increases with an increase in the number of thiophene rings, although a direct comparison is not possible as our molecular weight is much smaller than the one considered experimentally.

## Results and discussion

Production simulations were performed on systems of 64 chains of three repeat units for each of the systems, except 2TT, which after equilibration adopted an excessively elongated shape, provoking some undesired interactions between atoms and their PBC images. To avoid this finite size effect, 128 chains were used instead for this particular polymer. The results of the double-sized simulation of 2TT are presented in the following unless otherwise specified. System specifications are provided in Table 1.

The snapshots of the three simulated systems shown in Fig. 3 already indicate the presence of local ordering in this kind of material. 2TT and 6T appear to show more rigid chains that result in more visible  $\pi$ -stacking. The remainder of the manuscript focuses on the quantitative description of the oligomers' flexibility and the aggregation properties.

### Radius of gyration ( $R_g$ ) and end-to-end distance ( $D_{ee}$ )

A structural property to determine the flexibility of the polymeric chains and to study their conformation is the radius of

Fig. 2 Graphs presenting the specific volume as a function of temperature for three sets of simulated annealing in different colours for each system. The glass transition temperature is found by the intersection point between the two linear gradient fits of lower and higher range of temperatures. Dashed lines and the value of  $T_g$  in red are the average of the three sets.

Table 1 Simulation specification for the production runs

Polymer	Atoms/trimer chain	Number of chains	Number of atoms/simulation	Density (g cm <sup>-3</sup> )
2TT	458	128	58624	0.889
4T	482	64	30848	0.882
6T	524	64	33536	1.013

gyration ( $R_g$ ).  $R_g$  for a group of  $n$  atoms is defined as:<sup>92</sup>

$$R_g = \sqrt{\frac{1}{M} \sum_{i=1}^n m_i (\vec{r}_i - \vec{r}_{cm})^2} \quad (1)$$

where  $M$  is the total mass of the group,  $\vec{r}_{cm}$  is the centre of mass position,  $\vec{r}_i$  is the position of each atom in the group and  $m_i$  is the mass of each atom.  $R_g$  was computed for individual chains

**Fig. 3** Presentation of simulation boxes of the three polymers. The backbones are shown in red and the chain atoms are shown in grey while hydrogen atoms are omitted for simplicity. Snapshots were produced using the visual molecular dynamics (VMD)<sup>91</sup> software. Simulation boxes are not shown in the same scale.

as well as an ensemble average for each of the oligomers. Another property of the polymeric chains calculated to determine the rigidity of the chains is the end-to-end distance ( $D_{ee}$ ). End-to-end distances were computed as the distance between the two closing hydrogen atoms at either end of a chain. Comparing this value to that of an isolated fully elongated chain is an indication of how coiled the chains are. Tables 2 and 3 respectively show comparative values of  $R_g$  and  $D_{ee}$  both at 550 K and 0 K for the three systems. Comparative representation of the most coiled and the most elongated

chains is presented in Fig. 4 for each system, to exemplify the different conformational behaviour of the different systems. Considering the two systems of 2TT and 4T where both have the same number of conjugated moieties along the backbone, the existence of the extra torsional angles between individual thiophene rings provides additional degrees of freedom contributing to the flexibility of the chains and, therefore, a greater standard deviation for both  $R_g$  and  $D_{ee}$ . When considering the fraction of molecular volume taken up by the free chains, the free volume between the adjacent side chains increases in the order of 2TT, 4T and 6T. The extra free volume for 6T, compared to 2TT, in addition to the rotational degrees of freedom enhances the chance of 6T displaying more flexible and coiled conformations.

**Table 2** Calculated average of radius of gyration and its standard deviation during 400 ns production run at 550 K.  $R_g^0$  for a single chain at 0 K is used as an indication of how coiled the chains are

4T	16.38	1.067	10.41	19.20	17.58
6T	19.52	0.29	17.99	20.70	19.55

**Table 3** Calculated average of end-to-end distance and its standard deviation during 400 ns production run at 550 K.  $D_{ee}^0$  for a single chain at 0 K is used as an indication of how coiled the chains are

System	$\bar{D}_{ee}/\text{\AA}$	$\sigma D_{ee}/\text{\AA}$	Min $D_{ee}/\text{\AA}$	Max $D_{ee}/\text{\AA}$	$D_{ee}^0/\text{\AA}$
2TT	49.90	0.26	44.37	51.52	51.07
4T	48.82	3.52	2.94	62.28	59.16
6T	67.24	0.46	59.73	70.12	68.12

### Radial distribution function (RDF)

The radial distribution function (RDF)  $g_{ab}$  between atoms of class  $a$  and  $b$  was computed as:<sup>93,94</sup>

$$g_{ab}(r) = \frac{1}{N_a N_b} \sum_{i=1}^{N_a} \sum_{j=1}^{N_b} \langle \delta((\vec{r}_i - \vec{r}_j) - r) \rangle \quad (2)$$

where  $N_a$  and  $N_b$  are number of atoms in each of the classes,  $r_i$  and  $r_j$  are the coordinates of atoms belonging to each of the classes and  $r$  is the defined radius of a shell for which RDF is defined. Different atom classes were defined to best monitor the variation in structural properties. The DPP group was identified with its two carbon atoms closest to the DPP centre.

Fig. 4 Comparison between the most elongated (on the left) and the most coiled (on the right) chains for the three systems.

The S group consists of all the sulphur atoms in the thiophene or thienothiophene units, and the O and N groups contain the oxygen and nitrogen atoms of the DPP, respectively. Interchain pair distribution functions (*i.e.* excluding atom pairs with both atoms belonging to the same chain) between different atom groups were used to investigate any preferred direction of chain stacking.

It is evident from Fig. 5 that the dominant interactions for the aggregation are different between oligomers where the DPP-DPP interaction is more likely, for 2TT and 4T, while it is the interaction between DPP and S that seems to dominate the aggregations in 6T, making the DPP unit stacking with the thiophene units result in a shifted chain stacking. Interestingly, despite 4T and 6T oligomers being chemically similar, RDFs show that DPP-S aggregation is mostly non-existent in 4T while it is the main aggregation event in 6T, showing that a small change in the number of backbone repeat units can completely condition the structural properties of the material. The geometry of selected paired chains is depicted as insets of Fig. 5 to illustrate the preferential direction of chain stacking. These insets show that the DPP units are aligned in 2TT while for 6T the alignment of DPP units and thiophenes is preferred resulting in a stepwise stacking. The RDFs provide quite a comprehensive view of the tendency of DPP polymers to aggregate. As one can see from the plots, the height of the RDFs, *i.e.* the tendency to form stable  $\pi$ -stacking interactions, decreases in the order of 2TT > 6T > 4T. On the other hand, the existence of more pronounced second peaks in the order of 6T > 2TT > 4T indicates a different trend in the tendency of these materials to form longer range aggregates. Studying the position of RDFs

for the strongest interacting atom group pair indicated that the observed  $\pi$ -stacking for these systems is consistent with the structural information deriving from the study by Huang *et al.*<sup>34</sup> where DPP-4T has a shorter  $\pi$ -stacking distance.

#### Root mean square displacement

Root mean square displacement (RMSD) per atom type allows the determination of the dynamics of the polymer chains, both as a whole and by looking at each component separately. At short times, different atoms can exhibit a considerable gap in their RMSD, meaning that some parts can be more dynamic with respect to the centre of mass of the molecule than others. In a melt at long enough times, the gap between RMSDs of different atoms should become irrelevant as compared to the dynamics of the molecule as a whole. By contrast, in a solid (or a melt at short times), the molecule might be unable to diffuse but still have moieties with faster dynamics (or more freedom to move) than others. Fig. 6 shows the RMSD calculated for different atom groups as well as all atoms using the equation:<sup>95</sup>

$$\text{RMSD}(t) = \sqrt{\frac{1}{N} \sum_{i=1}^N (\vec{r}_i(t) - \vec{r}_i(0))^2} \quad (3)$$

As shown in Fig. 6 middle panel, in the case of 4T, which was previously discussed to be the most disordered and flexible system, all-atom groups seem to be following the same trend with little to no difference between the overall RMSD and the RMSD of different atom groups, indicating that the chain moving as a whole dominates the dynamics in this time range. For 2TT and 6T, as shown in Fig. 6 top and bottom panels, the backbone

Fig. 5 Inter-chain RDFs plotted for the atom groups belonging to the conjugated backbone of the systems with an inset of a selection of paired chains.

dynamics is much slower than that of the alkyl-chains, which indicates that the dynamics is dominated by the latter, with the backbone dynamics hampered by the structural micro-domains formed by these molecules. In particular, the faster alkyl chain dynamics observed for 6T is due to the larger free volume in between monomer units caused by the two extra thiophene rings in the backbone. The slow side chain dynamics in 2TT could be a consequence of a higher degree of backbone stacking and segregation of backbone and side chains. It is also worth mentioning that 2TT is the only one exhibiting an increasing backbone RMSD, which indicates that 4T and 6T, regardless of the side chain dynamics, do not behave as a melt in the time-range studied here.

#### Nematic order parameter

To be able to compute the liquid crystalline ordering across the three systems studied, the nematic liquid crystal order parameter was determined.<sup>96</sup> The calculations were carried out by identifying each monomer with a vector connecting

Fig. 6 RMSD calculations for the three systems showing that there is a greater range of movement associated with the atoms in the side chain for the case of 6T followed by 2TT and 4T.

the first and last carbon atom of a monomer unit depicted in Fig. 1. A snapshot of these sections (in red) imposed over the atomistic view of each system is depicted in Fig. 7. A unit vector is then assumed at the mid-point of each section to be used in calculations.

The order parameters were calculated for each of the systems using the following equation which constructs the  $Q_{\alpha\beta}$  tensor made up of all the unit vectors  $\hat{u}_i$  with  $N_m$  being the number of vectors.<sup>97,98</sup>

$$Q_{\alpha\beta} = \frac{1}{N_m} \sum_{i=1}^{N_m} \left( \frac{3}{2} \hat{u}_{i\alpha} \hat{u}_{i\beta} - \frac{1}{2} \delta_{\alpha\beta} \right), \quad \alpha, \beta = x, y, z \quad (4)$$

The order parameter  $P_0$  is equal to the largest eigenvalue of the  $Q_{\alpha\beta}$  matrix, taking values between 0 and 1, where 0 indicates a completely isotropic system and 1 a completely aligned system.

An average order parameter for the three polymers during 400 ns of production simulation at 550 K in an *NPT* ensemble

Fig. 7 Graphical representation of the vectors assigned for each monomer for a snapshot of the simulation for the three systems (side chains are omitted).

was calculated and represented in Fig. 8. The average value and their standard deviation are represented in Table 4 to compare the local structure ordering within the three systems.<sup>97,99</sup> The larger value of  $P_0$  for 2TT followed by 6T and 4T indicates a good agreement of the liquid crystallinity with the conformation analyses. Longer chains of 6T are more

susceptible to form longer-range ordered regions while it is the fused rings in the case of 2TT resulting in a high  $P_0$  compared to 4T. On comparing between 2TT and 6T, while the value of  $P_0$  is similar, there is no indication of different aggregation properties evident from the RDF. We have, therefore, considered an alternative measure of aggregation.

Fig. 8 Order parameter calculated for the three systems during 400 ns of production simulation.

#### Aggregation properties

To define a cluster of aggregates, a set of criteria were defined based on the same representation of trimers as three vectors explained in the previous section. Any two vectors from different oligomers are assumed to belong to the same cluster if they are closer than 10 Å to each other and make an angle smaller than 30°. Distances larger than ~12 Å resulted in the erroneous selection of chains not in the van der Waals contact while

Table 4 Average values calculated for the order parameter of each of the systems throughout 400 ns of simulations

System	Order parameter	Standard deviation
2TT	0.342	0.018
4T	0.107	0.033
6T	0.321	0.007

distances shorter  $\sim 8$  Å resulted in not including all the good  $\pi$ -stackings. A reasonable angle must be smaller than  $45^\circ$  since angles larger than  $45^\circ$  would include chains in closer-to-perpendicular alignment and we have seen that angles smaller than  $20^\circ$  showed to be too restrictive and excluding well stacked oligomers. The two parameters were chosen as representative of this range, within which the conclusion of analysis remains unchanged. Fig. 9 shows the snapshot of the systems where all monomers belonging to the same cluster are presented in the same colour.

Fig. 10a represents the number of monomer units in the largest aggregate at different snapshots over 400 ns production simulation at 550 K. In this part of the analysis simulations of the same number of oligomer chains were used for all systems for direct comparison. Consistent with previous analysis of the chain flexibility, RDFs and  $P_0$ , calculations of aggregate clusters demonstrate the existence of larger aggregates resulting in a higher level of ordering for 2TT and 6T compared to 4T. Unlike  $P_0$ , which is calculated for the overall simulation box, the calculations of local clusters reveal more dynamical properties of the aggregates. The largest aggregate in 2TT can have a varying number of monomers from 28 to 6, from 49 to 9 for 6T and from 20 to 5 monomer units for 4T. When considered with the  $P_0$  order parameter, the time evolution does not suggest an evolution toward a more ordered phase in time, which implies good equilibration and is consistent with the temperature being above the  $T_g$ . The greater fluctuation in the size of the largest aggregate for 6T is considered to be caused by the movement of monomers of this naturally longer chain between

aggregate clusters. Fig. 10b shows a distribution plot where the y-axis presents the number of times a specifically-sized cluster is formed during the 400 ns of production simulation and the x-axis presents the size of the clusters. It is shown that, for the least ordered system of 4T, the size of the aggregates does not exceed 20 monomers whereas it is increased to 28 for 2TT and 49 for 6T. The cluster size distribution is consistent with the observation made in the previous analyses and considered the most effective measure to differentiate the aggregation properties between oligomers.

### Extension to 300 K

In this work we have focused on the structural characterisation of semiconducting polymers at a temperature above  $T_g$ , where equilibration is easier to achieve and the results are highly reproducible. It is nevertheless instructive to compare the main RDFs with a simulation at 300 K to establish the changes that could be expected. This method of comparison allows determining if the observations made prior can be transferred to lower temperatures. To achieve simulations at 300 K, starting from the last snapshot of the equilibrated simulation at 550 K, a simulated annealing to 300 K was performed for each of the systems using the same cooling rate as the initial annealing ( $0.02$  K ps $^{-1}$ ). A further 50 ns equilibration simulation was then performed on each of the simulations at 300 K. Fig. 11 shows a comparison plot of RDFs between the simulations at 550 K (solid) and 300 K (dashed lines). Comparing the RDFs between the two temperatures, there are minimal differences in the intensity and the position of peaks for all important

Fig. 9 Graphical representation of clusters of aggregates. All units belonging to the same aggregate are coloured the same. Units in grey do not belong to any cluster and side chains are omitted for clarity.

Fig. 10 Plots showing (a) the size of the largest aggregate cluster for snapshots at 4 ns interval during 400 ns of production simulation at 550 K (b) the count of different sized aggregate clusters for each of the systems.

interactions. The increased noise in the RDFs for 300 K is likely caused by a poorer configuration sampling below the  $T_g$  in what is, effectively, a quenched phase. The RDFs of all systems have a better overlap at shorter ranges with the biggest difference between 300 and 550 K at longer ranges for 4T (middle panel in Fig. 11), the least ordered of the three systems.

#### Electronic structure of the ensemble of oligomers

The electronic structure of semiconducting polymers is often described in terms of the density of states (DOS) of the valence band, which provides an indication of the energetic position and disorder of the states occupied by the positive charge carriers.<sup>100,101</sup> Energetically narrower bands are associated with better transport properties and are thought to originate from more ordered conjugated backbones.<sup>102</sup> The interaction between chains was shown to influence the conformation and, therefore, the DOS but the electronic structure of the bulk polymer is to a great extent dictated by the electronic structure of individual chains.<sup>62</sup>

In this section we compute the DOS for individual chains extracted from 4 snapshots of the MD simulations separated by 15 ns at 300 and 550 K. A total of 64 chains for each of the 6

Fig. 11 Comparison between RDFs of different atom groups between an equilibrated simulation at 550 K in solid lines and 300 K in dashed lines. The definition of atom groups is the same as mentioned in the previous sections.

systems have been used. The electronic structure calculation was performed at the B3LYP/3-21G\* level, suitable for this kind of large scale electronic structure calculation and well correlated with calculation with higher basis sets.<sup>62</sup> The DOS, was obtained from broadening the orbital energies with a normalised Gaussian function of standard deviation 0.03 eV and the results are collected in Fig. 12 which focuses on the region immediately below the band gap. The choice of the Gaussian broadening parameter is not very critical for the discussion in this section as the features reported in Fig. 12 are much wider than this broadening ( $> 0.1$  eV), *i.e.* are due to the distribution of the energy levels rather than the broadening parameter. The DOS is approximately constant for broadening in the range 0.01–0.04 eV and would become too noisy if the broadening parameter is set to a value much smaller than the energy difference between orbital energies, *e.g.*  $< 0.005$  eV for the sample size considered here. The electronic structure

Fig. 12 Density of States (DOS) calculated for the three systems at 300 and 550 K.

calculations have been performed for the model system where the side chains have been shortened to  $-\text{CH}_3$ .

The first interesting observation is that there is no substantial change in the DOS shape in going from 550 to 300 K except for the (expected) slightly larger broadening of the peaks seen at 550 K where a greater range of inter-monomer dihedral angles is explored. This is useful in practice because simulations at higher temperatures are more easily equilibrated and it is possible to use them as a guide if the electronic structure of many polymers is to be considered. The most relevant feature of the DOS is the peak at higher energy. This is dominated by the DPP units which has the largest HOMO energy among the fragments with the position of the peak modulated by the remaining constituents of the chains. The polymer with the greatest order (6T) displays the narrower 300 K peak, which is a combined result of the greater structural order discussed in the previous sections and the greater distance between DPP units which tends to narrow down the highest energy band (*i.e.* to decrease the interaction between units).<sup>103</sup> As shown in a recent work, changing the composition of the backbone leads to the effect of changing both the conformational flexibility and the sensitivity of the electronic structure to the conformational flexibility.<sup>104</sup>

## Conclusion

Atomic MD simulations were employed to study the local structuring and morphological characteristics of three oligomers belonging to the same family of SCPs based on the DPP

monomer and different conjugated units constituting the backbone unit. The corresponding polymers of the systems studied here have displayed high charge carrier mobility, which is generally attributed to the ability of these materials to form partially ordered aggregates. An important difference among the polymers studied is their rigidity which depends on the chemistry of the constituents and also the ratio between the volume of the side chain and that of the conjugated part. The polymer containing 6 thiophene rings between the DPP units is more rigid than the one containing 4 thiophene units suggesting a role on the side chain in disrupting the ordering. Strong aggregation at short distances was observed for all three systems and was quantitatively analysed using RDFs that showed a higher degree of short-range stacking for 2TT followed by 6T and 4T. A stronger interaction between the DPP units and sulphur atoms for 6T compared to DPP units for 2TT points to the different reasons for the chain stacking across the oligomers. The dynamics of the side chains, identical for the three systems studied, is seen to be affected by the nature of the conjugated portion, with greater flexibility observed for 6T (where there is more space between side chains) and 2TT (the most rigid oligomer). The existence and the size of aggregate clusters were studied using the nematic liquid crystalline order parameter and the distribution of cluster sizes. The main structural features and the electronic structure of the oligomers are fairly similar above the glass transition temperature and at room temperature. In essence, polymers containing DPP fragments tend to form aggregates driven by the  $\pi$ -stacking of the conjugated units, however, this tendency is highly modulated by the polymer composition, which can influence the flexibility and the tendency to form extended stacks.
