## Synthesis, characterization and thermal behaviour of solid phases in the quasi-ternary system $\text{Mg}(\text{SCN})_2\text{--H}_2\text{O}\text{--THF}$ †

Markus Joos,<sup>a</sup> Maurice Conrad,<sup>b</sup> Rotraut Merkle,<sup>a</sup> Thomas Schleid,<sup>b</sup> Joachim Maier,<sup>a</sup> Robert E. Dinnebier<sup>a</sup> and Sebastian Bette<sup>a</sup>   

$\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$  can be converted into previously unknown compounds  $\text{Mg}(\text{SCN})_2\cdot(4-x)\text{H}_2\text{O}\cdot x\text{THF}$  with  $x = 0, 2$  and  $4$  by multiple recrystallization in tetrahydrofuran (THF). The phases were characterized by infrared spectroscopy (IR), thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC), and their crystal structures were solved from X-ray powder diffraction (XRPD) data. In the crystal structures isolated  $\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_{4-x}(\text{THF})_x$  units form layered motifs. The thermal behavior of  $\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$  and  $\text{Mg}(\text{SCN})_2\cdot 4\text{THF}$  was investigated by temperature dependent *in situ* XRPD, where  $\text{Mg}(\text{SCN})_2\cdot 4\text{THF}$  was found to acquire a room temperature ( $\alpha$ -form) and high temperature modification ( $\beta$ -form). The phase transformation is associated with an order-disorder transition of the THF molecules and with a reversion of the stacking order of the layered motifs. Further heating eventually leads to the formation of  $\text{Mg}(\text{SCN})_2\cdot 2\text{THF}$ . There thiocyanate related sulfur atoms fill the voids in the coordination sphere of magnesium, which leads to the formation of one dimensional electroneutral  $_{\infty}[\text{Mg}(\text{NCS})_{2/2}(\text{SCN})_{2/2}(\text{THF})_2]$  chains. All investigated  $\text{Mg}(\text{SCN})_2\cdot(4-x)\text{H}_2\text{O}\cdot x\text{THF}$  phases exhibit a remarkable anisotropic thermal expansion, and  $\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$  and  $\text{Mg}(\text{SCN})_2\cdot 2\text{THF}$  were found to show both positive and negative thermal expansion coefficients.

## Introduction

Magnesium halides and pseudo-halides exhibit a great variety of chemical and structural properties and are used in many different applications, which is why they have been extensively studied.<sup>1–5</sup> However, in the row of magnesium pseudo-halides, *i.e.* cyanides, cyanates, azides *etc.*, thiocyanates are often overseen, and only little chemical and structural knowledge is available for magnesium thiocyanates and their derivatives.

The first known crystalline magnesium thiocyanate phase was reported to be the tetrahydrate  $\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$  in 1930,<sup>6</sup> which was later confirmed by the elucidation of its crystal structure.<sup>7</sup> In addition, some reports have mentioned the existence of related phases, such as the pentahydrate

$\text{Mg}(\text{SCN})_2\cdot 5\text{H}_2\text{O}$  or anhydrous  $\text{Mg}(\text{SCN})_2$ ,<sup>8–11</sup> however, only little to no evidence was presented to support this. Several studies showed that  $\text{Mg}^{2+}$  when coordinated to  $\text{SCN}^-$  anions seems to be capable to form a diversity of solid ionic complexes with different organic molecules such as pyridine (Py), nicotinamide (NIA) and their derivatives,<sup>10–13</sup> although their crystal structures remain unknown.

Besides the tetrahydrate  $\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$ , crystal structure investigations of  $\text{Mg}(\text{SCN})_2$ -containing compounds have generally been neglected so far and only spectroscopic studies or thermal analyses are present.<sup>10,12</sup> Further structural studies of related  $\text{Mg}^{2+}\text{--SCN}^-$ -phases are only available for mixed cationic systems involving other cations like  $\text{K}^+$  or  $\text{Cd}^{2+}$ .<sup>14,15</sup> In contrast, other  $\text{MgX}_2$  salts with similar anions ( $\text{X} = \text{CN}$ ,  $\text{N}(\text{CN})_2$ ) are well known in terms of crystal structures and properties.<sup>16,17</sup>

Furthermore, unlike many other thiocyanate salts  $\text{M}(\text{SCN})_n$  ( $\text{M} = \text{Li}, \text{Na}, \text{K}, \text{Ca}, \text{Sr}, \text{Ba}, \text{Ni}, \text{Ag}, \text{Hg}, \dots, n = 1 \text{ or } 2$ ),<sup>18–25</sup> it is yet unclear how to obtain the anhydrous form of  $\text{Mg}(\text{SCN})_2$  and under what conditions it would be stable. As mentioned before, some studies suggest the formation of anhydrous  $\text{Mg}(\text{SCN})_2$  by simple heating of  $\text{Mg}(\text{SCN})_2\cdot x$  [L] complexes ( $[\text{L}] = \text{H}_2\text{O}$ , pyridine, ...);<sup>10</sup> however, the phase formation was not

analytically confirmed in any case. In fact, a more likely dehydration mechanism might be similar to that of  $\text{MgCl}_2$ , which forms a wide variety of hydrates.<sup>1,2,26–28</sup> The hexahydrate  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$  is a commonly occurring mineral named bischofite and finds a diversity of industrial usage.<sup>1–4,29</sup> Upon heating of  $\text{MgCl}_2$  hydrates different dehydration stages occur; however, the anhydrous state cannot simply be reached as the formation of oxychloride species prevails.<sup>2,3,27</sup> Solvent based methods or rather tedious thermochemical procedures are necessary to produce pure, anhydrous  $\text{MgCl}_2$ .<sup>3</sup>

Besides the rich hydrate chemistry of  $\text{MgCl}_2$ , it also forms different organometallic complexes, which are of great importance in organic chemistry (such as Grignard reagents or for Ziegler–Natta catalysis)<sup>30–33</sup> and have more recently even sparked interest in the battery community.<sup>34</sup> These complexes are formed by the inclusion of organic molecules such as pyridine (Py), dimethoxyethane (DME), tetrahydrofuran (THF) *etc.*, and a lot of research studies are devoted to their structural analysis, especially to understand the coordination between metals and organic molecules.<sup>30,33–38</sup>

Moving on from halides to pseudo-halides, the previously mentioned coordination chemistry between metals and organic molecules is still a rather unexplored field for crystalline, solid thiocyanates. Some examples of solvent complexes with dimethoxyethane (DME), tetrahydrofuran (THF) and acetonitrile (AN) can be found for rare earth metal thiocyanates and  $\text{Ca}(\text{SCN})_2$ .<sup>39</sup> There also exist coordination compounds with acetone (Ac) of transition metals (TM = Cr, Mn and Fe);<sup>40</sup> yet for  $\text{Mg}(\text{SCN})_2$ , only little is known about these kinds of complexes and no structural data are available so far.

In this study we report the synthesis, structure, spectroscopic properties and thermal behavior of the solid phases dithiocyanatetetraaquamagnesium(II)  $[\text{Mg}(\text{SCN})_2(\text{H}_2\text{O})_4]$  (also referred to as magnesium dithiocyanate tetrahydrate,  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$ ), bis(tetrahydrofuran)diaquadi-thiocyanatemagnesium(II),  $[\text{Mg}(\text{SCN})_2(\text{H}_2\text{O})_2(\text{THF})_2]$ , and dithiocyanatetetrakis(tetrahydrofuran)-magnesium(II),  $[\text{Mg}(\text{SCN})_2(\text{THF})_4]$  (from hereon we will address these compounds as  $\text{Mg}(\text{SCN})_2 \cdot (4-x)\text{H}_2\text{O} \cdot x\text{THF}$  with  $x = 0, 2, 4$ ).<sup>41</sup> The thermal behaviour of the title compounds was analysed in detail by temperature dependent *in situ* X-ray powder diffraction and a strong anisotropic lattice expansion as well as several phase transitions of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  eventually leading to the formation of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  were observed.

## Experimental

$\text{Mg}(\text{SCN})_2 \cdot (4-x)\text{H}_2\text{O} \cdot x\text{THF}$  ( $x = 0, 2, 4$ ) phases were synthesized by recrystallization in  $\text{H}_2\text{O}$  or THF or by ion exchange. The obtained products were characterized by X-ray powder diffraction (XRPD), infrared (IR) spectroscopy, thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), scanning electron microscopy (SEM) and energy dispersive X-ray (EDX) analysis. The handling and measurements of the samples were conducted under dry inert gas or vacuum

unless stated otherwise. All details of the synthesis and analysis can be found in the ESI.†

## Results

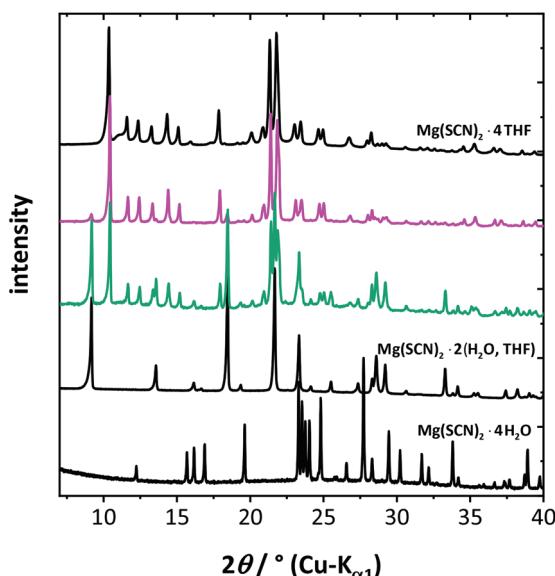

### Synthesis and characterization

Syntheses of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  have been reported in a number of different publications employing various synthesis routes, such as:<sup>6–8,10–12</sup>

The third synthesis route is employed in this study. However, it was discovered that after the removal of ethanol, the formation of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  crystals was severely inhibited, and precipitation required long vacuum treatment at rather high temperatures ( $\sim 150$  °C) with the possible formation of decomposition products. A much easier way to produce crystalline  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  without risking decomposition was, after removing most of the ethanol, to re-dissolve the obtained slurry in water and then use freeze drying to precipitate the crystals of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$ . Nonetheless, the purity of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  for both the synthesis routes 2 and 3 is limited due to the solubility product of  $\text{BaSO}_4$  in water ( $1.3 \times 10^{-5}$  mol L<sup>-1</sup>)<sup>42</sup> and KCl in ethanol ( $3.9 \times 10^{-5}$  mol L<sup>-1</sup>).<sup>43</sup> This problem does not occur in the synthesis route 1; however, additional heat treatments or neutralization is required to entirely remove  $\text{NH}_3$  or  $\text{CO}_2$ . To avoid the limits created by these methods, we used cation exchange *via* an ion exchanger, which directly yielded pure  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  without further treatments being necessary. Low requirements on the metal-base purity of the precursor KSCN are an additional advantage of this method, as impurity cations contained within the commercially available precursor material will be replaced by  $\text{Mg}^{2+}$  cations as well.

Both the syntheses of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  required an additional re-crystallization step using THF as the solvent. It was difficult to control the ratio of  $\text{H}_2\text{O}$  to THF, especially for  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$ , and several synthesis attempts produced a mixture of both  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (Fig. 1). In the case of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$ , this problem could be overcome by simply refluxing the solution in THF to remove any remaining  $\text{H}_2\text{O}$ , although this might have caused the formation of an amorphous side phase (more details can be found in the ESI†). With the above described methods three phases with  $x = 0, 2, 4$  in the ternary system  $\text{Mg}(\text{SCN})_2 \cdot (4-x)\text{H}_2\text{O} \cdot x\text{THF}$  were suc-

cessfully synthesized, all of which crystallize in a monoclinic lattice (Table 1).

The exchange of water with THF molecules leads to fundamental changes in the crystal lattice. From  $x = 0$  to  $x = 2$ , the

volume per formula unit strongly increases by  $179.15 \text{ \AA}^3$ , illustrated by the strong downshift of the 001 reflection. This increase is smaller than the volume of two free THF molecules ( $269 \text{ \AA}^3$ ). The SEM images in Fig. S4a and b† show that the grain morphologies become more platelet like, which indicated a more pronounced layered motif in the crystal structure after the THF incorporation. When the THF content is increased from  $x = 2$  to  $x = 4$ , the volume per formula unit increases by  $174.05 \text{ \AA}^3$ , which is very similar to the first exchange step. The  $C$ -centered monoclinic unit cell becomes primitive (space group  $P2_1/n$  for  $x = 4$ ) upon complete exchange.

Furthermore, the grains adopt a rod-shaped morphology with well-defined crystal faces, as can be seen in Fig. S4c.† The EDX results of  $x = 4$  shown in Fig. S5† match the proposed stoichiometry with an average Mg : S ratio of 1 : 2.

IR spectroscopy was employed to confirm the presence of thiocyanate and THF as well as to derive information on the coordination of  $\text{Mg}^{2+}$ . Fig. 2 shows selected excerpts of the IR spectra for all  $\text{Mg}(\text{SCN})_2 \cdot (4 - x) \text{H}_2\text{O} \cdot x\text{THF}$  phases.

The spectra show THF and water related bands situated in the high wavenumber region between  $2800$  and  $3600 \text{ cm}^{-1}$ . For  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  the bands of THF and  $\text{H}_2\text{O}$  are respectively absent (Fig. 2, black and orange line), while the spectrum of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  shows a combination of both (Fig. 2, blue line; further details can be found in Table 2). Interestingly, the characteristic bands  $\nu(\text{C}\equiv\text{N})$  ( $\sim 2080 \text{ cm}^{-1}$ ) and  $\delta(\text{H}-\text{O}-\text{H})$  ( $\sim 1630 \text{ cm}^{-1}$ ) of the  $\text{SCN}^-$  anion and  $\text{H}_2\text{O}$  are split for  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  and  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$ , respectively. In the case of the  $\text{SCN}^-$  anion, such a splitting was also observed for the dihydrate  $\text{Ca}(\text{SCN})_2 \cdot 2\text{H}_2\text{O}$ ,<sup>21</sup> the trihydrate  $\text{K}_2\text{Mg}_2(\text{SCN})_6 \cdot 3\text{H}_2\text{O}$ ,<sup>14</sup> and various rare earth metal thiocyanate complexes with different solvent molecules.<sup>39</sup> In the last case, the splitting was attributed to the bridging nature of  $\text{SCN}^-$  to two cations, enabling both symmetric and asymmetric  $\nu(\text{C}\equiv\text{N})$  modes. In contrast, here  $\text{SCN}^-$  does not have a bridging function (see below), and

**Fig. 2** IR spectra of  $\text{Mg}(\text{SCN})_2 \cdot (4 - x) \text{H}_2\text{O} \cdot x\text{THF}$  phases with  $x = 0$  (black, measured in Ar),  $x = 2$  (blue, measured in air),  $x = 4$  (orange, measured in Ar).

$\nu_1$ : symmetric stretch,  $\nu_2$ : asymmetric stretch;  $\delta$ : scissoring or bending;  $\omega$ : wagging;  $T$ : twisting;  $\rho$ : rocking; i-p: in-plane.

it is more likely that the splitting is connected to the complexity of molecules coordinated to the central cation in the vicinity of  $\text{SCN}^-$ . Since this splitting does not appear in the bands of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$ , it can be attributed to the coordination of THF molecules to  $\text{Mg}^{2+}$ , inducing polarization effects either in  $\text{H}_2\text{O}$  or  $\text{SCN}^-$ . However, an unambiguous explanation requires a more rigorous treatment of the spectroscopic features of these phases and is beyond the scope of this report.

In summary, the combination of XRPD and IR spectroscopy shows that THF molecules can successfully be introduced into the structure of  $\text{Mg}(\text{SCN})_2$  producing new crystalline phases with distinct properties.

### Thermal behavior

In the family of magnesium salts,  $\text{MgCl}_2$  is a close relative to magnesium thiocyanate for which the thermal behaviour has already been studied thoroughly, especially regarding the complexity of obtaining pure, anhydrous  $\text{MgCl}_2$ .<sup>2,3</sup> In comparison, the hydrates of  $\text{LiSCN}$ ,  $\text{NaSCN}$  and  $\text{Ca}(\text{SCN})_2$  were reported to be readily dehydrated by simple heating of the hydrated material.<sup>18,19,21</sup> Various anhydrous thiocyanate salts have been shown to melt congruently around 280–470 °C followed by decomposition above ~550 °C,<sup>22</sup> and bimetallic thiocyanates first dissociate before decomposing to sulphides and gaseous species.<sup>15</sup>

Fig. 3 shows the TGA measurement of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  along with the corresponding signals from mass spectroscopy (MS). According to the TGA and MS analyses, the tetrahydrate passes through different hydrates (nominal a dihydrate at 144 °C and nominal a monohydrate at 154 °C), until it finally decomposes starting around 161 °C. However, along with the recorded peaks for  $\text{H}_2\text{O}$  in the MS, another signal with a molar mass of 44 g mol<sup>-1</sup> (e.g.  $\text{CO}_2$ ) was observed, which could indicate that the dehydration is accompanied by a partial decomposition process already below 161 °C. The here recorded TGA measurement agrees with that from Mojumdar *et al.*,<sup>10</sup> even though the temperatures seem to be slightly shifted. Regarding the interpretation, however, some clarifications are necessary: (i) Given the hygroscopy of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$ , it is possible that the additional  $\text{H}_2\text{O}$  molecule reported in reference 10 was actually just adsorbed surface water. (ii) There is no evidence for the intermediate formation of anhydrous  $\text{Mg}(\text{SCN})_2$  and the MS analysis rather suggests a thermal decomposition. (iii) Even though the formation of  $\text{MgS}$  as a decomposition product is indeed possible and would be in line with other thiocyanate systems,<sup>15</sup> it remains challenging to substantiate this given the limited information obtainable by e.g. XRPD or IR spectroscopy (Fig. S9†).

Further TGA and DTA measurements of magnesium thiocyanate complexes with various incorporated organic molecules often show a step-wise mass loss of the organic molecule followed by thermal decomposition.<sup>10,12</sup> A similar mechanism was observed in the TGA measurement of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (Fig. 4) concerning the loss of THF. According to the combi-

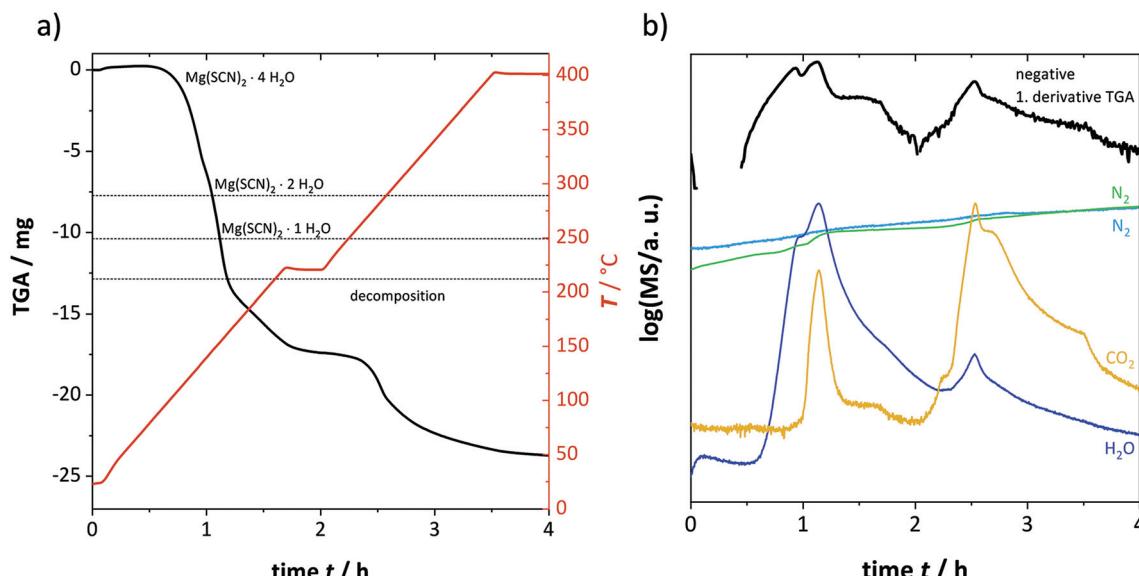

Fig. 3 TGA measurement of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  under  $\text{N}_2$ : (a) TGA signal; (b) MS signal.

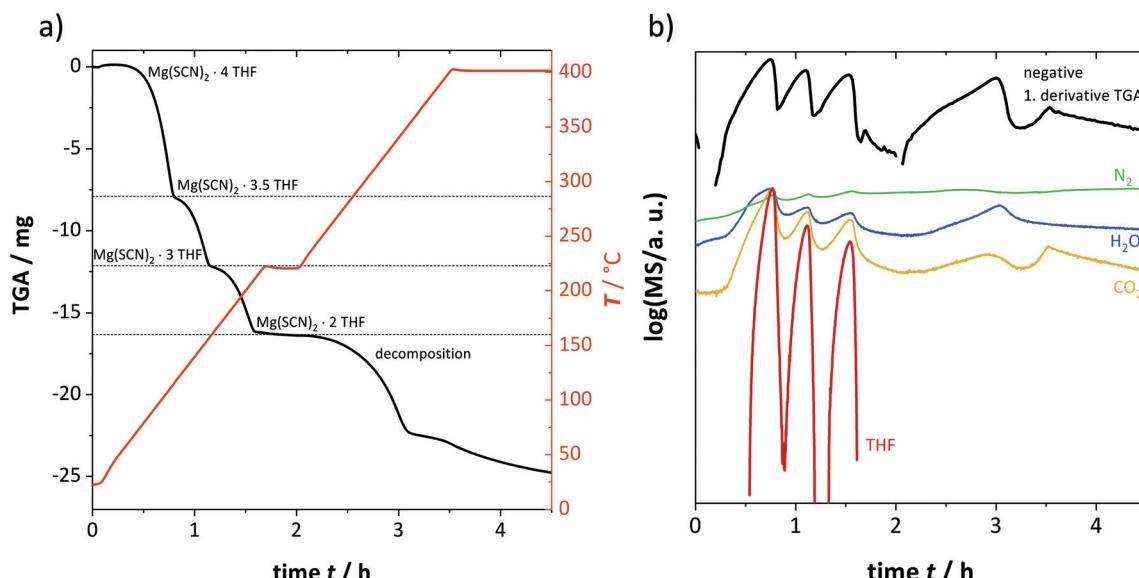

Fig. 4 TGA measurement of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  under  $\text{N}_2$ : (a) TGA signal; (b) MS signal.

nation of TGA and MS, three intermediates were formed with 3.5 (113 °C), 3 (156 °C) and 2THF (210 °C) molecules followed by thermal decomposition.

The thermal behavior of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  was further investigated by DSC (Fig. 5). The DSC measurements showed that in a semi-closed system (cold welded aluminium pan) the tetrahydrate melts at 144 °C with a pronounced hysteresis (supercooling) effect as crystallization does not occur before 80 °C. Beyond 144 °C the material showed further endothermic peaks starting at 167 °C, indicating thermal decomposition. The decomposition temperature

measured by DSC fits well to that observed by TGA in Fig. 3a. In contrast,  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  displayed higher thermal stability than the tetrahydrate with the first endothermic peak occurring at 197 °C. This finding is rather counterintuitive, since the exchange of  $\text{H}_2\text{O}$  with organic ligands would be expected to decrease the thermal stability of the material. Thereafter two more endothermic peaks are observed at 219 °C and 279 °C. Since no exothermic peaks appear in the cooling run as well as considering the results from TGA, we can assume that the peak at 279 °C indicates the thermal decomposition of the material. Furthermore, the TGA measurement showed

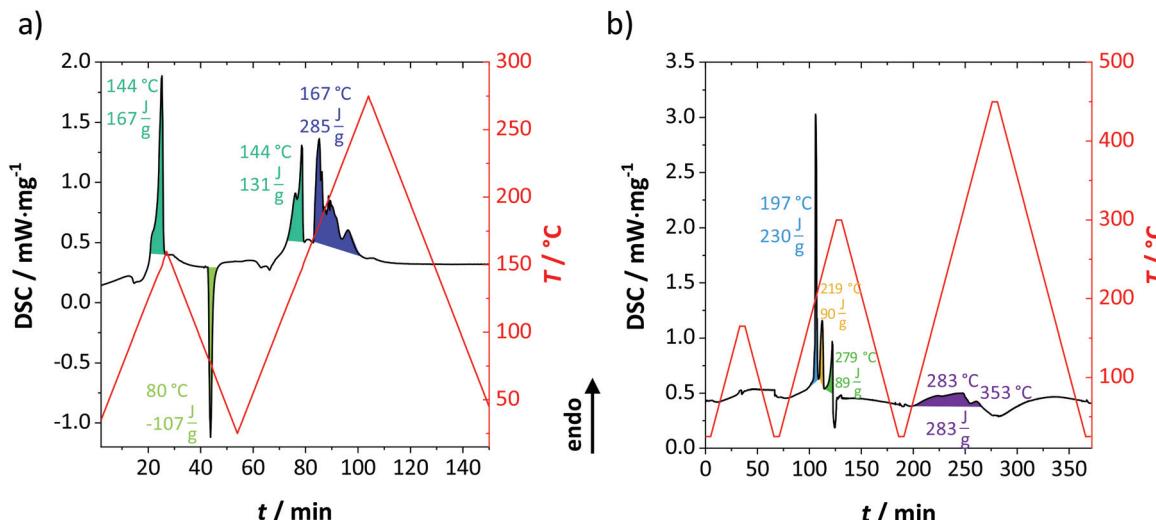

Fig. 5 DSC measurements of different phases in the series  $\text{Mg}(\text{SCN})_2 \cdot (4-x) \text{H}_2\text{O} \cdot x\text{THF}$  shown for (a)  $x = 0$  and (b)  $x = 4$ .

that at around  $210\text{ }^\circ\text{C}$  the material loses two THF molecules, which is connected with the DSC peaks at  $197\text{ }^\circ\text{C}$  and  $219\text{ }^\circ\text{C}$ . Subsequent heating to higher temperatures merely revealed further decomposition of the material.

In order to corroborate the above findings of TGA and DSC, temperature dependent *in situ* XRPD measurements were conducted for both  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (Fig. 6). For the tetrahydrate, all reflections in the XRPD pattern disappear between  $149\text{ }^\circ\text{C}$  and  $186\text{ }^\circ\text{C}$  in agreement with the melting point at  $144\text{ }^\circ\text{C}$  and the decomposition at  $167\text{ }^\circ\text{C}$  from DSC. The formation of a new phase is observed at  $190\text{ }^\circ\text{C}$ , distinctly different from the originally present  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  in terms of the XRPD pattern. Even though a structure solution of this emergent phase was not possible due to anisotropic peak broadening, it appears to be a yet unknown stacking faulted decomposition product of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$ .

$\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  undergoes several phase transitions upon heating before it melts or becomes amorphous (Fig. 6). At  $138\text{ }^\circ\text{C}$  a phase transition occurs from the parent structure  $\alpha\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  to a new polymorphic phase  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$ , evident from the changes in the XRPD pattern. It should be noted here that most likely this  $\beta$ -phase was not observed in the TGA measurement shown in Fig. 4, as THF first evaporated in the continuous  $\text{N}_2$  gas stream of the TGA before the  $\beta$ -phase could form. Yet with the sealed capillary employed in the temperature dependent *in situ* XRPD measurement, THF is contained long enough in the sample for the  $\beta$ -phase to evolve. It remains unclear, however, why for the  $\alpha$ -to  $\beta$ -transition no signal was observed in the DSC. Given the long measurement times in XRPD (hours for each temperature point), the kinetics of the phase transition are most likely slow. Furthermore, within the employed temperature ranges, any vibrational entropic contributions to the overall change in energy is probably small and difficult to resolve by

DSC. It is therefore very likely that the phase transition could not be resolved by DSC and was consequently not observed. Upon further heating THF loss is inevitable until at  $164\text{ }^\circ\text{C}$  (DSC:  $197\text{ }^\circ\text{C}$ , TGA:  $210\text{ }^\circ\text{C}$ ) a new phase starts to form yielding  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$ . The formation temperature here is a bit lower than that observed by TGA and DSC, which can be attributed to both different measurement set-ups as well as a different environment from the gas phases (the closed system in XRPD, the semi-closed system in DSC and the open system in TGA). The new phase  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  is stable up to  $234\text{ }^\circ\text{C}$  at which point, it first turns into an unknown, stacking faulted decomposition product and then finally melts or becomes amorphous starting around  $251\text{ }^\circ\text{C}$  (DSC:  $279\text{ }^\circ\text{C}$ ).

The obvious differences in thermal behaviour between  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  are rather surprising, especially considering their similar coordination chemistry. Even though it appears counterintuitive for the tetrahydrate to have a lower thermal stability, as the formation of bridging hydrogen bonds should stabilize the structure, without having any knowledge of anhydrous  $\text{Mg}(\text{SCN})_2$ , a direct comparison between the phases cannot be made analytically.

With both TGA and XRPD the formation of anhydrous  $\text{Mg}(\text{SCN})_2$  was not observed and it remains to be clarified under which conditions it could be obtained. The intermediately formed  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  phase is to date the only magnesium thiocyanate with only two coordinating molecules. Regarding the progression of reflections in the XRPD patterns (Fig. 6b and d), a significant shifting of selected reflections to lower angles was observed for both phases. This shifting indicates a strong and possibly anisotropic lattice expansion, which we will address later in more detail. Given the delicate synthesis and storage of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$ , we decided to only report the results of room temperature measurements.

**Fig. 6** Temperature dependent *in situ* XRPD data of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  (a and b) and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (c and d) in a sealed capillary under Ar showing (a and c) selected XRPD patterns and (b and d) the thermal progression of reflections.

### Structure description

In the series  $\text{Mg}(\text{SCN})_2 \cdot (4-x)\text{H}_2\text{O} \cdot x\text{THF}$  with  $x = 0$ ,  $x = 2$  and  $x = 4$ , the  $\text{Mg}^{2+}$  cations always exhibit a distorted octahedral coordination sphere with the thiocyanate anions located in the *trans* configuration with the N pointing towards  $\text{Mg}^{2+}$  (Fig. 7). In  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  water molecules occupy the equatorial positions (Fig. 7a, green atoms) and the magnesium is situated on the centre of inversion. After replacing two water molecules by THF in  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  all ligand pairs remain in the

*trans* configuration. The magnesium cation, the thiocyanate anion and the THF related oxygen atom are situated on a mirror plane, which leads to a positional disorder of the non-planar THF molecule (Fig. 7b, red and blue atoms and bonds). The complete replacement of water by THF yields a propeller-like complex  $[\text{Mg}(\text{NCS})_2(\text{THF})_4]$  with magnesium situated on the centre of inversion. Two out of four THF molecules in the *trans* configuration are positionally disordered (Fig. 7c, red and blue atoms and bonds). In all complexes the average bond lengths

Fig. 7 Octahedral coordination of  $\text{Mg}^{2+}$  with  $\text{SCN}^-$ ,  $\text{H}_2\text{O}$  and THF in the series  $\text{Mg}(\text{SCN})_2 \cdot (4-x) \text{H}_2\text{O} \cdot x\text{THF}$  for (a)  $x = 0$ , (b)  $x = 2$ , (c)  $x = 4$  ( $\alpha$ -phase). Two THF molecules (red and blue atoms and bonds) with identical oxygen positions were used to model the positional disorder.

Fig. 8 Packing diagrams in the series  $\text{Mg}(\text{SCN})_2 \cdot (4-x) \text{H}_2\text{O} \cdot x\text{THF}$  for (a and b)  $x = 0$ , (c and d)  $x = 2$ , (e and f)  $x = 4$ . Yellow and blue octahedra indicate different orientations, where the thiocyanate ions on top of the blue octahedra point to the front and on the bottom point to the back and the right hand thiocyanates of the yellow octahedra point to the front and the left hand point to the back.

between the central atom and ligands follow this trend:  $d[\text{Mg}-\text{N}] < d[\text{Mg}-\text{O}(\text{H}_2\text{O})] < d[\text{Mg}-\text{O}(\text{THF})]$ , which is to be expected.

In the crystal structures of  $\text{Mg}(\text{SCN})_2 \cdot (4-x) \text{H}_2\text{O} \cdot x\text{THF}$  isolated  $[\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_{4-x}(\text{THF})_x]$  octahedra form layered motifs (Fig. 8). The layers of the tetrahydrate consist of  $[\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_4]$  octahedra that show an alternating orientation along the  $a$ -axis (Fig. 8a, blue and yellow octahedra), a uniform orientation along the  $b$ -axis (Fig. 8b) and are stacked in the [001] direction in a distorted ABA'B' sequence (ESI, Fig. S11†). The substitution of two water molecules by THF leads to an increase of the inter layer distance. In  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  the  $[\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_2(\text{THF})_2]$  octahedra exhibit a uniform orientation within the layer plane and the layers are stacked in

a distorted AA-type fashion (Fig. 8c and d, ESI, Fig. S11†) in the [001] direction. Further replacement of water by THF molecules does not lead to an increase of the inter layer distances. This can be explained by the shift of the AA-stacking order in  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  to a distorted ABC-type stacking in  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (Fig. 8e) in the [110] direction and by an increase of the distances between  $[\text{Mg}(\text{NCS})_2(\text{THF})_4]$  octahedra within the layers.

In terms of layer constitution and stacking order,  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (Fig. 8e and f) exhibits strong similarities to  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$ , whereas  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  occupies an exceptional position in the row of  $\text{Mg}(\text{SCN})_2 \cdot (4-x) \text{H}_2\text{O} \cdot x\text{THF}$  structures.

Heating of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  ( $\alpha$ -form) leads to the high temperature modification of  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  and eventually to the formation of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  by the release of 2THF molecules. In the crystal structures of the  $\text{Mg}(\text{SCN})_2 \cdot x\text{THF}$  phases, magnesium is always coordinated octahedrally with the thiocyanate anions situated in the *trans* conformation (Fig. 9). The coordination patterns of  $\alpha$ - and  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  are almost identical (Fig. 9a and b). In the high temperature phase, all THF molecules are positionally disordered (Fig. 9b, blue and red atoms and bonds). After the release of two THF molecules at higher temperatures, the positional disorder of the remaining THF molecules increases (Fig. 9c, blue, red, yellow and green atoms and bonds), and the thiocyanate anions become

positionally disordered as well (Fig. 9c, magenta and violet atoms and bonds). Due to the release of two ligands during the formation of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$ , the emerging voids in the coordination sphere of magnesium are filled by thiocyanate related sulphur atoms, which leads to the formation of thiocyanate bridged  $\infty[\text{Mg}(\text{NCS})_{2/2}(\text{SCN})_{2/2}(\text{THF})_2]$  chains (Niggli formula:  $^1\infty\left\{ \left[ \text{Mg}(\text{N}, \text{S})_{4/2}^e \text{O}_{2/1}^t \right] \right\}$ ).

The constitution and the packing of the layered motifs are very similar for the room and the high temperature modification of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (Fig. 10a-d) and the seemingly increased interlayer distance after the phase transformation is attributed to the strong thermal expansion of  $\alpha\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  (see below). In the  $\beta$ -form the distorted ABC stack-

Fig. 9 Octahedral coordination of  $\text{Mg}^{2+}$  with  $\text{SCN}^-$  and THF for (a)  $\alpha\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$ ; (b)  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$ ; and (c)  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$ . Multiple THF molecules (red, blue, yellow and green atoms and bonds) and of  $\text{SCN}^-$  anions (magenta and violet atoms and bonds) were used to approximate the positional disorder in the structures.

Fig. 10 Packing diagrams of (a and b)  $\alpha\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  at 25 °C, (c and d)  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  at 150 °C and (e and f)  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  at 180 °C. In (f) the C atoms from the THF molecules are omitted for clarity. Yellow and blue octahedra indicate different orientations, where the thiocyanate ions on top of the blue octahedra point to the front and on the bottom point to the back and the right hand thiocyanates of the yellow octahedra point to the front and the left hand point to the back.

ing sequence of  $\alpha\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$  is reverted to a disordered ACB stacking sequence (ESI, Fig. S11†). Releasing two THF molecules from  $\text{Mg}(\text{SCN})_2\cdot 4\text{THF}$  causes drastic structural changes. In  $\text{Mg}(\text{SCN})_2\cdot 2\text{THF}$  the  $\infty[\text{Mg}(\text{NCS})_{2/2}(\text{SCN})_{2/2}(\text{THF})_2]$  chains are arranged in layers as well with a decreased interlayer distance (Fig. 10e). Within the layers the  $[\text{Mg}(\text{NCS})_{2/2}(\text{SCN})_{2/2}(\text{THF})_2]$  octahedra are oriented uniformly (Fig. 10e and f). Like  $\beta\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$ ,  $\text{Mg}(\text{SCN})_2\cdot 2\text{THF}$  exhibits a disordered ABC stacking sequence (ESI, Fig. S11†) in the [110] direction.

### Lattice expansion

The thermal expansion was investigated in detail for  $\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$ ,  $\alpha$ - and  $\beta\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$  and  $\text{Mg}(\text{SCN})_2\cdot 2\text{THF}$ . Plots showing the variation of the thermal expansion coefficient ( $\alpha$ ) with the principal directions  $X_1$ ,  $X_2$  and  $X_3$  (Table S10†) for these phases are presented in Fig. 11. All compounds exhibit a pronounced anisotropic thermal expansion and some even both positive (Fig. 11, red lines) and negative (Fig. 11, blue lines) thermal expansion. The thermal expansion properties can be correlated with certain aspects of the crystal structures.

$\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$  exhibits both a large positive thermal expansion of  $165(4) \times 10^{-6} \text{ K}^{-1}$  in the [100] direction, corresponding to the principal  $X_3$  direction and a negative thermal expansion of  $-44(2) \times 10^{-6} \text{ K}^{-1}$  in the [010] direction, corresponding to the principal  $X_1$  direction (Table S10†). Hence, both the positive and negative thermal expansions occur within the layered motifs, whereas the thermal expansion perpendicular to the layers (principal  $X_2$  axes) is only moderate ( $32(1) \times 10^{-6} \text{ K}^{-1}$ ). Fig. S12† shows four  $[\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_4]$  octahedra, which are arranged in a diamond motif within the layers. Strong hydrogen bonds between water molecules (dark grey, dashed bonds) and weaker bonds between water molecules and  $\text{SCN}^-$  related sulphur (light grey dotted bonds) mediate the interactions within the layers. During the thermal expansion the thiocyanate anions start to move slightly out of the layer plains (Table S10,† principal  $X_2$  axes). Accordingly, the  $[\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_4]$  octahedra, whose thiocyanate anions face in

the direction of the centre of gravity of the diamond motif (Fig. S12,† black globe), start to move towards each other (blue arrow, corresponding to the principal  $X_1$  axis). Due to steric reasons and in order to maintain a favourable  $\text{O}-\text{H}\cdots\text{S}$  angle close to  $180^\circ$ , the  $[\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_4]$  octahedra situated along the  $a$ -axis veer away from the center of gravity (red arrow, corresponding to the principal  $X_3$  axis). With respect to the centre of gravity, the expansion behaviour is comparable to Nuremberg scissors.

A complete exchange of water by THF molecules leads to an increase of the total volume expansion from  $153(2) \times 10^{-6} \text{ K}^{-1}$  to  $268(2) \times 10^{-6} \text{ K}^{-1}$  (Table S10†), which can be explained by the weaker interactions between  $[\text{Mg}(\text{NCS})_2(\text{THF})_4]$  octahedra. Even though the macroscopic structural motifs  $\alpha$ - and  $\beta\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$  are identical (Fig. 10a-d), the thermal expansion properties differ (Fig. 11b and c). Hence the growing disorder of the THF molecules that evolves during the transition from the  $\alpha$ - to the  $\beta$ -form has a major impact on the thermal expansion properties. The expansion occurs very anisotropically in  $\alpha\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$  (Fig. 11): while there is a strong positive expansion along the principal  $X_3$  axes of  $173(1) \times 10^{-6} \text{ K}^{-1}$  (Table S10†), along the principal  $X_1$  axis, there is hardly any positive thermal expansion ( $3(1) \times 10^{-6} \text{ K}^{-1}$ ). Within the structure, the strong (Fig. S13a and b,† along  $X_3$  red arrow) and medium (along  $X_2$  green arrow) thermal expansion lead to a beginning shift of the ABC stacking order of the layered motifs towards an ACB stacking. During the phase transition from the  $\alpha$ - to the  $\beta$ -form the ordered THF molecule becomes positionally disordered, which leads to a discontinuous increase in the unit cell volume of almost  $15 \text{ \AA}^3$  (Fig. S15†). The ACB stacking order of the  $\beta$ -modification appears to be more favourable with all THF molecules in the structure being disordered. In addition, the complete disorder of the THF molecules leads to a smaller volume expansion of  $217(3) \times 10^{-6} \text{ K}^{-1}$  (Fig. 11c). A strong positive expansion of  $128(3) \times 10^{-6} \text{ K}^{-1}$  occurs along the principal  $X_3$  axis, which corresponds to the [001] direction. Within the layers, rows of equally oriented  $[\text{Mg}(\text{NCS})_2(\text{THF})_4]$  octahedra (Fig. S13c and d,† red arrows) elongate. The thermal

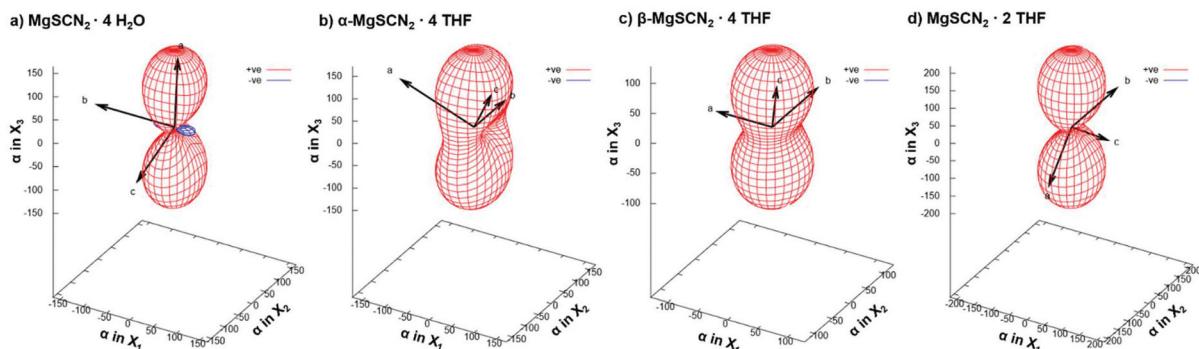

Fig. 11 Plots showing the variation of the thermal expansion coefficient  $\alpha$  with the principal directions  $X_1$ ,  $X_2$  and  $X_3$  (ESI, Table S10 and Fig. S14†) of (a)  $\text{Mg}(\text{SCN})_2\cdot 4\text{H}_2\text{O}$ , (b)  $\alpha\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$ , (c)  $\beta\text{-Mg}(\text{SCN})_2\cdot 4\text{THF}$  and (d)  $\text{Mg}(\text{SCN})_2\cdot 2\text{THF}$ . Red colour indicates expansion, and blue colour indicates compression.

expansion along the principal  $X_1$  and  $X_2$  axis occurs almost isotropically and corresponds to an expansion both within and in between the layers (Fig. S13c and d,† green arrows).

The release of two THF molecules leads to the formation of one dimensional thiocyanate bridged polyhedra forming  $\infty[\text{Mg}(\text{NCS})_{2/2}(\text{SCN})_{2/2}(\text{THF})_2]$  chains in the crystal structure of  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  (Fig. 10e and f). This phase shows a negative thermal expansion of  $-16(1) \times 10^{-6} \text{ K}^{-1}$  along these chains (principal  $X_1$  axis) and a strong positive thermal expansion of  $219(3) \times 10^{-6} \text{ K}^{-1}$  perpendicular to the layered motifs (principal  $X_3$  axes, Table S10†). The total volume expansion coefficient of  $240(1) \times 10^{-6} \text{ K}^{-1}$  is larger than in  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  ( $217(3) \times 10^{-6} \text{ K}^{-1}$ ) but smaller than in the  $\alpha$ -form ( $268(2) \times 10^{-6} \text{ K}^{-1}$ ).

## Discussion

In the group of alkali and earth alkaline metal thiocyanates, only  $\text{Be}(\text{SCN})_2$  has not been investigated and magnesium thiocyanate exists exclusively as coordination compounds  $\text{Mg}(\text{SCN})_2 \cdot x$  [L]. A close relative is  $\text{LiSCN}$ , which does exist in its anhydrous form, yet is extremely prone to form hydrates.<sup>18,47</sup> In both cases, the unfavourable bonding between  $A^{n+}$  ( $A = \text{Li, Mg}; n = 1, 2$ ) and sulphur atoms in  $\text{SCN}^-$  is the fundamental reason for their extensive solvent coordination chemistry. The investigations of  $\text{Mg}(\text{SCN})_2$ -coordination compounds reveal a complex thermal decomposition behaviour and disprove any previous claims about the existence of anhydrous  $\text{Mg}(\text{SCN})_2$ .<sup>8–10</sup> To date,  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  is the only  $\text{Mg}(\text{SCN})_2$  coordination compound with two solvent ligands, and additionally, the first known  $\text{Mg}^{2+}$  thiocyanate with  $\text{Mg-S}$  bonds. Further research of this compound might lead to a procedure to promote  $\text{Mg-S}$  bonding and successfully isolate anhydrous  $\text{Mg}(\text{SCN})_2$ . The anisotropic thermal expansion properties of the title compounds are interesting as well. Among the thiocyanates, it was already shown that in  $\text{KSCN}$  the lattice expansion occurs anisotropically with a linear increase until its well-known phase transition.<sup>48</sup> Other studies about the thermal expansion of thiocyanates are rather rare and typically limited to more complex systems, such as multi-cationic or organometallic compounds, which are of interest for nonlinear optics.<sup>49,50</sup> Both in  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  and in  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  we observed positive and negative thermal expansion, which is not an unusual phenomenon in pseudo halide compounds like  $\text{Ag}_3[\text{Co}(\text{CN})_6]$ .<sup>51,52</sup> In addition, there is an order-disorder phase transition in  $\text{Mg}(\text{SCN})_2 \cdot 4\text{THF}$ , which affects the thermal expansion properties. Disorder in coordination compounds is very common, *e.g.* one famous example being the rotational disorder of  $[\text{CH}_3\text{NH}_3]^+$  (MA) in  $\text{MAPbI}_3$  with its tetragonal to cubic phase transition.<sup>53</sup> The research of ligand disorder and its impact on the parent material's chemistry or properties is very established in extended systems, such as metal-organic frameworks (MOFs),<sup>54</sup> but much rarer in crystalline solids with molecular coordination units. Like other coordination polymers,<sup>55</sup>  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  exhibits a negative thermal expansion along the chains and a strong positive thermal expansion perpendicular to the chain axis.

In conclusion, the coordination chemistry of  $\text{Mg}(\text{SCN})_2$  turned out to be rich and has the potential to go beyond  $\text{H}_2\text{O}$  and THF as ligands. Moreover, magnesium is very similar to nickel in terms of ionic radius and preference for an octahedral coordination,<sup>56</sup> so exploring SCN-THF complexes appears to be an excellent opportunity to further expand the rich coordination chemistry of nickel(II) thiocyanates.<sup>57–60</sup> Indeed, similar  $\text{M}^{\text{II}}(\text{SCN})_2 \cdot 4\text{THF}$  complexes with  $\text{M} = \text{Ni, V}$  and a  $\text{M}^{\text{II}}(\text{SCN})_2 \cdot 2\text{THF}$  phase with  $\text{M} = \text{Co}$  have been found,<sup>61</sup> but the thermal behaviour and the polymorphism have not been investigated yet.

## Conclusion

The recrystallization of  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  in THF yields the hitherto unknown compounds  $\text{Mg}(\text{SCN})_2 \cdot 2\text{H}_2\text{O} \cdot 2\text{THF}$  and  $\alpha\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$ . While the mixed  $\text{H}_2\text{O}$ -THF phase is very sensitive to heat or moisture, and even slowly decomposes under an Ar atmosphere, the pure THF phase exhibits a higher thermal stability and can be stored under an inert atmosphere for at least several weeks. In the crystal structures isolated  $\text{Mg}(\text{NCS})_2(\text{H}_2\text{O})_{4-x}(\text{THF})_x$  units form layered motifs and magnesium is always situated on the center of inversion or on a mirror plane. The latter might be the reason why  $\text{Mg}(\text{SCN})_2 \cdot (4 - x) \text{ H}_2\text{O} \cdot x\text{THF}$  compounds with  $x = 1$  or 3 were not discovered. In the structure of  $\alpha\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  half of the THF molecules are positionally disordered. Heating of the compounds leads to a phase transformation into the  $\beta$ -form between 130 and 135 °C. After the phase transformation, all THF molecules are positionally disordered and the stacking order of the layered motifs is reversed. Further heating eventually leads to the release of two THF molecules at 170 °C. In  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  thiocyanate related sulfur atoms fill the voids in the coordination sphere of magnesium, which leads to the formation of one dimensional  $\infty[\text{Mg}(\text{NCS})_{2/2}(\text{SCN})_{2/2}(\text{THF})_2]$  chains. Anhydrous  $\text{Mg}(\text{SCN})_2$  cannot be obtained by further heating as the thiocyanate partially decomposes leading to the formation of a strongly disordered solid that cannot be characterized. All investigated  $\text{Mg}(\text{SCN})_2 \cdot (4 - x) \text{ H}_2\text{O} \cdot x\text{THF}$  phases exhibit a remarkable anisotropic thermal expansion, and  $\text{Mg}(\text{SCN})_2 \cdot 4\text{H}_2\text{O}$  as well as  $\text{Mg}(\text{SCN})_2 \cdot 2\text{THF}$  were found to show both positive and negative thermal expansion. The order-disorder transition of the THF molecules during the transformation from  $\alpha$ - to  $\beta\text{-Mg}(\text{SCN})_2 \cdot 4\text{THF}$  has a major impact on the thermal expansion properties, *i.e.* it reduces the overall volume expansion and makes it more isotropic.
