# Defect clustering in an Eu-doped NaMgF<sub>3</sub> compound and its influence on luminescent properties†

Afranio Sousa, <sup>a</sup> Adelmo Souza <sup>b</sup> and Heveson Lima <sup>\*c</sup>

Luminescent properties of compounds based on lanthanide ions are strongly influenced by defect clustering, and unfortunately, these defects are not fully understood in lanthanide-doped fluoroperovskite materials. In this context, we studied the structural properties and effects upon incorporation of divalent and trivalent Europium dopant ions in the orthorhombic phase of NaMgF<sub>3</sub>, combining classic atomistic simulations and crystal field models. We developed a new set of interatomic potentials that reproduce the structural properties, as well as lattice parameters, interatomic distances and volumes, and elastic properties, with good accordance with experimental results. Analysis of the solution energy revealed that Eu<sup>3+</sup> is most energetically favourable in the Mg site, while Eu<sup>2+</sup> is most favourable in the Na site. The mechanism of charge compensation was investigated in both cases. We also analysed the local symmetry, charge transfer in Eu–F chemical bonding, crystal field parameters, and <sup>7</sup>F<sub>1</sub> energy sub-levels of the Eu<sup>3+</sup> ion in the host matrix based on crystal field and electronegativity models. In addition, we discussed the photoionization cross-section and optically stimulated luminescence (OSL) decay pattern for Eu<sup>2+</sup>-doped NaMgF<sub>3</sub>. Thus, this work provides direction for new material design and opens up a framework to analyse structural and defect changes of fluoperovskite compounds upon lanthanide ion insertion.

## 1 Introduction

Perovskite compounds are a class of special materials that have attracted wide attention in recent years for interesting applications, such as magnetoelectrics,<sup>1,2</sup> photovoltaics devices,<sup>3–6</sup> light-emitting diodes,<sup>7,8</sup> lasers,<sup>9,10</sup> photocatalysis,<sup>11</sup> memristors,<sup>12</sup> and ionizing radiation detectors.<sup>13–15</sup> Fluoroperovskite materials, ABF<sub>3</sub> (where A and B stand for alkali and alkaline earth metals, respectively), are a sub-class of perovskite compounds. In particular, NaMgF<sub>3</sub> is a material inserted in this family, with interesting properties related to optics and ionizing radiation dosimetry.<sup>16,17</sup> Rare earth-doped NaMgF<sub>3</sub> compounds have been considered promising materials for personal dosimetry because of the effective atomic number, similar to human tissue, and high sensitivity at low dosages.<sup>18,19</sup> Unlike the other materials of this class, such as AMgF<sub>3</sub> (A = Rb, K, and Cs),

NaMgF<sub>3</sub> presents an orthorhombic perovskite structure with space group Pbnm at room temperature and standard pressure.<sup>20</sup>

Luminescent properties of NaMgF<sub>3</sub> nanoparticles doped with lanthanide ions and Mn, synthesized using a reverse micro-emulsion method, have been reported.<sup>21,22</sup> Furthermore, lanthanide ions doped into NaMgF<sub>3</sub> polycrystalline samples have also been prepared by the conventional solid-state reaction method.<sup>23,24</sup> In fact, lanthanide incorporation in compounds has been largely used to enhance luminescent properties. In particular, Eu<sup>3+</sup>-doped materials are a well-known red emitting phosphors, widely used as spectroscopic probes because of their unique emission characteristics.<sup>25–27</sup> Valuable characterization information, such as local symmetry of the optically active ion, occupancy number, and Stark levels, can be obtained from emission characteristics of the Eu<sup>3+</sup> ion. However, in many cases, the Eu ion is incorporated in a host matrix and aliovalent substitution occurs. The difference between the ionic radii of both ions (doped and host) is an important factor in evaluating the influence of aliovalent substitution, giving rise to material defects. Identifying these defects is crucial to accurately describing the spectroscopic properties and understanding specific mechanisms relevant to their application in optics and ionizing radiation detectors. Mechanisms of charge compensation are not yet established for Eu<sup>3+</sup>- and Eu<sup>2+</sup>-doped NaMgF<sub>3</sub>. Some reports have suggested

different types of charge compensation in materials of the same family ( $\text{KMgF}_3^{28-30}$  and  $\text{RbMgF}_3^{31}$ ) doped with different lanthanide ions. However, these discussions are based on ion sizes (doped and host), ignoring discussions about lattice solution energy. In addition, the symmetry site and coordination number of the optically active ion are not clear, as well as the substitution site in the host matrix. The optically stimulated luminescence (OSL) decay pattern and high sensibility of the  $\text{NaMgF}_3\text{:Eu}^{2+}$  compound for low dose levels are not fully established. Therefore, a systematic study is necessary to make predictions about the incorporation of defects in the  $\text{NaMgF}_3$  structure.

Classical atomistic simulation is a reliable tool for modelling a range of ionic materials and to help understand theoretical and experimental results. In this methodology, interactions between atoms are determined by interatomic potentials that are essential to studying physical properties of the simulated systems. Several studies have been widely used to examine structural, mechanical, elastic, and dielectric properties in solid-state materials.<sup>32-36</sup> Furthermore, atomistic simulation is able to perform studies on defect properties with low computational cost, compared with other methodologies, and has been successfully employed to study defects.<sup>37-40</sup> In addition, atomistic simulation procedures, combined with crystal field theory, is an practical method for describing spectroscopic properties of lanthanide ion-doped compounds and their dopant-related effects. Recently, Otsuka *et al.*<sup>41</sup> performed a study from a spectroscopic point of view, combining atomistic simulation, the simple overlap model (SOM),<sup>42</sup> and the method of nearest neighbours<sup>43</sup> (theoretical models of crystal field). The combination of both methodologies successfully described local symmetry and coordination number of the optically active ion, crystal field parameters, crystal field strength,  $^7\text{F}_1$  stark sub-levels, and splitting.

Thus, in this work, we used a combination of classic atomistic simulation-based ionic models and crystal field models to study the orthorhombic phase of  $\text{NaMgF}_3$ . Firstly, atomistic simulation was used to describe structural properties and the defect formation process with the incorporation of  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  ions into  $\text{NaMgF}_3$ . For this, we developed a new set of interatomic potentials to describe the interactions between ions for the compound in the orthorhombic phase and performed a study of the structural and elastic properties. We carried out a defect study to obtain the most favourable charge compensation mechanism. Secondly, crystal field models were used to study spectroscopic properties of  $\text{Eu}^{2+}$  and  $\text{Eu}^{3+}$  ion-doped  $\text{NaMgF}_3$ . Detailed local geometry of the optically active ion in this host matrix was obtained. In addition, photoionization cross-section calculations, associated with the first-order kinetic model, gave us information about the OSL decay pattern and high sensibility of the  $\text{Eu}^{2+}$ -doped  $\text{NaMgF}_3$  compound.

## 2 Methodologies

### 2.1 Computational simulation

The atomistic simulation technique was used to study the perfect structure and defective lattice of orthorhombic  $\text{NaMgF}_3$ ,

performed by GULP code.<sup>44</sup> Relaxation of the lattice parameters and atomic positions was completed to find the lowest energy. A description of the structural properties of the system depends on a set of potential parameters, adopted for a reliable description of fundamental interactions between the ions. Long-range interactions were calculated by Coulomb potential and short-range interactions by Buckingham potential. Eqn (1) shows the representation of repulsive (or Pauli repulsion) and attractive (or van der Waals interaction) terms of the Buckingham potential:

$$V(r) = A \exp\left(-\frac{r}{\rho}\right) - \frac{C}{r^6} \quad (1)$$

where  $A$ ,  $\rho$ , and  $C$  are parameters obtained by a fitting procedure, and  $r$  is interatomic distance between ions.

In addition, a model for efficient treatment of ionic polarization effects is necessary, and a simple model, known as the shell model,<sup>45</sup> was used. Ions in this model are represented by a core (massive, includes the nucleus plus core electrons) and shell (massless, includes valence electrons) connected by a harmonic constant. The formal charge of the ion is obtained by the sum of the core and shell charges.

The defect calculation was performed using a two-region strategy.<sup>46</sup> This method is very useful for calculating defects in atomistic simulations and has been used successfully.<sup>47-51</sup> The crystal lattice is divided into two spherical regions (I and II), where the defect (or defect cluster) is placed in the centre of these regions. The inner region I is the portion of the crystal located around the defect, allowing explicit relaxation of all the ion positions under the action of a force field. Region II is more distant from the defect and can be treated using an approximate continuous method, since ions in this region exhibit an interatomic displacement smaller than the ions in region I. To obtain reliable results, a convergence test, with an appropriate radius for these regions, is necessary. In this work, we used 12 and 18 Å for regions I and II, respectively. This corresponds to approximately 1000 ions in the region I and 2400 ions in region II. The total energy ( $E_T$ ) can be calculated by the expression  $E_T = E_1(x) + E_{12}(x,u) + E_2(u)$ , where  $E_1(x)$  is the energy of region I,  $E_2(u)$  is the energy of region II, and  $E_{12}(x,u)$  is the energy of the interaction region between them.

### 2.2 Crystal field parameters and Stark levels of the $^7\text{F}_1$ multiplet

Interaction between the lanthanide ion and its nearest neighbours (NNs) has been a discussion theme in research groups that work with lanthanide spectroscopy, for a long time. The point charge electrostatic model (PCEM)<sup>52</sup> was the first non-parametric model to discuss crystal field parameters from a theoretical point of view. The PCEM considers that the bond between the lanthanide ion and its chemical surrounding is purely ionic, where the charge factor is equal to ligand valence and is located at the NN's position. Although some considerations of the PCEM have led to unsatisfactory results from a quantitative point of view, it has been the base model for the development of other theoretical models.

The simple overlap model<sup>42</sup> used in our predictions is a theoretical model based on the PCEM, which has been largely used in lanthanide spectroscopy with satisfactory predictions.<sup>53,54</sup> The SOM introduces a small covalent character to describe Ln–NN chemical bonding. In this assumption, the effective interaction charge is defined as  $-\rho_j g_j e$  and is located around the Ln–NN middle distance ( $R_j/2\beta$ ).  $g_j$  is the charge factor devoted to Ln–NN chemical bonding,  $R_j$  is  $j$ -th NN distance from the Ln ion,  $e$  is the elementary charge, and  $\beta_j = 1/(1 \pm \rho_j)$  is a factor that determines the position of the effective charge in the middle distance. The minus sign is applied when the charge is closer to the Ln ion, and the plus sign is applied when the charge is closer to the ligand.  $\rho_j = \rho_0(R_0/R_j)^{3.5}$  describes the overlap of interacting wavefunctions, where  $R_0$  is the smaller Ln–NN distance, and  $\rho_0 = 0.05$  is the maximum overlap between the 4f and 2s (or 2p) orbitals.<sup>55</sup>

Through these considerations, the crystal field parameters ( $B_q^k$ ) of the SOM can be related to PCEM, as show eqn (2):

$$B_q^k(\text{SOM}) = \rho_j \left( \frac{2}{1 - \rho_j} \right)^{k+1} B_q^k(\text{PCEM}) \quad (2)$$

The  ${}^7F_1$  energy sublevels of  $\text{Eu}^{3+}$  can be obtained through diagonalization of the crystal field matrix within the  ${}^7F_1$  manifold.<sup>56</sup> Thus,

$$E_0 = \frac{2\sqrt{14}}{15} U^2 B_0^2 \quad (3)$$

$$E_- = \frac{-\sqrt{14}}{15} U^2 B_0^2 + \frac{7\sqrt{2}}{5\sqrt{3}} U^2 B_2^2 \quad (4)$$

$$E_+ = \frac{-\sqrt{14}}{15} U^2 B_0^2 - \frac{7\sqrt{2}}{5\sqrt{3}} U^2 B_2^2 \quad (5)$$

where  $E_0$ ,  $E_-$ , and  $E_+$  are energy sublevels for  $J = 1$ , measured in relation to the barycentre.  $U^2$  is the reduced matrix element.<sup>56</sup>

### 2.3 Photoionization cross-section of trap levels

The photoionization cross-section ( $\sigma$ ) is an essential quantity to understand the interaction processes of electromagnetic radiation with matter. Recently, Lima–Batista–Couto<sup>57</sup> proposed a model to obtain  $\sigma$  of localized traps in the band gap with activation energy  $E_i$  with respect to the conduction band, based on time-dependent perturbation theory. The model describes the trap level by a three-dimensional isotropic harmonic oscillator wavefunction with angular frequency  $\omega_0$ , and the electron in the conduction band is described by the plane wavefunction. Following the same steps reported previously<sup>57</sup> and using the

Fermi's golden rule, we obtain:

$$\sigma = \frac{4\alpha\hbar^2}{m^*\omega\omega_0} \sqrt{\frac{\pi\hbar}{m^*\omega_0}} \exp\left\{-\frac{\hbar}{m^*\omega_0} \left[k^2 + \left(\frac{\omega}{c}\right)^2\right]\right\} \\ \times 4\pi \left(\frac{1}{\gamma(\omega)}\right)^3 [\gamma(\omega) \cosh \cosh(\gamma(\omega)) - \sinh \sinh(\gamma(\omega))] \quad (6)$$

where  $\gamma(\omega) = 2k\hbar\omega/m^*\omega_0c$  is an energy function,  $\omega$  is the angular frequency of incident electromagnetic radiation,  $m^*$  is the electron effective mass,  $\alpha$  is the fine structure constant,  $\hbar$  is Planck's reduced constant,  $c$  is the speed of light, and  $k$  is the wavevector of the electron. This expression is obtained considering all multipole terms in the Hamiltonian that couple the linear moment of the electron with the radiation electromagnetic field. This model was applied successfully to predict  $\sigma$  in promising materials for personal dosimetry and explain the mechanism of electron de-trapping with light stimulation.<sup>57,58</sup>

## 3 Results and discussion

### 3.1 Interatomic potentials of NaMgF<sub>3</sub>

To analyse the structural properties and influence of defect clustering on the luminescent properties of the compound, describing the interactions between ions of the materials through a reliable set of interatomic potentials is necessary. We developed a new set of interatomic potentials for the orthorhombic phase of NaMgF<sub>3</sub> from an empirical fitting procedure, carried out with GULP code.<sup>44</sup> The empirical fitting was used to obtain Buckingham potential parameters for the Na–F interaction. The potential parameters used for Mg–F and F–F interactions were taken from a previous study<sup>33</sup> and have already been tested and validated for compounds of the same family, AMgF<sub>3</sub> (A = K, Cs, and Rb). Table 1 shows the interatomic potentials and shell model parameters used in all calculations of this work. A short range potential cutoff of 12 Å was used.

This set of interatomic potentials was validated, and the calculated lattice parameters of the NaMgF<sub>3</sub> compound are in excellent agreement with X-ray diffraction values, as well as mechanical properties. Elastic and dielectric constants are close to experimental values (see next section). The fluoride precursors NaF and MgF<sub>2</sub> are commonly used to synthesize NaMgF<sub>3</sub>. In addition, the same set of potentials is also capable of modelling precursor fluorides (NaF and MgF<sub>2</sub>). Even though the focus of this work was to analyse the orthorhombic NaMgF<sub>3</sub> phase, we were able to show that this set of interatomic potentials is transferable to the cubic phase of NaMgF<sub>3</sub>, as well.

Table 1 Buckingham potential and shell parameters for NaMgF<sub>3</sub>

Interaction	A (eV)	$\rho$ (Å)	C (eV Å <sup>6</sup> )	k (eV Å <sup>−2</sup> )	Y (e)	Ref.
Na <sup>+</sup> <sub>core</sub> –F <sup>−</sup> <sub>shell</sub>	1223.35	0.2682	0	—	—	This work
Mg <sup>2+</sup> <sub>core</sub> –F <sup>−</sup> <sub>shell</sub>	904.7	0.2825	0	—	—	Ref. 33
F <sup>−</sup> <sub>shell</sub> –F <sup>−</sup> <sub>shell</sub>	5050.2	0.2189	4	15	−1.378	Ref. 33

Calculations of the various precursor fluoride properties and cubic NaMgF<sub>3</sub> are shown in the supporting information (see Tables S1–S7, ESI†). These facts are important validation characteristics for successfully calculating defect properties.

### 3.2 Structural properties of the orthorhombic NaMgF<sub>3</sub>

Table 2 presents a comparison between calculated and experimental data from lattice parameters and cell volumes for orthorhombic NaMgF<sub>3</sub>. A relative error of less than 0.82% was calculated for all lattice parameters and cell volumes with respect to X-ray diffraction data.<sup>59</sup> Table 3 shows the most relevant interatomic distances for orthorhombic NaMgF<sub>3</sub> calculated in this work compared to experimental data.<sup>59</sup> The distances presented a relative error below 3% in all cases. These results show that our atomistic simulation has good acceptance in the reproduction of NaMgF<sub>3</sub> structural properties. In addition, a similar relative error was observed for all properties studied for cubic NaMgF<sub>3</sub> using the same set of interatomic potentials, as shown in the supporting information.

Fig. 1 presents the orthorhombic NaMgF<sub>3</sub> phase with space group *Pbnm* calculated for this work. The structure contains four non-equivalent (Na, Mg, F1, and F2) atoms. Mg<sup>2+</sup> ions are coordinated by six F atoms, organized into three pairs of Mg–F bonds with approximately the same distances (two pairs of Mg–F2 bonds are equatorials and one pair of Mg–F1 bonds is apical). The Na atom is coordinated by eight F atoms, with only two Na–F1 bonds, and almost all bond distances are between Na–F2. This compound presents a different structural behaviour at room temperature and pressure compared to other materials of the same family (AMgF<sub>3</sub>, A = Cs, Rb, and K).<sup>33</sup>

The elastic constants (*C*<sub>11</sub>, *C*<sub>22</sub>, *C*<sub>12</sub>, *C*<sub>13</sub>, *C*<sub>23</sub>, *C*<sub>33</sub>, *C*<sub>44</sub>, *C*<sub>55</sub>, and *C*<sub>66</sub>) of NaMgF<sub>3</sub> in the orthorhombic phase are shown in Table 4, and the values calculated in this work are compared with experimental data.<sup>60</sup> The elastic constants satisfy Born's criteria and prove its mechanical stability. The reproducibility of these properties validates the potentials and transferability, which is crucial for modelling physical properties under conditions different from the initial fitting procedure. The bulk modulus, shear modulus, static dielectric constant ( $\epsilon_0$ ), and high-frequency dielectric constant ( $\epsilon_\infty$ ) for orthorhombic NaMgF<sub>3</sub> are also shown in Table 4. In addition, our results show excellent transferability of these potentials for cubic NaMgF<sub>3</sub> (see ESI†). Having successfully completed this first step, we next analysed defect properties and their influence on spectroscopic properties of NaMgF<sub>3</sub>.

### 3.3 Defect calculations

The process of incorporating Eu<sup>3+</sup> and Eu<sup>2+</sup> ions into the NaMgF<sub>3</sub> compound requires a charge compensation mechanism to stabilize the local structure and accommodate extra charge in the relaxed structure. Interatomic potential used to describe Eu–F interactions was taken from a previous study for modelling natural apatite crystals,<sup>61</sup> and have already been tested and validated for Rare-Earth fluorides. The incorporation of defects into the crystalline structure, obtained by our

atomistic simulation, can estimate the preferred doping site and mechanism of charge compensation most favourably. Firstly, we consider the various possible schemes of charge compensation for the incorporation of  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  in the  $\text{NaMgF}_3$  compound. Tables 5 and 6 show the proposed chemical reaction schemes, expressed in Kröger–Vink notation,<sup>62</sup> for the incorporation of  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  ions, respectively. After that, the next stage is the calculation of solution energy ( $E_{\text{sol}}$ ) for each reaction, performed to predict the most energetically favourable scheme. The solution energy was obtained by a combination of defect energies, lattice energy of the fluoride precursor, and lattice energy of the dopant ion. In this work, the solution energies are calculated considering defects as isolated species (or unbound defects) and simulated in a cluster of defects (or bound defects). The motivation for calculating a cluster of defects is to account for the binding energy for different arrangements that frequently present the lowest energy. An example of how to calculate the solution energy for unbound ( $E_{\text{sol}}^{\text{unbound}}$ ) or bound defects ( $E_{\text{sol}}^{\text{bound}}$ ) is shown in eqn (7a) and (7b) for the first reaction (Scheme I)

in Table 5. For the other reactions, a similar procedure is employed.

$$E_{\text{sol}}^{\text{unbound}} = E_{\text{def}}(\text{Eu}_{\text{Na}}^{\bullet\bullet}) + 2E_{\text{def}}(\text{F}_i') + E_{\text{latt}}(\text{NaF}) - E_{\text{latt}}(\text{EuF}_3) \quad (7a)$$

$$E_{\text{sol}}^{\text{bound}} = E_{\text{def}}(\text{Eu}_{\text{Na}}^{\bullet\bullet} + 2\text{F}_i') + E_{\text{latt}}(\text{NaF}) - E_{\text{latt}}(\text{EuF}_3) \quad (7b)$$

where  $E_{\text{def}}$  is the defect formation energy, and  $E_{\text{latt}}$  is lattice energy. More details regarding the calculation of solution energies are found in ref. 48.

Tables S8–S12 in the ESI† show defect and lattice energies required to perform the solution energy calculations.

Fig. 2 presents a solution energy diagram for bound and unbound defects for each reaction of  $\text{Eu}^{3+}$ -doped  $\text{NaMgF}_3$ , represented by schemes shown in Table 5. Notably,  $\text{Eu}^{3+}$  prefers to be incorporated into the  $\text{Mg}^{2+}$  site ( $E_{\text{sol}}^{\text{bound}} = 2.129$  eV), compensated by a sodium vacancy (Scheme VII). Other reactions proposed here lead to values close to the red line. Reactions IV (entering into a  $\text{Na}^+$  site) and VI (entering into a  $\text{Mg}^{2+}$  site),

Fig. 2 Solution energies of bound and unbound defects for incorporation of  $\text{Eu}^{3+}$  into  $\text{NaMgF}_3$ .

Fig. 3 Solution energies of bound and unbound defects for incorporation of  $\text{Eu}^{2+}$  into  $\text{NaMgF}_3$ .

for instance, have approximate differences of 0.5 and 0.3 eV, respectively, with respect to the lowest point. Our predictions show that mechanisms involving two substitutional defects in  $\text{Na}^+$ ,  $\text{Mg}^{2+}$ , or both sites are practically unlikely in this configuration. In all cases, the calculations carried out in clusters lead to a decreased solution energy because of interactions between defects. Some reactions show considerable binding energy, leading to lower solution energy in comparison with unbound defect calculations.

In fact, the valence of ions is a determining factor for  $\text{Eu}^{3+}$  entering into the  $\text{Mg}^{2+}$  site instead of the  $\text{Na}^+$  site. The ionic radius varies with coordination number, charge states, and other parameters.<sup>63</sup> Even though  $\text{Eu}^{3+}$  (0.947 Å for a coordination number of six) has a larger ionic radius than  $\text{Mg}^{2+}$  (0.72 Å for a coordination number of six) and is smaller than  $\text{Na}^+$  (1.18 Å for a coordination number of eight),  $\text{Eu}^{3+}$  is preferable for replacing  $\text{Mg}^{2+}$  in the host matrix. In this case, the difference between the ionic radii of  $\text{Eu}^{3+}$  and  $\text{Mg}^{2+}$  ions are practically the same as  $\text{Eu}^{3+}$  and  $\text{Na}^+$  ions. Thus, according to our calculations, the difference in valence between the Eu and Na ions leads to less favourable charge compensations for the system, even though the  $\text{Eu}^{3+}$  ion could be better accommodated by replacing the Na site instead of the Mg site.

Fig. 3 shows solution energy *versus* proposed charge compensation schemes (see Table 6) for incorporation of  $\text{Eu}^{2+}$  into the Na site of  $\text{NaMgF}_3$ . The most favourable mechanism of charge compensation is through the sodium vacancy (scheme XV) and anti-site (scheme XVIII), both with energy solutions of approximately 1.5 eV (see red arrow). Analyses of scheme XXI show (see Table 6, but not shown in Fig. 3), evidently, that the  $\text{Eu}^{2+}$ -doped Mg site requires no compensation mechanism because these ions have the same valence. The solution energy calculated for this scheme is approximately 2 eV. In other words, the calculations show that the Na site is energetically most favourable for the incorporation of the  $\text{Eu}^{2+}$  ion, rather than at the Mg site. In addition, our predictions show that the solution energy of bound defects is lower than unbound defects in all proposed schemes. These results show the importance of defect clustering in this system.

The most probable mechanism of  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  ion incorporation into  $\text{NaMgF}_3$ , charge compensation is illustrated in Fig. 4. Analysing the proposed chemical reactions and calculation of solution energies, we see that when calculations are carried out considering defects and the respective mechanism of charge compensation, as a defect cluster, the solution energy is less than when calculated as isolated defects. The configuration of the local site is modified in terms of distances and distortions. Understanding these changes is of great importance for a better understanding of luminescent properties of optically active ions in the host matrix.

Table 7 shows the interatomic distances ( $d$ ) from the atomistic simulation after doping  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  ions into  $\text{NaMgF}_3$  for the most favourable schemes found in this work. The percentage difference between Eu–F and Na–F (or Mg–F) interatomic distances is represented by  $\Delta$  (%). The Na–F and Mg–F distances are taken from the pure  $\text{NaMgF}_3$  phase (see Table 3) for comparison. We note that some distances are reduced, while others are increased for both cases (schemes) involving  $\text{Eu}^{2+}$ . For the cluster  $(\text{Eu}_{\text{Na}}^{\bullet} + \text{V}_{\text{Na}}')$ , the atoms drastically approach  $\text{Eu}^{2+}$  with distances of less than 3 Å. For  $\text{Eu}^{3+}$ , in contrast with  $\text{Eu}^{2+}$ , all distances increase after doping. In this case,  $\Delta$  (%) is around 10% for all interactions.

Experimental results based on photoluminescence spectra indicate that both  $\text{Eu}^{2+}$  and  $\text{Eu}^{3+}$  ions can co-exist in  $\text{NaMgF}_3$ , even although the emission spectrum from  $\text{Eu}^{3+}$  is quite different from the  $\text{Eu}^{2+}$  ion. In this case, when the  $\text{NaMgF}_3$  is excited at 256 nm the emission from  $\text{Eu}^{2+}$  is observed at 366 nm, and when excited at 396 nm emission from  $\text{Eu}^{3+}$  at 590 nm is observed.<sup>22</sup> Although the  $\text{Eu}^{2+}/\text{Eu}^{3+}$  ratio depends on the chemical composition of the host,<sup>64</sup> the synthesis method<sup>65</sup> and exposure to ionizing radiation,<sup>66,67</sup> our calculations suggest that, from the perspective of solution energy, the Eu ion prefers to be incorporated into  $\text{NaMgF}_3$  in its divalent state (see Fig. 2 and 3). Unlike Eu in the Na site, our calculations reveal that on the  $\text{Mg}^{2+}$  site, both  $\text{Eu}^{2+}$  and  $\text{Eu}^{3+}$  trivalent Europium are energetically favourable, once the energy difference is about

Fig. 4 Illustration of  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  incorporation into  $\text{NaMgF}_3$  with the most favourable charge compensation mechanism: (a) pure  $\text{NaMgF}_3$ , (b)  $(\text{Eu}_{\text{Na}}^{\bullet} + \text{V}_{\text{Na}}')$  cluster, (c)  $(\text{Eu}_{\text{Na}}^{\bullet} + \text{Na}_{\text{Mg}}')$  cluster, and (d)  $(\text{Eu}_{\text{Mg}}^{\bullet} + \text{V}_{\text{Na}}')$  cluster.

Table 7 Comparison between interatomic distances ( $d$  in Å) of  $\text{Eu}^{2+}$  and  $\text{Eu}^{3+}$  ions doped in Na and Mg sites, considering the most favourable schemes

$\text{Eu}^{2+}$ into Na site, $(\text{Eu}_{\text{Na}}^{\bullet} + \text{V}_{\text{Na}}')$			$\text{Eu}^{2+}$ into Na site, $(\text{Eu}_{\text{Na}}^{\bullet} + \text{Na}_{\text{Mg}}')$			$\text{Eu}^{3+}$ into Mg site, $(\text{Eu}_{\text{Mg}}^{\bullet} + \text{V}_{\text{Na}}')$		
Eu-F	$d$ (Å)	$\Delta$ (%)	Eu-F	$d$ (Å)	$\Delta$ (%)	Eu-F	$d$ (Å)	$\Delta$ (%)

Eu-F1	2.936	-5.8	Eu-F1	3.121	0.1			

0.133 eV. Thus,  $\text{Eu}^{2+}$  emission can arise from Eu localized in the Na and Mg sites. In fact, experimental results show that  $\text{Eu}^{2+}$  is dominant at lower concentrations, but  $\text{Eu}^{3+}$  becomes important when concentration increases. This behaviour is similar to that reported for  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  in  $\text{CaF}_2:\text{Eu}$  crystals.<sup>68</sup>

### 3.4 Spectroscopic properties of Eu ions in $\text{NaMgF}_3$

**3.4.1 Local structure of the  $\text{Eu}^{3+}$  ion.** In order to analyse the local symmetry and charges transferred in Eu-F chemical bonding and to calculate the crystal field parameters and Stark levels from the  $^7\text{F}_1$  multiplet, relaxed positions of  $\text{Eu}^{3+}$  and its NNs are necessary. These positions are obtained from the most

favourable mechanism of atomistic simulation presented in Section 3.3. In scheme VII, the most energetically favourable,  $\text{Eu}^{3+}$  has the same coordination number (six NNs) when incorporated into the  $\text{Mg}^{2+}$  site.

Spherical coordinates of the  $\text{Eu}^{3+}$  ion, obtained by atomistic simulations of defect clustering, are shown in Table 8. In dealing with a distorted structure, all Eu-F distances are slightly different and, consequently, symmetry discussions here are approximate.

We chose the principal axis of symmetry ( $z'$ -axis) by diagonalizing the tensor of the quadrupolar field, which is experienced by the optically active ion. In this case, the eigenvector

**Table 8** Spherical coordinates with respect to the main axis of symmetry, with the  $\text{Eu}^{3+}$  ion at the origin of the system

Spherical coordinates <sup>a</sup>						
NN	Distorted $S_6$			Ideal $S_6$		
	$R$	$\theta$	$\phi$	$R$	$\theta$	$\phi$
F1	2.168	63.36	0	2.345	62.81	0
F2	2.161	60.77	240.83	2.345	62.81	240
F3	2.163	62.61	121.50	2.345	62.81	120
F4	2.197	128.30	302.49	2.345	117.19	300
F5	2.201	127.65	180.74	2.345	117.19	180
F6	2.205	130.11	61.56	2.345	117.19	60

<sup>a</sup> The ideal  $S_6$  point symmetry corresponds to one site of  $\text{Eu}^{3+}$  in C-rare earth sesquioxides, taken from ref. 69, for comparison. The radial coordinates are given in angstroms, and the angular coordinates are given in degrees. The centroid (F1, F2, F3) coming out of the  $x'-y'$  plane is taken as the  $z'$ -axis.

takes the highest eigenvalues. The centroid (coming out the  $x'-y'$  plane) between the F1, F2, and F3 atoms is taken as the  $z'$ -axis to measure the spherical coordinates.

F1, F2, and F3 have slightly different distances, as well as F4, F5, and F6 atoms. The  $C_3$  symmetry operation about the  $z'$ -axis takes, approximately, F2 to F1 and F1 to F3. Similarly, the atoms in the lower plane bounce off each other. Then, F1, F2, and F3 are approximately equivalent to each other. Likewise, F4, F5, and F6 may be considered approximately equivalent. This procedure reduces the degree of freedom in crystal field calculations by employing the same charge factor to equivalent atoms. Thus, we have used the charge factor  $g_1$  to yellow atoms and  $g_2$  to orange atoms.

Atomistic simulation was used to better understand the true nature of the defects in  $\text{NaMgF}_3$ , giving us information about spatial coordinates of the  $\text{Eu}^{3+}$  ion, which is not easily obtained by X-ray diffraction because of the low concentration of the Eu ion in the host matrix. Notably, a  $C_3$  symmetry operation (Fig. 5) following a  $\sigma_h$  operation (reflection plane that contains the  $x'-y'$  plane) takes the same structural pattern, approximately. The bond distances illustrated in Fig. 5 can be found in Table 8. A combination of  $C_3$  and  $\sigma_h$  operations is termed  $S_6$  symmetry in group theory.<sup>56</sup> In this case, a distorted  $S_6$  point symmetry occurs because all distances are slightly different, and the angles differ from that of ideal  $S_6$  symmetry. Once in  $S_6$  point symmetry, the electric dipole 4f–4f transitions are forbidden, and the distorted  $S_6$  symmetry explains the weak electric dipole 4f–4f transitions of  $\text{Eu}^{3+}$  observed in  $\text{NaMgF}_3$ .

**Fig. 5** Local symmetry of the optically active ion, and the axis adopted to obtain spherical coordinates. The centroid coming out the  $x'-y'$  plane is taken as the  $z'$ -axis.

Spectroscopic properties of  $\text{Eu}^{3+}$  in the Na sites must be quite different from  $\text{Eu}^{3+}$  substituting  $\text{Mg}^{2+}$ , due to low symmetry of the Na site. In addition, our simulation shows that there is also distortion when  $\text{Eu}^{2+}$  substitutes Na. This suggests that  $\text{Eu}^{2+}$  must be in a site with very low symmetry, which induces a high intensity 4f–4f transition. In fact, 4f–4f emission from  $\text{Eu}^{2+}$  in  $\text{NaMgF}_3$  has intensity comparable with broad  $4f^65d^1$ – $4f^7$  emission, which is an allowed transition and occurs with a high transition probability. On the other hand, experimental results show that  $\text{Eu}^{3+}$  in low symmetry sites are less unlikely, and this has also been predicted in our simulations, showing that  $\text{Eu}^{3+}$  in a Na site is less probable.

**3.4.2 Crystal field parameters.** Table 9 shows charge factors and the set of crystal field parameters,  $B_q^k$ , for the distorted  $S_6$  site. The  $B_q^k$  were calculated using spherical coordinates of  $\text{Eu}^{3+}$  ion incorporation into the Mn site of  $\text{NaMgF}_3$  (Table 8), a set of charge factors ( $g_1$  and  $g_2$ ) that describes the interaction Eu–F in this dielectric medium, and the maximum overlap,  $\rho_0$ ,

**Table 9** Crystal field parameters ( $B_q^k$  in  $\text{cm}^{-1}$ ) and charge factors<sup>a</sup> using  $\beta^-$  and  $\beta^+$ 

$B_q^k$	$\beta^-$	$\beta^+$
$B_0^2$	−299.6	−299.53
$B_2^2$	−8.144 − 27.578i	−7.555 − 26.408i

$B_{12}^6$	35.648–4.526i	22.963 − 3.444i
$B_{14}^6$	0.292 + 22.377i	0.333 + 14.947i
$B_{16}^6$	−282.947 − 53.841i	−187.929 − 25.489i
$g_1$	0.435	0.58
$g_2$	0.034	0.031

<sup>a</sup>  $\beta^-$  and  $\beta^+$  define the charge factor position around the middle distance of Eu–F. The minus signal means that g is closer to  $\text{Eu}^{3+}$ , and the plus sign indicates that g is closer to the ligands. A rotation ( $30.5^\circ$ ) about the principal axis was carried out to eliminate the imaginary part of  $B_2^2$ .

between 4f wavefunctions with ligand orbitals. In this case, we used the value ( $\rho_0 = 0.05$ ) obtained by Axe and Burns.<sup>55</sup> Notably, all  $B_q^k$  are nonzero, as expected, because the local structure of the optically active ion is distorted. The  $B_q^k$  also allow for identification of  $\text{Eu}^{3+}$  ion symmetry, as well as predicting the  $^7\text{F}_1$  state energy sublevels. In ideal  $S_6$  symmetry,<sup>56</sup> only the following  $B_q^k$  values are nonzero:  $B_0^2, B_0^4, B_3^4, B_0^6, B_3^6$ , and  $B_6^6$ . We observe that the contribution of  $B_q^k$  values that represent  $S_6$  symmetry are much higher than the others.  $B_1^2$  and  $B_2^2$  have approximately a 10% contribution in relation to  $B_0^2, B_1^4, B_2^4$ , and  $B_4^4$  have a contribution around 4% in relation to  $B_0^4$  and  $B_3^4$ . Likewise,  $B_1^6, B_2^6, B_3^6$ , and  $B_5^6$  contribute approximately 10% in relation to  $B_0^6, B_3^6$ , and  $B_6^6$ .

This leads us to conclude that  $\text{Eu}^{3+}$  occupies a distorted  $S_6$  point symmetry. Furthermore, we have calculated  $B_q^k$  using  $\beta^-$  and  $\beta^+$ , which define the charge factor positions around the middle distance of Eu–F.<sup>42</sup> The minus signal means that g is closer to the  $\text{Eu}^{3+}$  ion, and the plus signal means that g is closer to the ligands. This parameter is a way (according to the SOM) to include covalence effects on the chemical bond because the charge is localized in a middle distance ( $R/2\beta$ ) instead of being located at the position of the ligand, as proposed by the PCEM. In this case, the use of  $\beta^+$  leads to a lower contribution from  $B_q^k$  that does not belong to ideal  $S_6$  symmetry. In addition, the phenomenological charge factors, adjusted to reproduce the  $^7\text{F}_1$  state energy sublevels, are higher.

We also use the model proposed by Lima *et al.*<sup>70</sup> to calculate charge transferred to the Eu–F chemical bond. This model is valid for high symmetry systems, in which only one charge factor is needed to describe the system. With ideal  $S_6$  point symmetry, the model would be well applied, but for the sake of comparison, we have calculated one of the charges through this model using the following expression:

$$g = \Delta\chi(D)/R_{\text{Eu-F}} \quad (8)$$

where  $\Delta\chi(D)$  is the Pauling electronegativity difference in Debye units ( $D = 3.33 \times 10^{-30}$  C m), and  $R_{\text{Eu-F}}$  is the distance between the positive and negative charge centres.  $R_{\text{Eu-F}}$  can be obtained by the difference between the atomic and crystalline radii from the cations and anions (refer to ref. 71 for more information). By using benchmark values available in the publication by Shannon,<sup>63</sup> we find  $R_{\text{Eu-F}} = 0.982$  Å. Thus, we obtain  $g = 0.594$  using  $\Delta\chi(D) = 2.8$ . This value is closer to  $g_1$  adjusted with  $\beta^+$  (see Table 9).

The  $B_0^2$  sign defines the position of the  $^7\text{F}_1$  state ground sublevel from the barycentre. We see in Table 8 that it is

correctly predicted using  $\beta^-$  and  $\beta^+$  because  $B_0^2$  is negative, and the  $^7\text{F}_1$  state ground sublevel is non-degenerate. We will discuss this point in more detail in the next section.

**3.4.3  $^7\text{F}_1$  state energy sublevels of the  $\text{Eu}^{3+}$  ion.** Table 10 shows the experimental<sup>22</sup> and predicted  $^7\text{F}_1$  state energy sublevels and splittings. The energy sublevels are measured with respect to the barycentre of the  $^7\text{F}_1$  level. We use a set of phenomenological charge factors in the calculations of  $B_q^k$  to reproduce the energy sublevels and, consequently, the splitting. Our predictions were carried out using  $\beta^-$  and  $\beta^+$  for comparison.

The photoluminescence emission spectra of  $\text{NaMgF}_3$  nanoparticles containing Eu, excited at 396 nm, for 1% Eu show  $^5\text{D}_0 \rightarrow ^7\text{F}_j$  transitions from  $\text{Eu}^{3+}$ . The emission spectrum reported by Gaedtke and William<sup>22</sup> at room temperature presents one peak corresponding to the  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  transition, two peaks from  $^5\text{D}_0 \rightarrow ^7\text{F}_1$ , two peaks from  $^5\text{D}_0 \rightarrow ^7\text{F}_2$ , and four peaks from  $^5\text{D}_0 \rightarrow ^7\text{F}_4$ .  $^5\text{D}_0 \rightarrow ^7\text{F}_1$  is a magnetic dipole transition, which is not influenced by the crystalline environment. The number of lines and intensities in relation to the  $^5\text{D}_0 \rightarrow ^7\text{F}_2$  transition indicates if the system is lower or higher in symmetry. The other transitions are electric dipole moment transitions which are strongly influenced by the crystalline environment.

The second peak of the  $^5\text{D}_0 \rightarrow ^7\text{F}_1$  transition is doubly degenerate, and the  $^7\text{F}_1$  splitting is less than  $100 \text{ cm}^{-1}$ . The emission spectrum reported by Gaedtke and William<sup>22</sup> shows that the  $^5\text{D}_0 \rightarrow ^7\text{F}_1$  transition is approximately 50% more intense than the  $^5\text{D}_0 \rightarrow ^7\text{F}_2$  transition. This suggests that the  $\text{Eu}^{3+}$  ion occupies point symmetry with a distorted inversion centre, although the emission spectrum shows peaks corresponding to the  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  and  $^5\text{D}_0 \rightarrow ^7\text{F}_2$  transitions.

Schuyt and William,<sup>24</sup> based on the Tanner diagram,<sup>72</sup> suggested that the  $\text{Eu}^{3+}$  occupies sites with  $C_s$ ,  $C_{nv}$  or  $C_n$  symmetry because the  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  transition is presented in the emission spectrum.  $C_s$  is part of low symmetry groups, which is not the case here because the  $^7\text{F}_1$  splitting is less than  $350 \text{ cm}^{-1}$  (ref. 73). Analysing the number of lines for each transition in the emission spectrum and comparing it with the Tanner diagram<sup>72</sup> indicates  $C_{3v}$  or  $C_{4v}$  symmetry. Previous work carried out with  $\text{Eu}^{3+}$ -doped  $\text{KMgF}_3$  suggested the same symmetry.<sup>28–30</sup> However,  $C_{3v}$ ,  $C_{4v}$ , and  $C_n$  are symmetry groups without inversion centres. The crystal field parameters related to the odd part of the crystal field potential is different from zero for this symmetry set ( $C_{3v}$ ,  $C_{4v}$ , and  $C_n$ ). In this case, the  $^5\text{D}_0 \rightarrow ^7\text{F}_2$  transition, allowed by electric dipole and strongly influenced by the environment, would be more intense than the transition  $^5\text{D}_0 \rightarrow ^7\text{F}_1$ . This is not observed in the  $\text{NaMgF}_3:\text{Eu}$  emission spectrum. Thus, the most probable symmetry is distorted  $S_6$  point symmetry. Due to distortion in the luminescent site, other transitions, beyond  $^5\text{D}_0 \rightarrow ^7\text{F}_1$ , are apparent in the emission spectrum beyond transition.

$E_{-1}$  and  $E_{+1}$  are slightly different because  $B_2^2$  is nonzero. The distortion in  $S_6$  point symmetry leads to a small contribution of this parameter in relation to  $B_0^2$ . This behaviour is not observed in the emission spectrum obtained experimentally. However, Seo *et al.*<sup>28</sup> showed a slight splitting of the second line around 0.7 nm in  $\text{KMgF}_3:\text{Eu}$  using site-selective laser-excitation

**Table 10** Experimental<sup>22</sup> and predicted  $^7\text{F}_1$  state energy sublevels and  $\Delta E$ . The experimental energy sublevels with respect to the  $^7\text{F}_0$  level are shown in parentheses. The other values are measured in relation to the barycentre

$E (\text{cm}^{-1})$	$E_{\text{exp}}$	$E(\beta^-)$	$E(\beta^+)$
$E_0$	–65.344 (315.689)	–58.674	–58.660
$E_{-1}$	32.672 (413.705)	19.230	19.357
$E_{+1}$	32.672 (413.705)	39.444	39.303
$\Delta E$	98.016	98.118	97.963

spectroscopy. This agrees very well with our predictions because  $E_{-1}$  and  $E_{+1}$  are separated by approximately  $20\text{ cm}^{-1}$ . In fact, the spectrometer used has a lower resolution, and a splitting of  $0.7\text{ nm}$  cannot be identified in the emission spectrum.

Another point that deserves to be highlighted is the substitutional defect and charge compensation created by inserting  $\text{Eu}^{3+}$  into the host matrix. Reports for materials from the same family ( $\text{Eu}^{3+}$ -doped  $\text{KMgF}_3$ <sup>28–30</sup> and  $\text{RbMgF}_3$ <sup>31</sup>) have diverged in relation to substitutional defects and charge compensation. The reports for  $\text{Eu}$ -doped  $\text{KMgF}_3$  have suggested a Na substitutional defect,<sup>28–30</sup> while one report for  $\text{Eu}$ -doped  $\text{RbMgF}_3$  suggested an Mg substitutional defect.<sup>31</sup>

Our results for the  $\text{Eu}^{3+}$  ion in  $\text{NaMgF}_3$  show a Mg substitutional defect compensated by a Na vacancy in the calculations with defect clustering (see Fig. 2, scheme VII). The energy difference of the most favourable mechanism for  $\text{Eu}^{3+}$  incorporation in Na and Mg sites is around  $0.5\text{ eV}$ . Reaction (IV) in the Na site is less favourable; the local geometry of the optically active ion has a lower symmetry (with eight NNs) and higher distortion compared with the most favourable reaction. We tested this geometry in crystal field parameter calculations, but the predictions do not reproduce the emission spectrum characteristics through a set of positive charge factors. Moreover, values of  $B_q^k$  do not lead to any conclusion about the local symmetry of the  $\text{Eu}^{3+}$  ion (doped in the Na site). Thus, our conclusions are based on atomistic simulation, group theory, crystal field calculations, and emission spectrum characteristics of  $\text{NaMgF}_3\text{:Eu}$ . These results lead us to strongly believe that the  $\text{Eu}^{3+}$  ion is incorporated in the Mg site.

### 3.5 Photoionization cross-section and OSL decay pattern of $\text{NaMgF}_3\text{:Eu}^{2+}$

Polycrystalline  $\text{NaMgF}_3\text{:Eu}^{2+}$  has been shown to be a suitable material for application in personal dosimetry. The material has high sensitivity and is able to monitor small doses, having a linear dose-response behaviour between  $\mu\text{Gy}$  dose levels up to approximately  $100\text{ Gy}$ .<sup>18</sup> However, this behaviour and the mechanism of electron de-trapping are not completely explained in the literature.

In this section, we discuss this point based on the photoionization cross-section ( $\sigma$ ) of the trap level and associated it with the substitutional defect to understand the origin of the OSL signal from  $\text{NaMgF}_3\text{:Eu}^{2+}$ . We employed the model developed by Lima-Batista-Couto<sup>57</sup> to predict  $\sigma$ , and ref. 57 can be consulted for more details on the method.

Fig. 6 shows the photoionization cross-section as a function of the electromagnetic radiation energy for  $\text{NaMgF}_3\text{:Eu}^{2+}$ . The curve has a broad excitation interval that leads to electron de-trapping processes of localized traps in the band gap. OSL emission reported by Dotzler *et al.*,<sup>18</sup> excited at  $450\text{ nm}$ , shows a broad interval of the emission spectra from samples pre-irradiated with X-rays. This agrees with our predictions. We also observe that the maximum peak occurs for light stimulus at approximately  $2.2\text{ eV}$ , which corresponds to the maximum probability of electrons to be de-trapped from this localized trap.

We calculate the magnitude of  $\sigma$  to the specific wavelength,  $\lambda = 470\text{ nm}$ , which was the same wavelength used in the most

Fig. 6 Photoionization cross-section versus electromagnetic radiation energy for  $\text{NaMgF}_3\text{:Eu}^{2+}$ . Inset shows experimental data from ref. 77 and theoretical OSL decay patterns for  $\text{NaMgF}_3\text{:Eu}^{2+}$ . The experimental decay curve was obtained after irradiation with an X-ray dose of  $219\text{ mGy}$ .<sup>77</sup>

OSL measurements. The phonon frequency used here is  $325\text{ cm}^{-1}$ , obtained from ref. 74  $\text{CaF}_2\text{:Yb}^{2+}$ . The electron effective mass used is  $0.74m_e$ , reported for fluoroperovskites in ref. 75. The activation energy used is  $1.2\text{ eV}$ .<sup>72</sup> By using these values in eqn (6), we obtain  $\sigma = 0.244 \times 10^{-20}\text{ m}^2$  for the  $\text{NaMgF}_3\text{:Eu}^{2+}$  compound. This value is close to that obtained by Daniel *et al.*<sup>76</sup> for  $\text{NaMgF}_3\text{:Eu}^{2+}$ ,  $\text{Ce}^{3+}$  using the fitting method of the linearly modulated (LM)-OSL experimental curve. There, the fitting curve was carried out with four components, and one value of  $\sigma$  was obtained for each component. The dominant term presents a magnitude of  $0.112 \times 10^{-20}\text{ m}^2$ .

Using the value of  $\sigma$  calculated here, we estimate the OSL decay pattern of  $\text{NaMgF}_3\text{:Eu}^{3+}$  based on the first-order kinetic approximation (no re-trapping), which assumes the OSL signal decay with stimulation time is due to de-trapping of captured electrons and subsequent radiative recombination. Fig. 6 (inset) shows the experimental and theoretical OSL decay patterns. The experimental OSL decay curve was obtained after irradiation with an X-ray dose of  $219\text{ mGy}$ .<sup>77</sup> The decay time is slower than that exhibited in the commercial material,  $\text{Al}_2\text{O}_3\text{:C}$ .<sup>58</sup> We note that the theoretical curve deviates slightly from the experimental curve because the model used here is the first-order kinetic model.

The rate at which electrons captured in the trap are optically excited to the conduction band is proportional to  $\sigma$ , and the OSL decay pattern is governed by  $\sigma$ . Our predictions show that  $\sigma$  of  $\text{NaMgF}_3$  is on the same order of magnitude ( $10^{-20}\text{ m}^2$ ) as the calculated value for  $\text{Al}_2\text{O}_3\text{:C}$ .<sup>58</sup> This explains the high sensibility when stimulated with blue light.

## 4 Conclusion

In summary, we combined classical atomistic simulation and crystal field models to describe the origin of defects and their

influence on luminescent properties of Eu-doped NaMgF<sub>3</sub> in the orthorhombic phase. We proposed a new set of interatomic potentials that reproduce the main properties of the orthorhombic phase. Defect calculations based on these interatomic potentials provide information regarding the energetic balance of dopant incorporation in this fluoroperovskite compound. In addition, using crystal field calculations, we explored, in detail, the type of defect and spectroscopic properties of the optically active ion. The main findings of this work are summarized below.

– The new set of interatomic potentials reproduced structural and elastic properties in the orthorhombic phase and precursor fluorides. In addition, the interatomic potential is transferable to the cubic phase, consistent with the literature.

– Defect calculations show that incorporation of Eu<sup>3+</sup> ions into the Mg site, compensated by the Na vacancy, is the most energetically favourable. Further, the Eu<sup>2+</sup> ion prefers to incorporate into the Na site, compensated by a Na vacancy or anti-site, in the host matrix. In addition, the solution energy with Eu<sup>2+</sup> is lower than with Eu<sup>3+</sup>.

– We predict the local symmetry and <sup>7</sup>F<sub>1</sub> energy sub-levels of the Eu<sup>3+</sup> ion by using the simple overlap model and the local geometry obtained in defect calculations.

– The weak intensity of the <sup>5</sup>D<sub>0</sub>–<sup>7</sup>F<sub>2</sub> transition, as well as the small splitting of the second peak of the <sup>5</sup>D<sub>0</sub>–<sup>7</sup>F<sub>1</sub> transition (observed in emission spectrum as doubly degenerate), occurs due to the distortion in S<sub>6</sub> local symmetry occupied by Eu<sup>3+</sup> ions.

– Our predictions of the photoionization cross-section and OSL decay pattern show that NaMgF<sub>3</sub>:Eu<sup>2+</sup> presents a high sensibility for stimulus over a large range of wavelengths.

The new insights presented in this work show the importance of defect calculations, combined with crystal field and photoionization cross-section models, to successfully describe the luminescent properties of lanthanide-doped compounds.
