Jitendra Mata^c and Naved Malek^{‡*a}

Designing stimuli-responsive therapeutic scaffolds to deliver hydrophobic chemo drugs with controlled and sustained release at the tumor site would be promising in cancer treatment. In a quest for the stimuli-responsive drug delivery system with sustained release, herein we have fabricated an active pharmaceutical ingredient-based ionic liquid (IL) based hydrogel with self-healable and injectable properties. The ionic hydrogel makes a localized, long-term co-delivery system with self-healable, injectable, and stimuli-responsive properties. Further, the smart hybrid ionic hydrogel was constructed through encapsulating doxorubicin (DOX) within the 3D matrix of the ionic hydrogel, which response to intracellular biological stimuli (e.g., pH and temperature) and releases DOX in 57 h. Experimental results of IL–IL and IL–DOX interactions are supported through Density Functional Theory (DFT) calculations. *In vitro* cellular studies revealed that the DOX-loaded hybrid ionic hydrogel shows a synergistic anticancer effect against MCF-07 cells. These results demonstrate the ability of the ionic hydrogel as a promising candidate for local cancer therapeutics.

Introduction

Breast cancer, the most frequent cancer among women and impacting 2.1 million women every year, causes significant cancer-related deaths.¹ The conventional treatment methods including surgery, radiotherapy, immunotherapy, and chemotherapy suffer side effects because of drug reactions, low therapeutic index, drug tolerance, and poor cancerous cell targeting.² To circumvent these limitations, novel drug administration strategies including nano-drug carrier-based treatment such as liposomes, polymeric nanoparticles, surfactants and polymeric micelles, vesicles, dendrimers, hydrogels and recently discovered ionogels have been proposed. But they

register slow drug release and irreversible deformation and therefore are not suitable for sustained and local administration.³ Hydrogels, despite significant progress, could be promising if they come with excellent biocompatibility, high mechanical properties, negligible cytotoxicity, high swelling properties, prominent drug-encapsulating capability and stimuli responsiveness.^{4–11} Ionic liquid (IL) based hydrogels, also known as ionic hydrogels, are the best alternatives because of their inherent properties that can be easily fine-tuned by judiciously selecting the constituting cations/anions of ILs.^{12–15}

Polymeric hydrogels having 1-methyl-3-hexadecylimidazolium bromide as an additive with stimuli-responsive, self-healable, adhesive, and injectable properties are recently reported. When bromide was replaced by salicylate through metathesis with the sodium salicylate (NaSal), SAIL formed an ionic hydrogel at 4.45% w/v in an aqueous medium.⁹ We had selected a gelator concentration of 6.00% (w/v) and solution pH of 7.4 for all the studies. NaSal is a non-steroidal anti-inflammatory drug that can also activate mitogen-activated protein kinase that induces apoptosis in cancer cells.^{16,17} Zhao *et al.* reported salicylate-based hydrogels with integrated anti-fouling and antimicrobial capacities against Gram-negative *Escherichia coli* RP437 and Gram-positive *Staphylococcus epidermidis*.¹⁸ Kaule *et al.* used salicylate-based coatings in the drug-coated balloon catheter as it shows high paclitaxel

‡ M. K. and D. K. P. share equal contribution

encapsulation efficiency with a smooth surface and good aqueous solubility compared to the hyaluronic acid (body-own hydrogel), and polyvinylpyrrolidone.^{19,20} Lin and co-workers reported thermo-responsive phase transition from a viscoelastic wormlike micelle solution to an elastic hydrogel in a mixture of 1-hexadecyl-3-methylimidazolium bromide, and NaSal.²⁴ Zheng's group reported the fabrication of a 3D hydrogel from *N*-methyl-*N*-cetylpyrrolidinium bromide using NaSal as an external additive.²¹ Zhao *et al.* studied wormlike micelle formation by *N*-hexadecyl-*N*-methyl piperidinium bromide with the aid of NaSal.²² Raskova presented the effect exerted by the presence of NaSal in Carbomer-based hydrogel systems, which shows antimicrobial properties against Gram-positive and Gram-negative bacterial strains, yeasts and moulds.²³

Combining different ionic functionalization to the judiciously composed structural architecture of the IL can specifically exploit the advantages of both, IL and solid polymer structures, enhancing the mechanical stability and improving the processability and durability of the hydrogels.¹² Bearing in mind all above-described considerations and in the framework of our interest in obtaining supramolecular gels from ILs, herein we synthesized an active pharmaceutical ingredient based IL, *i.e.* 1-methyl-3-hexadecylimidazolium salicylate (C_{16} MeImSal) as the LMWG. The C_{16} MeImSal forms an ionic hydrogel that exhibited gel to sol transformation as a function of temperature. The ionic hydrogel was studied for the encapsulation and sustained release of the chemotherapeutic drug doxorubicin (DOX) and studied for its biological evaluation in breast cancer cell lines.²⁵ The clinical application of DOX is restricted owing to its dose-dependent non-site-specific toxicity, such as cardio-toxicity and prevalence of off target effects is circumvented through hydrogel based new age drug delivery systems. Further, we used quantum chemical calculations through DFT to support our experimental results and to (i) obtain a greater insight into the intermolecular interactions in the hydrogel matrix, (ii) study the arrangements and interactions in the ionic hydrogel matrix and (iii) understand the DOX-IL interactions. Structures of the C_{16} MeImSal and DOX are drawn in Scheme 1.

Scheme 1 Chemical structures of 1-methyl-3-hexadecylimidazolium salicylate (C_{16} MeImSal) and doxorubicin hydrochloride (DOX).

Materials and methods

Materials

1-Methylimidazole ($\geq 99.0\%$), 1-bromohexadecane (97.0%) and doxorubicin hydrochloride (98.0–100.0%) were procured from Sigma Aldrich. The MCF-07 cell line was obtained from NCCS, Pune, India. All solutions were prepared using Milli-Q water (Millipore) with an electrical resistivity of $18.2 \text{ M}\Omega \text{ cm}^{-1}$ at 25°C . For SAXS and NMR, samples were prepared in D_2O . C_{16} MeImSal was synthesized and characterized as per a reported procedure that can be found in the ESI[†] (Scheme S1).⁹

Fourier transform infrared spectroscopy (FTIR)

The FTIR spectra of solid C_{16} MeImSal and ionic hydrogel were recorded using a Shimadzu FTIR-8400S spectrophotometer.

Morphology

Morphology of the ionic hydrogel was studied through Scanning Electron Microscopy (SEM). For the detailed experimental description, see ref. 18.

Small-angle X-ray scattering (SAXS)

The SAXS measurements were performed on a Bruker Nano-STAR II SAXS instrument at ACNS, ANSTO. 1.541 \AA wavelength was used from a rotating anode Cu $K\alpha$ radiation source. Data were collected at a fixed detector distance, giving a q range of $0.012\text{--}0.390 \text{ \AA}^{-1}$. Sealed quartz cells were used with a sample path length of 2 mm under vacuum. SAXS data were reduced at the instrument using Bruker software and then were analyzed using SasView software. SAXS data were analyzed using a cylinder model with the structure factor. The slope at low q gives information about the possible structure that can be described through the form factor of a cylinder with a radius R and a length L as discussed for the transparent ionogel.^{26–28}

The output of the scattering intensity function for randomly oriented cylinders is given by eqn (1) and (2): where the form factor $P(q)$

$$P(q) = N \int_0^{\pi/2} F^2(q) \sin(\gamma) d\gamma \quad (1)$$

with

$$F(Q) = 2(\Delta\rho)V \frac{\sin\left(\frac{1}{2}qL \cos \gamma\right)}{\frac{1}{2}qL \cos \gamma} \frac{J_1(qR \sin \gamma)}{qR \sin \gamma} \quad (2)$$

where J_1 is the first-order Bessel function and γ is the angle between the axis of the cylinder and the q vector, $V = \pi R^2 L$ is the volume of the cylinder and $\Delta\rho$ (contrast) is the scattering length density difference between the scatterer and the solvent. The structure factor $S(q)$ was determined through SASView.

Rheology

A rheology test was carried out on a Physica MCR 301 (Anton Paar) rheometer at 25°C with a 40 mm-diameter parallel plate attached to a transducer. The gap was set to 1 mm. The ionic

hydrogel was placed between the parallel plate and the platform with special care to avoid evaporation of the solvent. Angular frequency sweep measurements were performed at 1–100 rad s^{−1} under a constant strain of 1%. These measurements were carried out within the viscoelastic region where G' and G'' are storage and loss modulus and are independent of strain amplitude. Strain scans were performed from 0.1 to 10% with a constant frequency of 1 rad s^{−1}. The critical strain was quoted as the point that G' starts to deviate for linearity and ultimately crosses over G'' , resulting in gel breakdown. Thixotropic properties or step strain sweep measurements were carried out to investigate the self-recovery properties of the hydrogels in response to applied shear forces. The strain was changed from 1% to 20% at the constant frequency value (1.0 Hz).

Swelling behavior

Ionic hydrogels with confirmed weights (W_a) were immersed in phosphate buffer solution (PBS) at pH 7.4 and pH 5.0 (37 °C).

$$DL (\%) = \frac{\text{Initial drug concentration} - \text{Drug concentration after loading}}{\text{Initial drug concentration}} \times 100 \quad (4)$$

$$EL (\%) = \frac{\text{Loading efficiency} - \text{initial drug concentration} (\mu\text{g mL}^{-1})}{\text{Initial hydrogel concentration} (\mu\text{g mL}^{-1})} \times 100 \quad (5)$$

This procedure was repeated until no further weight increment occurred (W_b). At a pre-determined time, the ionic hydrogel was taken out and weighed. The weight of the swollen gel (W_x) was determined after removing the surface water gently with tissue paper. The swelling ratio (SR) of the hydrogel was calculated from the equation

$$SR = \frac{W_a - W_b}{W_b} \quad (3)$$

where W_a is the weight of water molecules in the swollen 3D ionic hydrogel network under certain conditions and W_b is the weight of the dry ionic hydrogel.

Gel-to-sol transition

Phase transition was confirmed through (i) turbidity measurements and (ii) tube inversion method. A phase transition was confirmed through two different procedures.

(i) The ionic hydrogel to ionic solution transition of hydrogels (pH = 5.0) was studied upon increasing the temperature from 25 to 60 °C on a Cary 50 UV-Vis spectrometer with a Peltier-controlled variable temperature cell holder.

(ii) The tube-inverting experiment was used to measure the ionic hydrogel to ionic solution transition. Briefly, 1 mL ionic hydrogel was injected into 15 mL glass vials and equilibrated at 15 °C for 6 h. Next, the glass vial containing the ionic hydrogel was immersed in a water bath at a given temperature for 5 min and then inverted 180°. If no visible flow was observed within 60 s, the sample was considered as a gel. The observation was conducted from 25 to 60 °C with an increment of 1 °C each step.

Dynamic light scattering (DLS) and zeta potential measurement

DLS and zeta potential measurements were carried out in a Zetasizer Nano ZS (Malvern, UK) by varying the pH and temperature of the ionic hydrogel.

Drug loading and encapsulation studies

The ionic hydrogel was loaded with DOX using a modified breathing-in mechanism and put on a shaker for 3 h. After loading, the solution was centrifuged at 10 000 rpm for 10 to 15 min. The supernatant obtained was diluted and the concentration of the drug in the supernatant was measured using a UV-Vis spectrometer at 480–485 nm. Drug loading ratio and encapsulation efficiency of DOX in the ionic hydrogel were 15.12% and 93.20%, respectively. Drug loading (DL) and encapsulation efficiencies (EE) were calculated using the following equation:

In vitro drug release study

To measure the effect of temperature and pH changes on DOX release, the drug-loaded ionic hydrogel was immersed in 37 °C; pH = 5.0, 37 °C; pH = 7.4, 25 °C; pH = 5.0, and 25 °C; pH = 7.4 PBS at 150 rpm. At pre-determined time intervals, the drug release media were removed and substituted with fresh PBS. The amount of DOX concentration in the PBS release medium was measured with a UV-Vis spectrophotometer at 480–485 nm.

The release profiles of DOX were further analyzed based on mathematical drug release kinetics models. (i) Zero-order equation, (ii) first-order eqn and (iii) Higuchi release using the following plots: M_t vs. t , $\log(M_0 - M_t)$ vs. t and M_t vs. square root of t , respectively.

Confocal laser scanning microscopy detection

The MCF-7 cells were seeded in confocal microscope (Leica Microsystems) dishes at 2×10^4 cells per well and cultured overnight. Then, the MCF-7 cells were exposed to bare DOX (1 $\mu\text{g mL}^{-1}$) and DOX loaded ionic hydrogel for 4 h, respectively. After the residual particles were removed, the cells were fixed with paraformaldehyde (4%), and the cell nuclei were stained with 10 mM 4,6-diamidino-2-phenylindole. Last, A Leica Microsystems confocal laser scanning microscope (Leica, Heidelberg, Germany) was utilized to capture the fluorescence images of the DOX (1 $\mu\text{g mL}^{-1}$) loaded ionic hydrogel.

Cellular uptake

To determine the cellular uptake of DOX and DOX loaded ionic hydrogel with MCF-7, cells were seeded in 6-well plates at 2×10^5 cells per well and cultured overnight. Then, the MCF-7 cells were treated with bare DOX and DOX (1 $\mu\text{g mL}^{-1}$) loaded ionic

hydrogel at the same DOX dose of $0.5 \mu\text{g mL}^{-1}$. After 12 h, cells were collected using centrifugation at 1000 rpm. Finally, the cells were suspended in 500 μL PBS, and the cellular uptake of DOX was measured with an FACS Calibur flow cytometer (BD Biosciences, USA).

In vitro cytotoxicity

The cell viability by a neat ionic hydrogel, DOX, and DOX loaded ionic hydrogel was assessed using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay on human breast cancer (MCF-7 cell lines). The cells were seeded at a density of 10^4 cells per well in 96-well plates and cultured overnight. Subsequently, the cells were exposed to serial concentrations of DOX and DOX loaded hydrogel in culture medium, respectively. As controls, cells were incubated in a 5% CO_2 incubator at 37°C . After cultivation for 24 h, the medium was removed, and the cells were washed carefully with PBS and incubated with fresh medium containing 5 mg mL^{-1} MTT for another 4 h. Medium was removed again, and DMSO (200 μL per well) was added. The plates were incubated at 37°C for 10 min, and then the absorbance was recorded at 540 nm. The IC_{50} values were calculated with GraphPad Prism Version 7.0 software (GraphPad Software, USA).

Computational methodology

The global minima on the potential energy surface of the $\text{C}_{16}\text{MeIm}^+$ cation, Sal^- anion, doxorubicin (DOX) molecule, $\text{C}_{16}\text{MeImSal}$ ionic liquid (IL), dimers of the IL and complex of the IL with DOX (IL-DOX) were computed by density functional theory (DFT) with the *Gaussian 16* suite of software.²⁹ A hybrid B3LYP functional with a 6-31G** basis set in *Gaussian 16* was utilized for the geometry relaxation.^{29,30} This 6-31G** basis set with the B3LYP functional is an ideal level of theory to investigate the interaction mechanism in medium to large molecular systems and has previously also produced reliable and accurate results for a variety of molecular systems at minimum costs.^{31–35} The frequency estimation at the same level of theory was performed with the aim to find out the true ground state geometries of studied systems (at 298.15 K and 1 atm)³⁶ and the optimized structures have been verified as a true minimum with no imaginary frequency. Dimers of the IL were used as a model of the ionic hydrogel. To investigate the nature and type of interactions in the hydrogel, the polarizable-continuum model with integral equation formalism (IEFPCM) was employed with water as a solvent as its dielectric constant (ϵ) is 78.35.³⁷ To investigate the contribution of weak interactions in these systems, Multiwfn 3.7 software was utilized to analyze the reduced density gradient (RDG) of IL and IL-DOX systems.³⁸ The geometry of optimized structures and molecular electrostatic potential (MESP) maps were visualized using the GaussView 6 program³⁹ and Multiwfn³⁸ with Visual Molecular Dynamics (VMD)⁴⁰ 1.9.3 software was used for the RDG surface visualization.

Eqn (7) and (8) were used for the calculation of binding energies (BEs) of the IL and IL-DOX complex (ΔE):

$$\Delta E_{\text{IL}} = E_{\text{IL}} - (E_{\text{cation}} + E_{\text{anion}}) \quad (6)$$

$$\Delta E_{\text{IL-DOX}} = E_{\text{IL-DOX}} - (E_{\text{IL}} + E_{\text{DOX}}) \quad (7)$$

where E_{cation} , E_{anion} , E_{DOX} , E_{IL} , and $E_{\text{IL-DOX}}$ are ground state optimized energies of cation, anion, DOX, IL and IL-DOX systems, respectively. The following equation was used to obtain the solvation energy of the IL:

$$\Delta E_{\text{Solv}} = E_{\text{Sol}} - E_{\text{gas}} \quad (8)$$

where E_{Sol} and E_{gas} represent the total energies in the solution and gas phases, respectively. The values of chemical activity descriptors such as chemical hardness (η),⁴¹ chemical softness (S),⁴¹ chemical potential (μ),⁴¹ and electrophilicity index (ω)⁴² were determined from the DFT calculation-based highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energies from the following equations:

$$\eta = \frac{I - A}{2} \quad (9)$$

$$S = \frac{1}{2\eta} \quad (10)$$

$$\mu = -\frac{I + A}{2} \quad (11)$$

$$\omega = \frac{\mu^2}{2\eta} \quad (12)$$

where $I \approx -E_{\text{HOMO}}$ and $A \approx -E_{\text{LUMO}}$.

Results and discussion

Molecular interactions within the ionic hydrogel

Molecular interactions involved in the formation of the ionic hydrogel were studied through performing FTIR of the solid $\text{C}_{16}\text{MeImSal}$ and ionic hydrogel (Fig. S1, ESI†). The frequency value of the $\text{C}=\text{O}$ group at 1652 cm^{-1} for the powder sample is shifted to 1639 cm^{-1} for the ionic hydrogel because of hydration. The $\text{C}-\text{N}$ and $\text{C}=\text{O}$ stretching vibrations, located at 1586 cm^{-1} and 1187 cm^{-1} in powder $\text{C}_{16}\text{MeImSal}$, are shifted to 1575 and 1174 cm^{-1} for the ionic hydrogel, respectively. These results suggest the electrostatic and hydrogen bonding interaction playing a dominant role in the formation of the ionic hydrogel.^{14,17,43}

Further, we initiated quantum chemical calculations based on DFT to obtain a greater insight into the intermolecular interaction in the hydrogel matrix and contribution of weak non-covalent interactions in the drug-hydrogel complex. DFT-based quantum chemical calculations are employed in different fields of science to illustrate the electronic structures of various chemical species and have become an excellent method for addressing fascinating chemical challenges and mechanisms of reactions. Here, before investigating the interaction in the ionic hydrogel and drug-hydrogel complex, we first computed the ground state geometries of the isolated cation, anion and DOX.

Fig. 1 The atomic numbering scheme for the DFT calculated and optimized structures of (A) the $C_{16}MeIm^+$ cation, (B) Sal anion and (C) DOX molecule.

The optimized structures are shown in Fig. 1 including the atomic numbering scheme. The Sal^- anion is positioned at the C_2 position of the $C_{16}MeIm^+$ cation to obtain the minima on the potential energy landscape of $C_{16}MeImSal$, as it is well established that the C_2-H_9 position is the most acidic and important site for interaction with different anions and molecular systems in imidazolium cations.^{44–50,54,55} In order to investigate the strength of ion-pair interaction, the BE for $C_{16}MeImSal$ was calculated. The calculated optimized energies of cations, anions, DOX, ILs (both in gas and solvent phases), the dimers of ILs and IL-Drug complex with BEs are listed in Table 1.

The BE for the IL ($-122.16 \text{ kcal mol}^{-1}$) demonstrates that $C_{16}MeImSal$ is energetically stable at the ground state.^{47,50} The optimized geometry of the IL demonstrates that the anion interacts with the cation through $C-H \cdots O$ type hydrogen bonds (Fig. S2A, ESI†). There are four hydrogen bonds between the cation and anion and one intramolecular hydrogen bond in the salicylate anion. Here, one can clearly distinguish the difference in the structure of the anion in both isolated form and ion-pairs (Fig. 1B and Fig. S2A, ESI†). A well-established criterion suggested by Arunan *et al.* for the determination of the strength

of hydrogen bonding in ILs was adopted here.⁵¹ It is difficult, however, to classify the strength of a hydrogen bond; in the following, we consider an interaction to be strong if $r < 2.3 \text{ \AA}$ and weak for $2.3 \text{ \AA} < r < 2.6 \text{ \AA}$. Such parameters have been chosen based on the $H \cdots O$ distances being shorter than the sum of the respective van der Waals radii. Based on this, the intramolecular hydrogen bond in the Sal^- anion $O_{64}-H_{65} \cdots O_{62}$ is found to be strong with a bond length of 1.59 \AA . Similarly, the $C_2-H_9 \cdots O_{62}$ hydrogen bond between the cation and anion is found to be stronger in comparison to other hydrogen bonds between the cation and anion. Here, the Sal anion is also able to interact with both the methyl ($-CH_3$) and alkyl $-CH_2$ group of the alkyl chain of the $C_{16}MeIm^+$ cation by $C-H \cdots O$ type of weak interaction, FTIR spectra *vide supra* (Fig. S2A, ESI†). This case is considered to be comparable to that of experimental evidence available *via* the ^{19}F NMR chemical shifts for alkyl chain interaction in BF_4 based-ILs.⁵²

To investigate various intra and intermolecular interactions involved in the ionic hydrogel formation of the $C_{16}MeImSal$ in aqueous media, we have studied the effect of solvation on the structure, energetics and reactivity of $C_{16}MeImSal$ in comparison to the gas phase. By simulating the surrounding of the $C_{16}MeImSal$ as a dielectric continuum with $\epsilon = 78.35$, using the IEFPCM model, the effect of an aqueous medium was analyzed. The solvation energy of the studied IL was $-18.09 \text{ kcal mol}^{-1}$, indicating that solvation of the IL is a spontaneous process and suggesting that water increases the stability of the studied IL which is also clear from the more negative optimized energy of the IL in the solvent phase (Table 1). From Fig. S2B (ESI†), it is clear that the Sal^- anion slightly shifted towards the methyl group of the $C_{16}MeIm^+$ cation in the solvent phase. In the Sal anion, the intramolecular hydrogen bond becomes stronger and the calculated bond length is 1.53 \AA ; similarly, the $C_6-H_{12} \cdots O_{63}$ bond becomes stronger and the calculated bond length is found to be 1.90 \AA . The vibrational spectra that can be used to assist the interpretation of experimental FTIR data have also been calculated here. The frequency values of the $-C=O$ group, which is at 1656 cm^{-1} for the gas phase, is shifted to 1646 cm^{-1} for the solvent phase *i.e.*, ionic hydrogel, likely due to the hydration of the $-C=O$ group in the gel phase. The $C-N$ and $-C-O$ stretching vibrations, which are located at 1619 cm^{-1} and 1162 cm^{-1} in the gas phase of $C_{16}MeImSal$, are shifted to 1610 and 1159 cm^{-1} for the $C_{16}MeImSal$ in the

Table 1 DFT calculated optimized and binding energies of ground-state geometries using the B3LYP/6-31G** level of theory

solvent phase, respectively (Table 2). Our DFT calculated IR spectra support the experimental findings of FTIR which predicts the dominant role of electrostatic interactions and hydrogen bonding in the formation of the three dimensional (3D) network structure of the ionic hydrogel. Here, it is very clear from the close inspection of Fig. S2A and B (ESI†) that the DFT computations also predict the presence of inter- and intra-molecular hydrogen bonding in C₁₆MeImSal, both in the gas and solvent phases.

It is interesting to explore the arrangements of the ionic hydrogel to understand the shape of the gelator. We studied the morphology of the ionic hydrogel through SEM. The SEM image (Fig. S3, ESI†) shows the formation of a 3D branched fibrous network made of tightly winded cylindrical tubules. The ionic hydrogel is expected to be formed by encapsulating the water molecules within the network of the percolated gelator and inside the branched 3D structures.⁵³

Internal structure of the ionic hydrogel

SAXS was further employed to verify the size and shape of the aggregates within the ionic hydrogel matrix. Fig. S4 (ESI†) shows the experimental SAXS data of the ionic hydrogel. SAXS data clearly indicate the characteristic q^{-1} behavior that is consistent with cylindrical shaped aggregates, SEM results *vide supra*.¹⁷ There is also a very strong structure factor peak at mid- q .¹⁵ A similar peak was reported in our earlier work with an imidazolium based ester functionalized ionic hydrogel.¹⁵ Local structures of the ionic hydrogel can be described by a cylinder of radius 2.10 nm and length 42.90 nm. The cylindrical structure of the ionic hydrogel is due to the micelle like assembly (through hydrogen bonding and electrostatic interactions) between the long cation and anion of the C₁₆MeImSal at the interiors of the micelles.

Structural optimization was performed for the C₁₆MeImSal dimer using DFT computations to gain deeper insight into the arrangements and interactions in the ionic hydrogel. Without requiring extensive computing resources, a dimer may deliver valuable insights into the early-stage of aggregation. In parallel/parallel-displaced or perpendicular or vertically tilted configurations, aromatic moieties can be aligned.^{56–58} The nitrogen atom containing imidazolium rings, however, is predicted to prefer a parallel or near-parallel configuration so that rings can enhance π - π interactions along with the hydrogen bonding. The optimum arrangement of the dimer of C₁₆MeImSal will be controlled by the interplay of interactions of mainly H-bond and π - π interactions between the imidazolium rings of the cation. Hence, in the present study, three configurations of dimers were prepared. In the first, cation rings are opposite sides of each other, in the second, both the rings are stacking in parallel and in the last, both the rings are in Y-shaped configuration.

Fig. 2 displays the ground state geometries of all the configurations of the dimers. Fig. 2B presents the most stable dimer geometry with a BE of $-22.45 \text{ kcal mol}^{-1}$ where two imidazolium rings are arranged in such a way that maximizes their π - π interactions through parallel stacking and anion- π^+

Fig. 2 Ground state geometries of dimer configurations along with their BEs. (A) Cation rings of C₁₆MeIm⁺ are opposite, (B) cations rings are stacking in parallel, and (C) cation rings are in Y-shaped configuration.

interactions in ion-pairs. The second most stable structure (Fig. 2C) in which the aromatic moieties are arranged perpendicular to each other (Y-shaped) is quite different from the structure in Fig. 2B and less stable. We predicted two lowest energy configurations of dimers, which can guide us to predict the arrangements of the ionic hydrogel to understand the formation and branching in the gel on the basis of dimer energetics. From Fig. 2B and C, one can notice that when the minimum energy structures are obtained, imidazolium rings are stacked and long alkyl chains are in parallel arrangements. Imidazolium rings take preferential on-top parallel orientations to increase the π - π stacking that enhances the layering structure in ILs, despite the electrostatic repulsion and also hydrogen-bonding arrangements. This is the possible reason why the ionic hydrogel takes the cylindrical structure.^{59–61}

Mechanical properties of the ionic hydrogel

The gel was subjected to the strain sweep and angular frequency sweep dynamic rheological test to explore its mechanical properties. At a fixed strain of 1%, storage modulus (G') was higher than loss modulus (G'') within the whole frequency range (Fig. 3A), indicating the unstable colloidal particles that form a 3D network within the ionic hydrogel, SEM image, *vide infra*. The strain amplitude sweep of the hydrogel (Fig. 3B) demonstrated the elastic response typical of the polymeric hydrogel. Beyond the critical strain (γ_c) of 8.4%, G' decreased rapidly, and the cross-over occurred at 9.3%. Above γ_c , G' decreases through breaking of the 3D network within the ionic hydrogel. The hydrogel studied here exhibits rapid recovery of its mechanical properties after a large amplitude oscillatory breakdown, known as thixotropic properties (Fig. 3C).⁶² Under the application of a large amplitude oscillatory force ($= 20\%$; $= 1 \text{ rad s}^{-1}$), the G' decreases from 1949.23 to 525.61 Pa, resulting in a quasi-liquid state of the hydrogel ($\tan \delta = 0.46$). However, when the amplitude is decreased ($= 1\%$; $= 1 \text{ rad s}^{-1}$), G' immediately recovers its initial value and returns to the quasi-solid state ($\tan \delta = 0.49$).⁶³

According to the results of the rheological recovery property (Fig. 3C), the ionic hydrogel was converted to the solution state under higher shear strain and returned to the ionic hydrogel

Fig. 3 (A) Strain sweep dynamic rheological data for the ionic hydrogel at 25 °C ($\omega = 1 \text{ rad s}^{-1}$), (B) frequency sweep dynamic rheology data at 25 °C (strain 1%), (C) thixotropic data of the ionic hydrogel, obtained by step-strain measurements at 25 °C at a constant frequency (1 rad s^{-1}), (D) the gel can get through a 26-gauge needle smoothly without blockage, and (E) self-healing properties.

state when the stress was removed. Therefore, the ionic hydrogel could be used as an injectable gel for localized treatments. When the gel in the syringe was compressed, the pressure, which acted like a high dynamic strain, made the gel “flow” like a liquid to pass through the needle (Fig. 3D). This is due to the dissociation of hydrogen bonds. Then the extruded gel returned to the gel state once the pressure was removed. The self-healing and injectable behaviours of the gel indicate that it may be used to deliver drugs and implanted in the body with a minimally invasive strategy. In addition, after the cut, within 5–7 minutes, the damaged gel could repair itself without any

external stimulus (Fig. 3E), demonstrating the good self-healing abilities of the ionic hydrogel.⁶⁴

Swelling behavior of the ionic hydrogel

The hydrogel (Fig. 4A) shows excellent water absorbing capacity; that is, the ionic hydrogel can absorb 42 (pH = 7.4) and 70 (pH = 5.0) times more water than its initial weight and take 280 and 320 min to reach a saturated state. The interactions of network components in ionic hydrogels restrain the whole matrix and limit the swelling ratio. The morphology of the ionic hydrogel directly influences its application as a drug

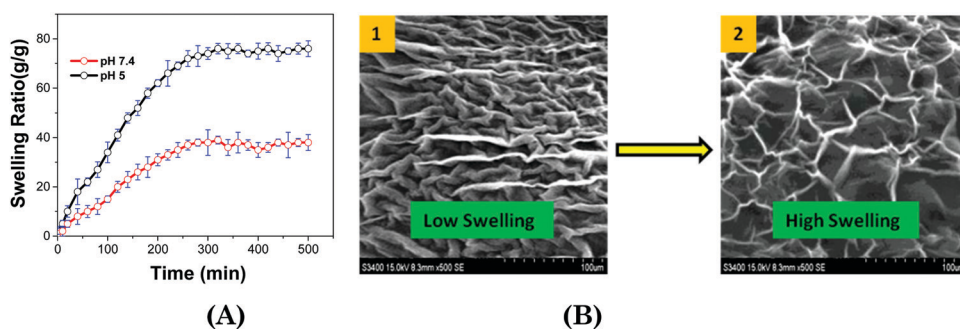

Fig. 4 (A) Swelling kinetics of the ionic hydrogel at 37 °C, and (B) SEM images of swollen ionic hydrogels at (i) pH 7.4 and (ii) pH 5.0 at 37 °C.

carrier, while the release mechanism will be affected by the mesh size.^{65,66}

Both the ionic hydrogels showed porous 3D structures in PBS with different pH values at 37 °C. The pore sizes of the ionic hydrogel in PBS with pH 5.0 are higher than at 7.4 pH (Fig. 4B). It might be due to the positive head group charge, which gets more protonated. The intermolecular electrostatic repulsion and enhanced hydrophilicity would make the ionic hydrogel swell considerably.⁶⁷

Size and zeta potential of the ionic hydrogel

To effectively use the ionic hydrogel for targeted drug delivery, it is recommended to investigate whether the ionic hydrogel is stimuli responsive. To counter this argument, we hereby studied the hydrodynamic sizes of the gelators within the hydrogel matrix through DLS under the influence of temperature and pH. The data also help us to define the conditions for the drug encapsulation and release. The ionic hydrogel was in more hydrated form and showed the maximum swelling state with the size of the aggregates in the range of 434 ± 5 nm at 25 °C (Table 3 and Fig. 5). However, as the temperature rises to 37 °C, the size of the aggregates within the hydrogel decreases to 403 ± 5 nm, which may be due to the exclusion of water molecules from the hydration shell. This eventually resulted in the collapse of the hydrogel due to volume phase transition (VPT) and resulted in a more compact gel network because of the increased hydrophobicity.^{65,68} It is worth mentioning here that PDI values decrease with temperature (0.24 at 25 °C and 0.12 at 37 °C), indicative of the phase transition (Table 3).

Table 3 Temperature and pH dependent size distribution of ionic hydrogels

Ionic hydrogel	Temperature (°C)		pH (25 °C)		pH (37 °C)	
	25	37	5	7.4	5	7.4
Size	437 ± 5	403 ± 5	530 ± 5	496 ± 5	640 ± 5	580 ± 5
PDI	0.24	0.12	0.21	0.28	0.29	0.20

Further, zeta potential data of the hydrogel with and without DOX exhibited a minor change in the surface charge from +22.5 to +21.5 mV (without DOX), −17.4 to −19.7 mV (with DOX-25 °C, pH = 5), and −11.2 to −14.3 mV (with DOX-37 °C, pH = 7.4) across the temperature range that indicates the cationic ionic hydrogel stability with temperature (Fig. 5B).⁶⁹

An inverse correlation was observed between the temperature and pH on the size of aggregates within the hydrogel. The interplay of forces responsible for swelling of the hydrogel is certainly responsible for the changes observed at higher temperature and acidic pH (Fig. 5 and Table 3). At pH 5.0, the ionic hydrogel gets protonated and attracts a higher amount of water molecules on its surface through H-bonding and increases the size of the aggregates. Higher degree of swelling at acidic pH further strengthens the claim, *vide infra* (Fig. 5). It was found that the ionic hydrogel has the desired characteristics with an optimum size in response to temperature (37 °C) and pH (5.0) as shown in Table 3, while the rest of the other formulations did not show any particular trend. These data are the basis of our drug encapsulation and release of the entrapped drug from the ionic hydrogel.

DOX-IL interaction studies through DFT calculations

After investigating the role of weak non-covalent interactions in the formation of the ionic hydrogel (IL in both gas and solvent phases and dimer), we studied the drug-hydrogel interaction through DFT calculations. It has been observed that when molecules vary considerably in their sizes, the geometric mixing concept seems insufficient, as is the scenario in the present research.^{70,71} Using DFT computations, we computed the binary interplay between the IL and DOX to resolve this constraint. Ideally, to measure this sort of interactions, one will conduct a thorough molecular dynamics (MD) simulation, but this would be an excessively time-consuming process. In addition, classical simulations are based on the empirical force fields and their accuracy and reliability can often be suspected unless the accuracy of the force field is confirmed by substantial experimental results.⁷² For this justification, we have adopted a

Fig. 5 Temperature and pH dependent size distribution of ionic hydrogels.

methodology that does not depend on empirical force fields and does not necessitate substantial computing facilities. Hence, in order to investigate such interactions in the drug-hydrogel complex, the interaction between the single unit of the IL and the drug (DOX) molecule was carried out to mimic the experimental results. The optimized structure of the IL-DOX complex is presented in Fig. S2C (ESI†). The ground-state structure of the complex reveals that the molecule of the DOX interacts with the IL by hydrogen bonds of type C-H...O, where the DOX acts as a hydrogen-bonding donor. The drug molecule interacts with the IL by two C-H...O (with cation) and one O-H...O (with anion) type hydrogen bonds *i.e.* C₆-H₁₃...O₇₈, C₅-H₁₁...O₇₇ and O₇₉-H₈₀...O₆₃ with bond distances of 2.29 Å, 2.76 Å and 1.69 Å, respectively (Fig. S2C, ESI†). We have calculated the BE for this complex in the gas phase and the value is -49.89 kcal mol⁻¹ (Table 1). The negative BE value suggests that the mechanism of complex formation is thermodynamically stable and demonstrates the stability of the IL-DOX complex. Our computed BE value for the IL-DOX complex suggests that the DOX drug will bind to the carrier of the hydrogel (IL), but this interaction is not so strong as to prevent the drug at the target site from being desorbed. For adsorption and drug delivery, the binding energy of ~30 kcal mol⁻¹ is appropriate.⁷³ Our calculated DFT results, however, only demonstrate the drug-hydrogel complex interaction mechanism and do not illustrate the temperature and pH-dependent characteristics, but are able to provide deeper insights into the mechanism of interaction. The primary purpose of our research is to better understand the mechanism of interaction, so we will address the formation of weak non-covalent interactions in these systems by examining the molecular electrostatic potentials (MESP) and reduced density gradient (RDG).

Electronic properties

To gain insight into the relationship between molecule structure and activity, MESP were computed. Due to electron density distribution, the MESP is represented as the potential encountered by a unit positive charge close to the molecular system. The MESP directs the quantitative polarity of the molecule; electrophilic attack sites can be predicted by a positive potential, while nucleophilic attack sites are indicated by a negative potential. The expression for ESP is given by the following equation at any point r in the space near the molecule:^{74,75}

$$V(r) = \sum \frac{Z_A}{|R_A - r|} - \int \frac{\rho(r')dr'}{|r' - r|} \quad (13)$$

where the charge on the nucleus A observed at R_A is Z_A and the electron density is $\rho(r)$.

$V(r)$ describes the net electrostatic effect of the molecule's total charge distribution (electrons + nuclei) at point r . Negative ESPs depict the nucleophilic sites of attack (red colour) on the molecular surface in Fig. S5 (ESI†), whereas positive ESPs show the electrophilic sites (blue colour). Green colour is used for zero-potential surfaces. The entire surface of the imidazolium ring is shown in Fig. S5A (ESI†) to be blue and light blue can be

observed over the alkyl chain, reflecting the most positive ESPs. While red colour is present near -C=O and -OH groups in the isolated Sal⁻ anion, yellow colour is present in the entire ring area, indicating the presence of negative ESPs (Fig. S5B, ESI†). Charge re-distribution occurs after ion-pair formation, resulting in a mixture of red, blue, yellow, and green colours. The red colour is only present on the oxygen atoms and blue colour on the cation in Fig. S5D (ESI†), which shows the possibility of the strong interaction between these two moieties by the bifurcated C-H...O type non-covalent bonds. The red colour on the -OH group also justifies the experimental finding that predicts the intramolecular hydrogen bonding in the Sal anion. In addition, all the colours are present in the DOX molecule and the red colour can be seen near the -C=O and -OH group, while the blue colour can be seen on the other -OH group linked to the ring-containing -NH₂ group. In the drug-hydrogel complex, the presence of blue colour on these -OH groups increases the possibility of strong hydrogen bonding. The red colour of the drug molecule (DOX) on O₇₉ provides it with an opportunity to interact with the hydrogel, which further confirms the findings of the structural component determined by DFT and thus confirms the experimental findings.

Further, we have evaluated the values of HOMO and LUMO energy levels to calculate the chemical reactivity descriptors such as chemical potential (μ), softness (S), hardness (η), and electrophilicity-index (ω). The significant chemical-reactivity descriptors (μ , S , η , and ω) including the dipole moment for the hydrogel (IL) carrier, drug molecule (DOX), and IL-DOX complex are provided in Table 4. In terms of these descriptors, the electronic properties and stability such as electron-transfer in a complex molecule are demonstrated quite well. Significant aspects of the IL-DOX complex have been observed. The complex IL-DOX was softer (0.47 eV⁻¹) than the IL (0.25 eV⁻¹) and DOX molecules (0.28 eV⁻¹), which is illustrated by the higher chemical softness and lower values of chemical hardness (Table 4). Compared to the chemical hardness η of IL (1.99 eV) and DOX molecules (1.72 eV), the chemical hardness of the IL-DOX complex (1.04 eV) was lower. The chemical potential of the complex IL-DOX (-4.01 eV) was greater than that of the molecules of IL (-2.73 eV) and DOX (-4.00 eV), with a higher negative chemical potential of the complex implying the stability of the complex. The dipole moment of the complex increased from the 4.44 D of the drug molecule (DOX) to 8.24 D, which corresponds to increasing solubility as well. The electrophilicity-index assesses the energy decrease associated

Table 4 HOMO and LUMO energy levels, band gap energies E_g , dipole moment p , chemical potential (μ), chemical softness (S), chemical hardness (η), and electrophilicity index (ω) of C₁₆MelmSal, DOX and C₁₆MelmSal-DOX complex in the gas phase

	E_{HOMO} (eV)	E_{LUMO} (eV)	E_g (eV)	Dipole moment p	η (eV)	S (eV ⁻¹)	μ (eV)	ω (eV)
IL	-4.73	-0.73	3.99	12.81	1.99	0.25	-2.73	1.86
DOX	-5.73	-2.28	3.44	4.44	1.72	0.28	-4.00	4.65
IL-DOX	-5.05	-2.96	2.08	8.24	1.04	0.47	-4.01	7.71

with a complex system obtaining additional charges from the surroundings. The chemical reactivity parameters described above, such as lower hardness, greater electrophilicity-index value, high charge-transfer and negative chemical potential of the IL-DOX complex, clearly demonstrate that this complex can be used as an efficient cancer therapy drug delivery system.

Non-covalent interaction (NCI) analysis

To envisage the non-covalent interactions (NCI) such as hydrogen bonding, van der Waals interactions, and steric-repulsions among the non-covalently interacting systems, NCI analysis is an essential tool. This approach is based on electronic densities and their derivatives, such as reduced density gradients (RDGs).⁷⁶ The RDG function can be defined using the following formula:

$$\text{RDG}(r) = \frac{1}{2(3\pi^2)^{\frac{1}{3}}} \frac{|\Delta\rho(r)|}{\rho(r)^{\frac{4}{3}}} \quad (14)$$

where $\rho(r)$ is the electron density.

Weak non-covalent interactions play an important role in the determination of the physicochemical properties in ILs and their derived hydrogel systems. The NCI visual representation of the IL is shown in Fig. S6 (ESI†) and is plotted between the $\text{sign}(\lambda_2)\rho$ and reduced-density gradient (RDG). It depicts the presence of strong hydrogen bonding (H-bond) and weak van der Waals interactions between the $\text{C}_{16}\text{MeIm}^+$ cation and anion. An essential parameter employed to detect the existence of chemical bonding in the complex is the $\text{sign}(\lambda_2)\rho$ in the scatter plot of NCI analysis. The values of $\text{sign}(\lambda_2)\rho$ below zero indicate hydrogen bonding and beyond zero display steric repulsions and spikes around the zero regions of $\text{sign}(\lambda_2)\rho$ indicate van der Waals interactions. The 3D-colour filled iso-surface for the IL is depicted in Fig. 6A, which also illustrates the existence of non-covalent interactions between cation and anion moieties. The presence of blue colour between $\text{C}_2\text{-H}_9$ and O_{62} ; and $\text{O}_{64}\text{-H}_{65}$ and O_{62} atoms shows the area where intermolecular and intramolecular hydrogen bonding takes place, and the areas of weak van der Waals forces and strong steric repulsion in the imidazolium and Sal^- anion rings are indicated by green and red colour, respectively.

Similarly, Fig. 6B presents the NCI visual representation, which depicts the presence of weak non-covalent interactions in the drug-hydrogel complex (IL-DOX complex). Surprisingly, for the IL-DOX complex, all categories of NCIs were observed, *viz* weak van der Waals forces, hydrogen bonding, and steric-repulsions. The NCI between the IL and DOX molecule are also demonstrated by the 3D colour-filled iso-surface presented in Fig. 6B. Van-der Waals forces are shown by green-colour between the IL and DOX, while the blue-region occurs due to hydrogen bonding interactions. These interactions are highly in line with the $\text{C-H}\cdots\text{O}$ and $\text{O-H}\cdots\text{O}$ type weak interactions observed in the geometrical analysis of IL and IL-DOX complexes.

In this way, our DFT calculation-based NCI analysis is perfectly able to demonstrate the contribution of interactions

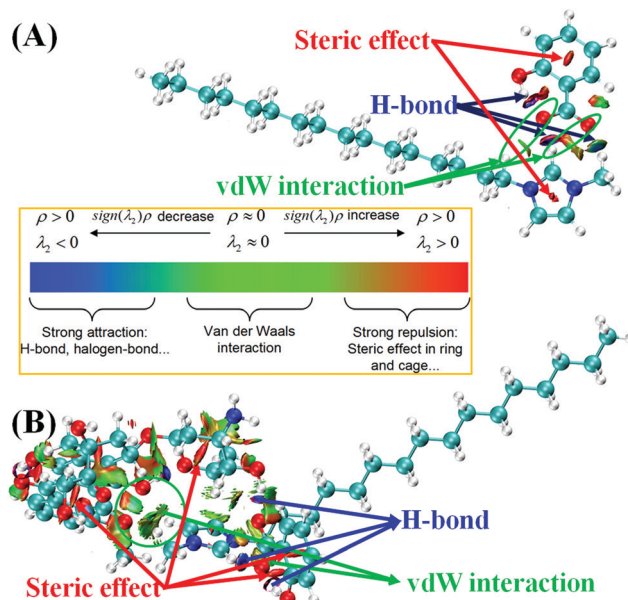

Fig. 6 3D colour filled RDG iso-surfaces of (A) $\text{C}_{16}\text{MelmSal}$, and (B) $\text{C}_{16}\text{MelmSal-DOX}$ complex showing the nature of the interaction between the cation-anion, and $\text{C}_{16}\text{MelmSal}$ and DOX molecule.

in the hydrogel and IL-DOX complex. In addition, the presence of weak drug-hydrogel carrier interactions plays a key role in drug-off loading at the target site. Further, these low-cost computational calculations by considering only single ion-pair (IL), DOX and IL-DOX molecule allowed us to see what an immediate site-specific interaction would be like.

Gel-to-sol transition

The ionic hydrogel exhibited semi solid like behavior and non-flowing characteristics with almost zero transmittance at 25 to 40 °C (pH = 5.0) (Fig. S7, ESI†). With increasing the temperature from 40 to 60 °C, the transmittance increased gradually, and at 47 °C the ionic hydrogel transformed into a transparent solution. From the tube inversion method, we observed ionic hydrogel-to-solution transition at a temperature of 47 ± 2 °C (Fig. S7B, ESI†). Such a phase transition was reversible and is probably because of the association and disassociation of the non-covalent interaction between IL-IL when the temperature and pH were changed.⁷⁷

In vitro drug release study

At 37 °C and 5.0 pH, the % of release of DOX from the ionic hydrogel was well-controlled and lasted for over 57 h (Fig. S8, ESI†). No fast DOX release was observed at the initial stage, and the % of release was over ~86.4% at the later stage. The % of release was found to be around ~45.3% at pH 7.4 over a period of 57 h. Similar results were observed when the hydrogel was incubated at 25 °C. The cumulative DOX release was ~33.2% at pH 5.0 and ~18.2% at pH 7.4. As expected, the acidic pH increased the release process of DOX, attributed to the increased hydrophilicity of DOX and de-solubilization inside the ionic hydrogel fibrous network. Further, more drug was

Fig. 7 *In vitro* cytotoxicity study of the neat ionic hydrogel, DOX, and DOX loaded ionic hydrogel.

released at 37 °C, likely due to the increased permeability within the hydrogel network.⁷⁸ In conclusion, these smart ionic hydrogels demonstrate a release of anticancer drugs controlled by dual stimuli, temperature and pH.⁴²

Taking them altogether, the % of DOX release from the ionic hydrogel system (37 °C, pH 5.0) exhibited a sustained co-delivery approach as long as 57 h, and the % release amounts of the DOX exceeded 86.4%. The release data were further evaluated *via* mathematical models of the drug release kinetics

(Table S1, ESI†). The results showed that the release of DOX from the ionic hydrogel system was well-fitted by the Higuchi release equation with good correlation coefficients ($R^2 \approx 0.97$).⁷⁹ The presence of stimuli (5.0 pH and 37 °C) in the ionic hydrogel network resulted in intermolecular interactions and affected the DOX release mechanisms.

In vitro cytotoxicity study

The cell viability study suggested that the neat ionic hydrogel had excellent biocompatibility and no cytotoxicity. The data are in good agreement with the MCF-07 cell line assay, while neat DOX and DOX loaded ionic hydrogels indicate that they could induce tumor cell death and inhibit cell growth. Further, the IC_{50} values were determined from the dose response curve for neat DOX and DOX loaded ionic hydrogels against MCF-7 cell lines using GraphPad Prism Software (Fig. 7). Regardless of incubation time, the percentage of living cells in the presence of the DOX loaded ionic hydrogel was lower than that of neat DOX. This could be due to the slow release of DOX from the ionic hydrogel network. The IC_{50} values in the cases of neat DOX and DOX loaded polymeric hydrogels for MCF-07 cells were found to be 0.94 and 0.62 $\mu\text{g mL}^{-1}$ at 24 h of the exposure. Apparently, the loaded ionic hydrogels exhibited good anti-cancer activity with a lower IC_{50} value than the neat DOX in MCF-7 cells.

DOX uptake study

The cellular uptake of neat DOX and DOX loaded ionic hydrogel in the MCF-07 cell line, depicted in MCF-07 cells, was viewed

Fig. 8 (A) Representative fluorescence images of MCF-07 cells incubated with DOX, and DOX loaded ionic hydrogel at an equivalent DOX concentration of 1 $\mu\text{g mL}^{-1}$ for 4 h; scale bar is 20 μm , (B) quantitative measurement of DOX uptake in MCF-07 cells by flow cytometric analysis, and (C) the mechanism for enhancing DOX delivery.

with a confocal laser scanning microscope (CLSM) where the cell nuclei exhibited strong blue fluorescence (Fig. 8A). The red fluorescence of DOX was clearly seen in the cytoplasm and nuclei of MCF-07 cells, which are prepared with neat DOX and DOX-ionic hydrogel. The uptake of DOX in the DOX loaded ionic hydrogel was higher than that of the neat DOX. This may be a result of the difference in the cellular uptake mechanism.⁸⁰ The cellular uptake of neat DOX is through passive diffusion, while the ionic hydrogel transports into cells by both endocytosis and passive diffusion. The combination of the two pathways might explain the high uptake of the DOX-ionic hydrogel. In summary, the DOX-ionic hydrogel could help the DOX enter the cells and to be released from the 3D network of the ionic hydrogel efficiently (Fig. 8B), which was consistent with the above results obtained by laser scanning confocal microscopy. To quantify the cell uptake, we performed flow cytometry measurements. Fig. 8C clearly shows a remarkably increased cellular uptake and greatly enhanced nucleus localization in cells treated with the DOX loaded ionic hydrogel with more systematic intracellular DOX release. Evidently, the DOX loaded ionic hydrogel has appreciable possibilities to achieve cell-specific drug delivery.

Conclusions

Herein, we designed a local drug administrative system for the poorly water-soluble drug DOX using an amphiphilic ionic hydrogel as the stimuli-responsive and injectable drug carrier. The hydrogel was successfully realized as a sustained co-delivery system for the DOX. DOX could be effectively encapsulated into the cores of cylindrical micelles formed by the amphiphilic hydrogel in water and released from the ionic hydrogel formulation in a well-controlled and sustained manner at 37 °C and pH 5. *In vitro* cytotoxicity and uptake, results confirmed a synergistic anticancer effect of the DOX-delivery system against the human breast cancer cell line (MCF-7). Here, we have employed the DFT calculations, which helped us to investigate the interaction mechanism in the ionic hydrogel and drug-hydrogel interaction. Overall, this stimuli responsive ionic hydrogel provides an ideal drug carrier for breast cancer treatment.
