# The interaction of size-selected Ru<sub>3</sub> clusters with RF-deposited TiO<sub>2</sub>: probing Ru–CO binding sites with CO-temperature programmed desorption†

Liam Howard-Fabretto,<sup>ab</sup> Timothy J. Gorey,<sup>c</sup> Guangjing Li,<sup>c</sup> Siriluck Tesana,<sup>d</sup> Gregory F. Metha,<sup>id e</sup> Scott L. Anderson<sup>id c</sup> and Gunther G. Andersson<sup>id \*ab</sup>

Small Ru clusters are efficient catalysts for chemical reactions such as CO hydrogenation. In this study 3-atom Ru<sub>3</sub> clusters were deposited onto radio frequency (RF)-deposited TiO<sub>2</sub> which is an inexpensive, nanoparticulate form of TiO<sub>2</sub>. TiO<sub>2</sub> substrates are notable in that they form strong metal–substrate interactions with clusters. Using temperature programmed desorption to probe Ru–CO binding sites, and X-ray photoelectron spectroscopy to provide chemical information on clusters, differences in cluster–support interactions were studied for Ru<sub>3</sub> deposited using both an ultra-high vacuum cluster source and chemical vapour deposition of Ru<sub>3</sub>(CO)<sub>12</sub>. The TiO<sub>2</sub> was treated with different Ar<sup>+</sup> sputter doses prior to cluster depositions, and SiO<sub>2</sub> was also used as a comparison substrate. For cluster source-deposited Ru<sub>3</sub>, heating to 800 K caused cluster agglomeration on SiO<sub>2</sub> and oxidation on non-sputtered TiO<sub>2</sub>. For cluster source-deposited Ru<sub>3</sub> on sputtered TiO<sub>2</sub> substrates, all Ru–CO binding sites were blocked as-deposited and it was concluded that for the binding sites to be preserved for potential catalytic benefit, sputtering of TiO<sub>2</sub> before cluster deposition cannot be applied. Conversely, for Ru<sub>3</sub>(CO)<sub>12</sub> on sputtered TiO<sub>2</sub> the clusters were protected by their ligands and Ru–CO binding sites were only blocked once the sample was heated to 723 K. The mechanism for complete blocking of CO sites on sputtered TiO<sub>2</sub> could not be directly determined; however, comparisons to the literature indicate that the likely reasons for blocking of the CO adsorption sites are encapsulation into the TiO<sub>x</sub> layer reduced through sputtering and also partial oxidation of the Ru clusters.

## Introduction

Metal clusters are generally defined as groups of metal atoms with sizes less than ~300 atoms.<sup>1–6</sup> They often possess unique electronic and catalytic properties which are highly tuneable, such that the addition or subtraction of just one atom to a small cluster can be a deciding factor on whether it functions as a catalyst or not.<sup>7</sup> For this reason, experiments often focus on a single cluster size. Ru clusters in particular have been shown

to be among the most active catalysts for industrial and environmentally relevant reactions such as CO and CO<sub>2</sub> hydrogenation.<sup>8–17</sup> Two of the main ways to deposit Ru clusters onto substrates is through the preparation of bare clusters in vacuum using an ultra-high vacuum (UHV) cluster source, or through depositing ligand-stabilized clusters such as Ru<sub>3</sub>(CO)<sub>12</sub> using chemical vapour deposition (CVD)<sup>18–22</sup> or a solution-based deposition.<sup>23</sup> This process of depositing metal carbonyl compounds using CVD is well explored in the literature and has been used to deposit clusters onto a number of substrates such as; metals (*e.g.* Au), metal oxides (*e.g.* TiO<sub>2</sub>), non-metal oxides (*e.g.* SiO<sub>2</sub>) and others such as zeolites.<sup>19,24–29</sup> When depositing ligand-stabilized clusters, extra post-deposition surface treatments such as heating are needed to remove the ligands if bare metal clusters are desired on the substrate.

TiO<sub>2</sub> is a photocatalytically active substrate<sup>30</sup> and is a common choice as a substrate for the deposition of clusters.<sup>19,20,31–43</sup> Here we used RF-deposited TiO<sub>2</sub> as a substrate. It is a nanoparticulate form of TiO<sub>2</sub> made by radio frequency (RF) sputtering a TiO<sub>2</sub> wafer onto a substrate (sputter deposition) under UHV, in the present case Si(100). This process produces a dense, uniform, stoichiometry-controlled layer of TiO<sub>2</sub> more cheaply and readily than TiO<sub>2</sub>(110).<sup>44</sup> RF-deposited TiO<sub>2</sub> is

polycrystalline and does not have a surface as flat as a single crystal. RF-deposited TiO<sub>2</sub> does, however, more closely reflect the situation of TiO<sub>2</sub> as used in a real catalyst than single crystal samples. Our previous studies have shown RF-deposited TiO<sub>2</sub> does not feature X-ray diffraction peaks related to a specific crystal phase prior to heat treatment, however heating under vacuum or atmosphere results in anatase phase formation, and strong heating to 1373 K for 18 hours under atmosphere results in the emergence of a rutile crystal peak in addition to anatase.<sup>45</sup>

A key problem of clusters deposited onto surfaces is maintaining the properties of size-selected clusters by preventing them from agglomeration, in particular at elevated temperatures.<sup>46</sup> One method to help with this is to induce defects on the substrate surface prior to cluster deposition.<sup>47,48</sup> Clusters are known to preferentially bind to defect sites, as their surface energy is greater than the corresponding perfect crystal structure.<sup>48</sup> As a specific example regarding TiO<sub>2</sub> substrates, a study by Krishnan *et al.*<sup>48</sup> showed that for Au<sub>9</sub> clusters supported on atomic layer deposited (ALD) TiO<sub>2</sub>, sputter-treating the surface with Ar<sup>+</sup> prior to cluster deposition was able to help prevent cluster agglomeration. The anchoring of clusters to defect sites on TiO<sub>2</sub> has also been demonstrated by DFT calculations of Au clusters on TiO<sub>2</sub>(110).<sup>49</sup> However, the cluster–substrate interaction, and therefore agglomeration characteristics, will be different for each cluster/substrate combination.

There are two main types of defects: oxygen vacancies and interstitial titanium ions<sup>30</sup> both resulting in the presence of Ti<sup>3+</sup> in the TiO<sub>2</sub>. The transport of each in the substrate can be explained by vacancy and interstitial models respectively.<sup>30,50–52</sup> Interstitials are atoms present within crystal lattice locations where they should not normally be present. Ar<sup>+</sup> sputter treatment of TiO<sub>2</sub> removes O atoms more preferentially than Ti atoms from the surface, and the main surface defect sites from sputtering are predominantly vacancies in the bridging oxygen rows of the TiO<sub>2</sub>.<sup>30,53</sup> These defect sites act as electron donors to clusters because the oxygen removal leaves behind two electrons which previously occupied O<sub>2p</sub> valence band levels.<sup>30,54</sup>

Previous studies on the effects of heating systems of small, size-selected Ru clusters on TiO<sub>2</sub> have often focussed on Ru deposited using Ru<sub>3</sub>(CO)<sub>12</sub>: two separate studies by Zhao *et al.* and Rizzi *et al.*<sup>18,19</sup> have been performed on Ru<sub>3</sub>(CO)<sub>12</sub> deposited by CVD onto TiO<sub>2</sub>(110), using X-ray photoelectron spectroscopy (XPS) and/or CO-temperature programmed desorption (CO-TPD). Both studies found that there is partial decomposition of Ru<sub>3</sub>(CO)<sub>12</sub> when deposited onto room-temperature TiO<sub>2</sub>(110).<sup>18,19</sup> Furthermore, Zhao *et al.*<sup>19</sup> demonstrated using XPS and TPD that heating to 700 K under UHV yielded almost pure Ru particles on the surface, but heating to 600 K while dosing O<sub>2</sub> resulted in oxidised Ru. The latter point was also supported in the Rizzi *et al.* study using XPS.<sup>18</sup> The specific cluster–substrate interaction can have a large effect on the state of supported clusters, even for differing forms of TiO<sub>2</sub>; CO-TPD spectra have been shown to have different CO desorption features for Ru<sub>3</sub>(CO)<sub>12</sub> deposited onto varying forms of TiO<sub>2</sub>, such as TiO<sub>2</sub>(110),<sup>19</sup> polycrystalline P25 TiO<sub>2</sub>,<sup>23</sup> and TiO<sub>2</sub>/Mo(110).<sup>20</sup> Other studies have used differing Ru/TiO<sub>2</sub> systems with different thermal stability results, including one study by

Komaya *et al.*<sup>55</sup> for large Ru particles deposited with Ru(NO)(NO<sub>3</sub>)<sub>3</sub> onto P25 nanocrystalline TiO<sub>2</sub>, where heating to 573 K resulted in the encapsulation of Ru by an amorphous titania layer. These studies show that it is unclear how Ru clusters interact with the substrate when deposited onto titania, in particular when heating of the cluster/substrate system is involved. It is therefore important to test the interaction and stability of Ru clusters on RF-deposited TiO<sub>2</sub> because studies performed on differing TiO<sub>2</sub> forms cannot predict the results for this substrate. Of particular interest is agglomeration of the clusters and encapsulation into the substrate.

The aim of this study was to determine whether defects induced in RF-deposited TiO<sub>2</sub> substrates help to avoid agglomeration of bare Ru<sub>3</sub> and Ru<sub>3</sub>(CO)<sub>12</sub> clusters upon deposition, and how the clusters interact with TiO<sub>2</sub> substrates upon heating to ~800 K. The clusters were deposited both from a cluster source (bare Ru<sub>3</sub>) and evaporation of Ru<sub>3</sub>(CO)<sub>12</sub> *via* chemical vapour deposition (CVD). To the knowledge of the authors no previous studies exist for size-selected Ru deposited by a cluster source onto TiO<sub>2</sub>, and thus comparison between the results of these two common deposition methods is of critical importance. CO-TPD is used to probe the available CO adsorption sites on the metal clusters, as well as for probing the removal of ligands with heating in the case of CO-stabilized clusters.<sup>19,20,56–60</sup> XPS is used to analyse the composition of the surface and to determine concentration depth profiles.

## Methodology

### Materials

P-type, boron-doped Si(100) wafers were purchased from MTI Corporation and used without further modification. RF-deposited TiO<sub>2</sub> substrates (referred to as TiO<sub>2</sub>) were prepared by RF magnetron-sputtering using a 99.9% pure TiO<sub>2</sub> ceramic target, where TiO<sub>2</sub> is deposited *via* sputtering of the target onto a substrate, in this case a Si(100) wafer. This was under high vacuum using an HHV/Edwards TF500 Sputter Coater at a pressure <2 × 10<sup>-5</sup> mbar, using 10 sccm Ar for sputtering the TiO<sub>2</sub> surface. The power was ramped up at 50 W per minute to 500 W, and a shutter was then removed from the target for 50 minutes, allowing the deposition of material onto the rotating wafer. The thickness of the TiO<sub>2</sub> was approximately 150 nm, which is thick enough that the SiO<sub>2</sub> wafer beneath would not be detectable in the electron spectra. This thickness was estimated based on SEM measurements previously performed on wafers prepared using similar methodology on the same apparatus.<sup>45</sup>

Clusters were prepared by depositions using (i) chemical vapour deposition (CVD) of ligated clusters and (ii) depositing bare clusters from a gas phase cluster source (CS). CVD depositions were performed with Ru<sub>3</sub>(CO)<sub>12</sub>; this was prepared as a powdered sample, according to synthesis procedures reported by Faure *et al.*<sup>61</sup> CVD depositions were performed under UHV in a separate instrument for CO-TPD and XPS analysis. CS depositions were performed by a laser ablation cluster source which has been used and described in several previous publications.<sup>58,60,62</sup> For cluster source-deposition of bare Ru<sub>3</sub> clusters, the source was a 99.9% pure target of Ru.

## Substrates and samples

Ru<sub>3</sub> was deposited onto four different types of substrates: two TiO<sub>2</sub> substrates modified by Ar<sup>+</sup> sputter treatment (prior to the deposition of Ru clusters) at two different Ar<sup>+</sup> doses, non-sputtered TiO<sub>2</sub>, and non-sputtered SiO<sub>2</sub> for comparison. The different sputter dosages for TiO<sub>2</sub> have been designated as follows: “low-dose sputtered TiO<sub>2</sub>” was treated with  $4 \times 10^{13}$  Ar<sup>+</sup>/cm<sup>2</sup>, and “high-dose sputtered TiO<sub>2</sub>” was treated with  $6 \times 10^{14}$  Ar<sup>+</sup>/cm<sup>2</sup>. Additionally, a “non-sputtered TiO<sub>2</sub>” sample was used. In the text these will be abbreviated to LDS-TiO<sub>2</sub>, HDS-TiO<sub>2</sub>, and NS-TiO<sub>2</sub>, respectively. A list of the substrates and their abbreviated names are given in Table 1. Deposition of Ru<sub>3</sub> from CS was performed on all 4 substrates. However, deposition of Ru<sub>3</sub>(CO)<sub>12</sub> from CVD was only undertaken on an HDS-TiO<sub>2</sub> substrate. Clusters deposited by CS will herein be referred to as “Ru<sub>3</sub>”, while clusters deposited by CVD will be referred to as “Ru<sub>3</sub>(CO)<sub>12</sub>”. 5 samples were analysed with CO-TPD overall, and blank measurements CO-TPD were performed prior to the deposition of Ru clusters. Additional samples were prepared for further XPS analysis, and thus the XPS measurements in some cases were of samples prepared with an identical method, rather than the same sample as was analysed with CO-TPD. A list of all samples analysed is given in the ESI (Table S1†).

## Instrumentation

CS depositions, as well as XPS, CO-TPD, and Ar<sup>+</sup> sputter treatment were performed using a UHV apparatus with a main chamber base pressure of  $<2 \times 10^{-10}$  mbar at the University of Utah. All CS measurements and analysis were performed on this apparatus (*i.e.* all measurements except CVD depositions and the XPS of metallic Ru reference material, which are described separately). Samples were stored in the main chamber when depositing clusters using the cluster source. The instrument featured liquid N<sub>2</sub> cooling and resistive heating. A C-type thermocouple was spot welded to the backing plate of the sample holder to monitor the temperature. The instrument includes capabilities for continuous temperature control and automatic, linear temperature ramping, and soft landing of small metal clusters. A soft-landing deposition energy of  $\sim 1$  eV per atom was used for the Ru<sub>3</sub> clusters. Previous studies of the deposition of small Ir clusters onto TiO<sub>2</sub> and SiO<sub>2</sub> showed that impact energies in the tens of eV per atom are required to embed the clusters into these substrates (*e.g.* at least 10 eV per atom for small Ir clusters on TiO<sub>2</sub>).<sup>63,64</sup> Thus, the  $\sim 1$  eV per atom deposition energy is considered suitable to not cause Ru cluster

damage or embedding during depositions. Further details on the CS instrument and depositions are provided in the ESI.†

The chemical vapor deposition (CVD) of ligated Ru<sub>3</sub>(CO)<sub>12</sub> clusters was performed using a UHV apparatus at Flinders University in Adelaide. The substrates were prepared in a main chamber featuring a base pressure of  $<2 \times 10^{-10}$  mbar, which included electron bombardment heating and Ar<sup>+</sup> sputter treatment. Chemical vapour depositions (CVD) of ligated Ru<sub>3</sub>(CO)<sub>12</sub> clusters were performed *ex situ* in a separate loading chamber, with a base pressure of  $<8 \times 10^{-8}$  mbar. Further details on the CVD process are provided in the ESI.† These samples were transported from Flinders University to the University of Utah for CO-TPD analysis.

The Utah and Adelaide instruments use different sputter guns; the substrates for the CVD sample (Adelaide) was prepared using 3 keV Ar<sup>+</sup>, while the substrates for the CS samples (Utah) were prepared using 2 keV Ar<sup>+</sup>. The defects may extend deeper into the bulk for the CVD sample due to the higher Ar<sup>+</sup> impact energy.<sup>33,34</sup> This was not corrected for, and a slight variation in defects on the substrate was deemed not to be of critical importance for this experiment.

## CO-temperature programmed desorption (CO-TPD)

CO-TPD is used to investigate the desorption of CO molecules from the various samples. CO molecules are typically first dosed onto a sample under UHV, but the technique can also be used to analyse the de-ligation of CO-ligated clusters such as Ru<sub>3</sub>(CO)<sub>12</sub>, where CO does not need to be dosed prior to measurements.<sup>12,19,20</sup> When the CO dosing and temperature ramping procedure is repeated for multiple cycles, CO-TPD can show the effect of heating on the available CO binding sites on the surface, which can give insights into cluster/substrate interactions.

For CO-TPD measurements (excluding CO de-ligation), the sample was dosed with isotopically labelled <sup>13</sup>CO (mass 29) at 180 K. They were exposed to 10 L <sup>13</sup>CO, which was above the saturation dose. CO exposure was through a dosing tube which terminated approximately 2 cm from the surface of the substrate; this increased the gas flux at the surface by a factor of approximately 10 compared to dosing the gas into the chamber without the tube. This increase factor was determined previously as per the method described by Kaden *et al.*<sup>56</sup>

For each substrate, CO-TPD measurements were performed before and after CS cluster depositions. After a deposition, the CO procedure was initiated as quickly as practicably possible. This is for all samples except the CVD sample which was not

**Table 1** Summary of the different supporting substrates used in this study. The designated sample names are given as well as abbreviated names for the TiO<sub>2</sub> substrates

| Substrate material        | Ar <sup>+</sup> sputter dose (Ar <sup>+</sup> /cm <sup>2</sup> ) | Designated sample name               | Abbreviated name     |
|---------------------------|--|--------------------------------------|----------------------|
| TiO <sub>2</sub>          | None   | Non-sputtered TiO <sub>2</sub>       | NS-TiO <sub>2</sub>  |
| TiO <sub>2</sub>          | $4 \times 10^{13}$   | Low-dose sputtered TiO <sub>2</sub>  | LDS-TiO <sub>2</sub> |
| TiO <sub>2</sub>          | $6 \times 10^{14}$   | High-dose sputtered TiO <sub>2</sub> | HDS-TiO <sub>2</sub> |
| SiO <sub>2</sub> /Si(100) | None   | SiO <sub>2</sub>                     | SiO <sub>2</sub>     |

deposited *in situ*. The standard procedure for CO-TPD cycle is as follows. After CO dosing, the sample was positioned at a distance of 0.5 mm from the differentially pumped quadrupole mass spectrometer (QMS) entrance, which is a 2.5 mm diameter aperture in a skimmer cone. The temperature was then ramped at a rate of 3 K s<sup>-1</sup> from 170 K to 800 K, while masses corresponding to CH<sub>3</sub>, O, H<sub>2</sub>O, <sup>12</sup>CO, <sup>13</sup>CO, O<sub>2</sub>, <sup>12</sup>CO<sub>2</sub>, <sup>13</sup>CO<sub>2</sub> were monitored in 50 ms total cycles using a QMS made by UTI. Masses apart from <sup>12</sup>CO and <sup>13</sup>CO were only monitored for irregularities or unexpected reaction products. Between 700 K and 750 K the sample holder “degassed” CO resulting in a sharply increased background. Data points beyond this temperature and up to 800 K were therefore not considered for analysis. After the completion of a CO-TPD cycle, the sample was cooled again, and the cycle was repeated 3 to 4 times per sample. Additional details on the calibration of the QMS signal, integration of the CO-TPD spectra, and the accuracy of the measurement and calibration are provided in the ESI.†

The CO-TPD procedure for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> was slightly different; the samples were cooled to 180 K and the CO-TPD heat ramping process was initiated with no further treatment (there were no samples of Ru<sub>3</sub>(CO)<sub>12</sub> on NS-TiO<sub>2</sub> or LDS-TiO<sub>2</sub>). The clusters were already saturated with <sup>12</sup>CO ligands, and thus for the 1<sup>st</sup> cycle no <sup>13</sup>CO was dosed, and <sup>12</sup>CO was the mass of interest. As this sample had been exposed to atmosphere before measurements, there may have been a small component of the CO-TPD signal which was due to the desorption of adsorbed CO contamination. This was not corrected for but due to the large number of CO ligands measured desorbing in the 1<sup>st</sup> CO-TPD cycle, any effects from contamination were deemed minimal in comparison to the signal strength. The temperature was only ramped to 723 K on the 1<sup>st</sup> CO-TPD cycle. <sup>13</sup>CO was dosed as per the standard procedure for the CO-TPD on the 2<sup>nd</sup> and 3<sup>rd</sup> cycles. An additional complication was that on the 1<sup>st</sup> cycle the CO desorption rate reached the maximum count limit of the QMS which caused two effects; the <sup>12</sup>CO spectrum was distorted due to saturation, and the measured <sup>13</sup>CO signal clearly was actually due to overlap of the adjacent <sup>12</sup>CO mass peak signal. This detection of a small fraction of the overlapping <sup>12</sup>CO signal at mass 29 allowed us to correct the <sup>12</sup>CO spectrum for saturation by scaling the <sup>13</sup>CO spectral intensities so that they matched the <sup>12</sup>CO signal at low temperature, where the signal was well below the saturation level. Note that after the 1<sup>st</sup> TPD on the CVD sample, and in all TPD experiments with CS clusters, the <sup>12</sup>CO signal was small, and unsaturated.

### XPS methods

For XPS measurements of cluster-deposited samples (in Utah), the Ru 3d, C 1s and O 1s regions were measured for each sample, while the Ti 2p and Si 2p regions were additionally measured for TiO<sub>2</sub> and SiO<sub>2</sub> substrates, respectively. The Ru 3d and C 1s regions overlap and will be referred to as the Ru 3d/C 1s region. XPS of cluster samples was performed *in situ* (except for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>) using an Al K $\alpha$  source and 10 eV pass energy. X-ray photons were incident to the surface at 54.7°, and ejected photoelectrons were measured normal to the sample.

No evidence for charging was found for any sample. A hemispherical analyzer (HSA, Physical Electronics) was used; this featured an area-selective lens with a 1.1 mm diameter analysis area, which was optimised to measure cluster spots of 2 mm in diameter without XPS signal from the surrounding bare substrate. Binding energies were calibrated to C 1s = 285.0 eV. Details for the XPS data analysis including peak fitting, line shapes used for fitting (Table S2†) and uncertainties are provided in the ESI.†

An XPS spectrum of an Ru reference material was measured on a separate XPS instrument (in Adelaide) with a Mg K $\alpha$  excitation and a Phoibos 100 HSA (SPECS, Germany). The Ru reference sample was taken from a 99.9% pure Ru metal sample (Fig. S1, ESI†). A measurement was first performed with no surface treatment, and then again after heating to 1073 K for 10 minutes and sputtering with 3 keV Ar<sup>+</sup> for 1 hour to remove the surface Ru oxide layer and any hydrocarbon contamination. The BE scale for these measurements was calibrated to the C 1s peak for the pre-treatment XPS spectrum before hydrocarbon removal. Additionally, an *in situ* measurement of the Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> was performed on the XPS same instrument before removing the sample from vacuum, to estimate the number of ligands on the clusters (results shown in ESI Table S3†).

## Results

### Temperature programmed desorption

**CO-TPD of Ru<sub>3</sub>/SiO<sub>2</sub>.** Fig. 1a shows CO-TPD measurements of blank SiO<sub>2</sub> and Ru<sub>3</sub> on SiO<sub>2</sub>. CO-temperature programmed desorption (CO-TPD) is an analysis technique useful for probing the available CO adsorption sites on metal clusters, as well as for probing the removal of ligands with heating in the case of CO-stabilized clusters.<sup>19,20,56–60</sup> When discussing peaks in CO-TPD figures, they will be labelled based on the temperature corresponding to the peak CO desorption rate. It is assumed that higher temperature peaks correspond to sites with stronger CO binding. Due to the continuous temperature ramping of the CO-TPD measurements the temperature at the peak CO desorption rate is typically greater than the minimum temperature required for CO desorption to occur for that particular binding site. SiO<sub>2</sub> was used for reference measurements because it is a nonreducible oxide substrate that is stable at the temperatures being used and does not form a strong metal support interaction (SMSI) with clusters under typical conditions.<sup>65–67</sup>

Fig. 1a shows that very little CO has desorbed from blank SiO<sub>2</sub>, with two small features centred at 210 K and 285 K. Furthermore, there was no change between the blank measurements over 3 repeated TPD cycles (traces not shown in figure), indicating the affinity of the surface for CO was not strongly affected or changed by heating to 800 K. The 1<sup>st</sup> CO-TPD cycle for Ru<sub>3</sub>/SiO<sub>2</sub> features a small peak at 210 K, which is related to desorption of CO from the SiO<sub>2</sub> substrate. The remaining features in the spectrum are due to CO desorbing from Ru–CO binding sites. Notably, there is a small peak at 260 K and then a large, main desorption peak at 530 K. In this study, these two features will be treated as the reference Ru–CO

**Fig. 1**  $^{13}\text{CO}$ -TPD from  $\text{Ru}_3$  CS-deposited onto various substrates. Blank measurements were performed before  $\text{Ru}_3$  deposition, and the spectra are averages of 3 blank cycles each where there were no noticeable changes (except for (d), discussed below). (a)  $\text{Ru}_3/\text{SiO}_2$ . Quantification of CO molecules desorbing per Ru atom is shown in the top left corner. For comparison purposes the quantified blank  $\text{SiO}_2$  desorption assumes the same number of Ru atoms were deposited as the cluster-loaded measurements. The uncertainty of CO molecules desorbing per atom is  $\sim 50\%$  (see ESI†). (b)  $\text{Ru}_3/\text{NS-TiO}_2$ . (c)  $\text{Ru}_3/\text{LDS-TiO}_2$ . (d)  $\text{Ru}_3/\text{HDS-TiO}_2$ . For HDS- $\text{TiO}_2$  two blank measurements are shown: the 1<sup>st</sup> cycle and an average of the 2<sup>nd</sup> and 3<sup>rd</sup> cycles. There was presumably a change in the blank spectrum after the 1<sup>st</sup> cycle because the HDS- $\text{TiO}_2$  blank featured more hydrocarbons adsorbed from the vacuum before the  $\text{CO}$ -TPD cycle, resulting from defected  $\text{TiO}_2$  being more reactive than pristine  $\text{TiO}_2$ .<sup>30</sup>

desorption peaks for CO desorbing from supported Ru clusters which have not chemically reacted with the substrate or formed an SMSI state. In the 2<sup>nd</sup> to 4<sup>th</sup> cycles, the 260 K desorption feature increased in size (Fig. 1a). Also, the larger high temperature CO peak changed shape with successive CO-TPD cycles by decreasing in size and shifting to lower temperatures. By the 4<sup>th</sup> cycle the main desorption peak was at 500 K, and the total number of CO molecules desorbing had decreased to half the value in the 1<sup>st</sup> cycle.

**CO-TPD of  $\text{Ru}_3/\text{TiO}_2$ .** Fig. 1b–d shows the CO-TPD of  $\text{Ru}_3$  on the three  $\text{TiO}_2$  substrates; (b) NS- $\text{TiO}_2$ , (c) LDS- $\text{TiO}_2$  and (d) HDS- $\text{TiO}_2$ . For each substrate, a “Blank” CO-TPD measurement with no clusters was also performed for 3 cycles, which are shown as average spectra in the figures. For the NS- $\text{TiO}_2$  substrate (Fig. 1b), the blank measurement shows 2 desorption features at

210 K and 380 K. The 1<sup>st</sup> CO-TPD cycle for the cluster-loaded  $\text{Ru}_3/\text{NS-TiO}_2$  features a similar CO-TPD spectrum to the 1<sup>st</sup> cycle on  $\text{SiO}_2$  (Fig. 1a). The peak at 180 K was still present when  $\text{Ru}_3$  clusters were deposited onto the  $\text{TiO}_2$  substrate but was reduced in size by approximately half. This was a result of the  $\text{Ru}_3$  binding to, and covering, these low temperature CO binding sites on the substrate. In addition, a shoulder peak at 380 K and a large desorption peak at 560 K (the main peak) now appear. These appeared to be shifted versions of the 260 K and 530 K peaks present for the  $\text{Ru}_3/\text{SiO}_2$  sample.

The 2<sup>nd</sup> and 3<sup>rd</sup> heating cycles for  $\text{Ru}_3/\text{NS-TiO}_2$  (Fig. 1b) have a consistent CO desorption shape which is different to that of the 1<sup>st</sup> cycle. They still have the 380 K feature from the 1<sup>st</sup> cycle, with a slightly increased height and width, but the 560 K main desorption peak has been completely removed. Thus, heating to

800 K caused the loss of the most strongly-binding and most numerous CO binding site on the Ru clusters. The increase in desorption of the 380 K peak after heating was not proportional to the loss in signal of the 560 K peak, indicating that after heating there were fewer CO binding sites available overall. The changes in the CO-TPD spectra cannot be associated with cluster agglomeration alone, because the result would be a CO desorption shape more like that of Ru<sub>3</sub>/SiO<sub>2</sub> on the 2<sup>nd</sup> to 4<sup>th</sup> CO-TPD cycles (Fig. 1a), where agglomeration occurred but the peak was not lost completely. As such, agglomeration was ruled out as the sole cause for the change in CO desorption after the 1<sup>st</sup> cycle. The XPS results for the XPS samples provided further insights into the loss of the main desorption peak, by providing evidence that heating to 800 K caused a change in oxidation state of the clusters. It is likely that the clusters were oxidised by the surface when heated, which blocked the main Ru-CO binding site. This is discussed further in detail below. Some agglomeration may have also contributed to the loss of the peak, which cannot be ruled out with this data.

The blank CO-TPD spectra for the sputtered substrates, namely LDS-TiO<sub>2</sub> and HDS-TiO<sub>2</sub> (Fig. 1c and d respectively) feature one main peak at 210 K, which was larger than that for the blank NS-TiO<sub>2</sub> (Fig. 1b). Because the CO desorption rate for the 210 K peak increased for sputtered TiO<sub>2</sub>, it is likely that this peak was related to CO adsorbed to defected surface regions on the blank TiO<sub>2</sub>. The second, 380 K peak present for the blank NS-TiO<sub>2</sub> was not present on blank LDS-TiO<sub>2</sub> or HDS-TiO<sub>2</sub>; however, the blank LDS-TiO<sub>2</sub> spectrum has a second, wider desorption feature at 500 K which may be a shifted version of the 380 K peak seen for the blank NS-TiO<sub>2</sub> sample (Fig. 1b). For the blank HDS-TiO<sub>2</sub> spectrum (Fig. 1d) there is no such desorption feature, which may indicate the 380 K feature for blank NS-TiO<sub>2</sub> was from CO binding sites on non-defected, pristine TiO<sub>2</sub> regions, and the binding site was modified by sputtering (for LDS-TiO<sub>2</sub>) before being lost completely at a higher sputter dosage (for HDS-TiO<sub>2</sub>).

The CO-TPD spectrum for the Ru<sub>3</sub>/LDS-TiO<sub>2</sub> sample (Fig. 1c) features a broad CO desorption peak for all cycles which was not seen for the blank sample, with deviation from blank at 550 K. For Ru<sub>3</sub>/HDS-TiO<sub>2</sub> (Fig. 1d) there was a similar deviation from the blank sample above 550 K, although the exact shape was not the same. None of the characteristic CO desorption features seen in the Ru<sub>3</sub>/SiO<sub>2</sub> sample were present for Ru<sub>3</sub> on either sputtered TiO<sub>2</sub> substrate. This means the clusters were interacting with the sputtered TiO<sub>2</sub> in such a way that all Ru-CO binding sites were blocked, both before and after the sample was heated for CO-TPD. Although agglomeration and/or oxidation may have contributed to the loss of Ru-CO binding sites, the complete loss of all sites suggests a different mechanism for the blocking of sites on LDS-TiO<sub>2</sub> and HDS-TiO<sub>2</sub> substrates. The cause of site-blocking for these samples was most likely that the clusters were not present on the outermost layer of the sample. This is expanded upon in detail in the Discussion section. There was good repeatability between the three CO-TPD cycles for both Ru<sub>3</sub>/LDS-TiO<sub>2</sub> and Ru<sub>3</sub>/HDS-TiO<sub>2</sub>, showing the resultant Ru/TiO<sub>2</sub> systems were stable and not changed significantly by heating to 800 K.

**CO-TPD of Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>.** The 1<sup>st</sup> cycle CO-TPD desorption shape for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> (Fig. 2) features a smaller peak at 300 K and a larger peak at 600 K. The CO-TPD shape is very similar to the 1<sup>st</sup> cycle of both Ru<sub>3</sub>/SiO<sub>2</sub> (Fig. 1a) and Ru<sub>3</sub>/NS-TiO<sub>2</sub> (Fig. 1b). The peak CO desorption rate from the 1<sup>st</sup> cycle in Fig. 2 is  $6.0 \times 10^{11}$  molecules per s, which is  $\sim 12$  times greater than that of Ru<sub>3</sub>/NS-TiO<sub>2</sub>, which had a maximum of  $5.2 \times 10^{10}$  molecules per s (Fig. 1b), and  $\sim 7$  times greater than Ru<sub>3</sub>/SiO<sub>2</sub> which had a maximum of  $8.3 \times 10^{10}$  molecules per s (Fig. 1a). This higher desorption rate must be due to a greater number of CO molecules bound per Ru atom on the ligated clusters, in addition to a  $\sim 3$  times greater surface coverage for the Ru<sub>3</sub>(CO)<sub>12</sub> sample. This was determined according to XPS atomic concentrations (at%) shown in Table 3 in the XPS results (*vide infra*). For the 2<sup>nd</sup> and 3<sup>rd</sup> cycles, the shape and intensity of the <sup>13</sup>CO desorption changes significantly from <sup>12</sup>CO in the 1<sup>st</sup> cycle (Fig. 2), and has a shape unique from that of the earlier CS-deposited samples. No characteristic Ru-CO binding sites are present which indicates the Ru-CO sites are being blocked, but there is a broad CO desorption peak from 180 K to 650 K, which retains the same shape and intensity between the 2<sup>nd</sup> and 3<sup>rd</sup> cycle. The similarity of the CO-TPD spectrum of the first cycle Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> and the first cycle Ru<sub>3</sub>/SiO<sub>2</sub> suggests that the Ru<sub>3</sub>(CO)<sub>12</sub> clusters do not agglomerate upon deposition onto TiO<sub>2</sub>.

There are differences between the 1<sup>st</sup> cycle CO desorption spectra of Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> (Fig. 2) and the 1<sup>st</sup> cycle spectra of the previously discussed CS-deposited samples; Ru<sub>3</sub>/SiO<sub>2</sub> (Fig. 1a) and Ru<sub>3</sub>/NS-TiO<sub>2</sub> (Fig. 1b). The Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> sample low temperature peak was at 300 K, while Ru<sub>3</sub>/SiO<sub>2</sub> and Ru<sub>3</sub>/NS-TiO<sub>2</sub> featured desorption peaks at 260 K and 380 K, respectively. Another difference between the 1<sup>st</sup> cycle CO-TPD spectra of the samples is the temperatures of the main, higher-temperature desorption peaks: 600 K for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>, 560 K for Ru<sub>3</sub>/NS-TiO<sub>2</sub>, and 530 K for Ru<sub>3</sub>/SiO<sub>2</sub>. This

Fig. 2 CO-TPD for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>. The <sup>12</sup>CO spectrum (CO ligands) is shown for the 1<sup>st</sup> cycle and <sup>13</sup>CO spectra (*in situ* dosed CO) are shown for the 2<sup>nd</sup> and 3<sup>rd</sup> cycles. <sup>13</sup>CO was only dosed in vacuum for the 2<sup>nd</sup> and 3<sup>rd</sup> cycles.

indicates that although the Ru–CO binding sites were similar in these cases, the highest binding energy site was strongest for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>, followed by Ru<sub>3</sub>/TiO<sub>2</sub>, then Ru<sub>3</sub>/SiO<sub>2</sub>. However, the main peak starts at ~400 K for each of these samples, and because the Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> sample extends to the highest temperature this may indicate it has a slightly wider range of binding sites with differing energies that were not individually resolved in the spectra. The difference in peak desorption temperatures for the large peak between the samples may be due to a combination of multiple effects. Firstly, the direct contact of clusters to the substrate for the bare Ru<sub>3</sub> may alter the electron density in the clusters and weaken the bond with CO compared to the ligated sample. Secondly, this could be due to less CO binding to the bare CS clusters, which affects the Ru–CO binding energy. Lastly, because Ru<sub>3</sub>/SiO<sub>2</sub> had the lowest peak temperature, it follows that the strong interaction between Ru<sub>3</sub> and TiO<sub>2</sub> stabilised the Ru–CO bonding when compared to the less strongly interacting SiO<sub>2</sub> substrate.

A key difference comparing the full set of CO-TPD cycles for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> (Fig. 2) to Ru<sub>3</sub> on sputtered TiO<sub>2</sub> (Ru<sub>3</sub>/LDS-TiO<sub>2</sub> and Ru<sub>3</sub>/HDS-TiO<sub>2</sub>, see Fig. 1) was that for the bare CS samples, Ru–CO binding sites were completely blocked for the as-deposited samples, but for Ru<sub>3</sub>(CO)<sub>12</sub> the sample needed to be heated in the CO-TPD procedure before Ru–CO sites were blocked. It would appear that the CO ligands on Ru<sub>3</sub>(CO)<sub>12</sub> prevented the Ru–CO sites from being blocked by the HDS-TiO<sub>2</sub> substrate until the ligands were removed by the heating process during the 1<sup>st</sup> CO-TPD cycle. That is to say, the cluster–substrate interaction which blocks the Ru–CO sites does not preferentially replace ligands which are already present on the clusters. The mechanism for this site blocking is discussed below in detail together with the CS-deposited samples. Since the clusters will pin to the defect sites on sputtered TiO<sub>2</sub>,<sup>48,49</sup> these ligated Ru clusters were likely to be well-pinned to the substrate and present as unique,

monodispersed cluster complexes before the ligands were removed due to heating. An additional difference is that the Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> was the only sample deposited *ex situ* and exposed to atmosphere. This caused the passivation of defect states in the titania due to interaction with atmospheric gasses (shown and discussed below in the XPS Results section). This most likely accounts for the differences in shape between the 2<sup>nd</sup> and 3<sup>rd</sup> cycle CO-TPD spectra between Ru<sub>3</sub>/HDS-TiO<sub>2</sub> (has a small feature at high temperature) and Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> (has a much broader desorption feature starting at a lower temperature); even after the ligand removal, the differing cluster–surface interaction between the Ru and titania due to the passivated defects of the CVD sample changed the resultant available CO sites on the modified substrate.

### XPS results

**Ti 2p region – surface defects.** The Ti 2p regions were measured for TiO<sub>2</sub> substrates and fitted using two sets of peak doublets, shown in Fig. 3a for NS-TiO<sub>2</sub> and Fig. 3b for HDS-TiO<sub>2</sub> as examples. The doublets correspond to the Ti<sup>4+</sup> and Ti<sup>3+</sup> oxidation states; for the 2p<sub>3/2</sub> state the former is found at 459.4 eV ± 0.2 eV, and the latter at 457.8 eV ± 0.2 eV. A higher Ar<sup>+</sup> sputter dose will yield more Ti<sup>3+</sup>, which is related to titania defect states. The fitting of Ti 2p is complicated by a changing background signal between the lower and higher BE peaks of the Ti doublets, which led to a consistent discrepancy between the measured and the fitted spectra for all samples in the region between the peaks. To reduce the relative uncertainty, the fitting and analysis procedure was kept consistent for all Ti 2p measurements. The procedure for determining the errors for the XPS measurements are described in the ESI.† The results from the XPS fitting procedure are shown in Table 2. Ti<sup>Total</sup> is the sum of both peak areas, and the ratio of Ti<sup>3+</sup>/Ti<sup>Total</sup> was used as an approximation for the concentration of surface defects for each substrate. As can be seen from Table 2, there is

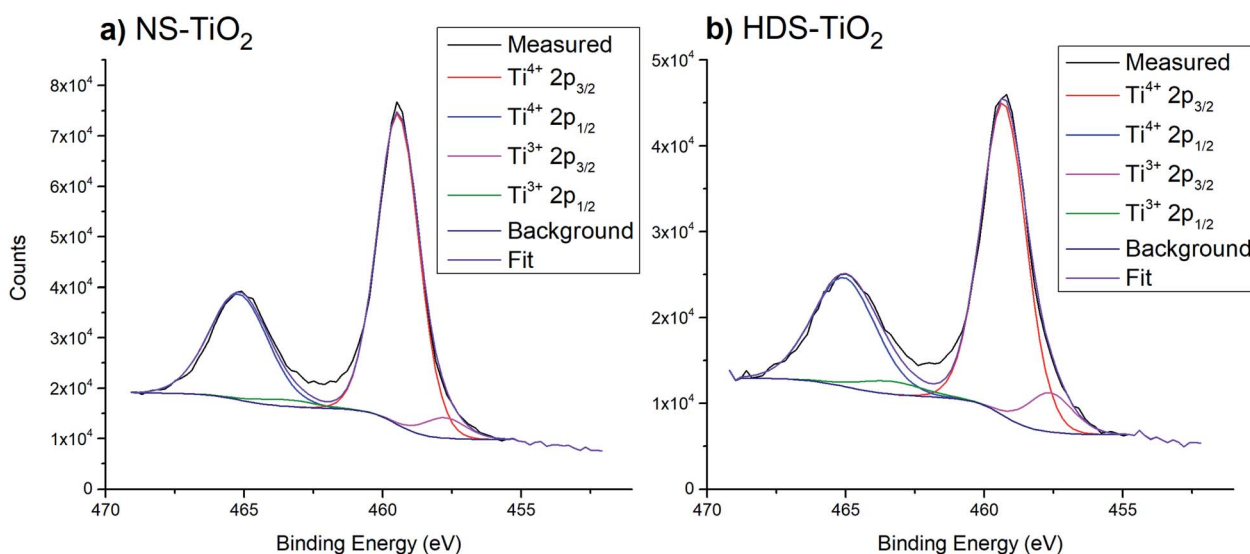

Fig. 3 Example peak fittings for Ti 2p region, after heating samples to 800 K. (a) NS-TiO<sub>2</sub>. (b) HDS-TiO<sub>2</sub>.

**Table 2** Summary of XPS atomic concentrations in % (at%) for  $\text{Ti}^{4+}$  and  $\text{Ti}^{3+}$  for blank and Ru cluster-loaded  $\text{TiO}_2$  samples. The  $\text{Ti}^{3+}/\text{Ti}^{\text{Total}}$  ratio in % was calculated according to  $\frac{100\% \times \text{at}\%(\text{Ti}^{3+})}{\text{at}\%(\text{Ti}^{\text{Total}})}$ . The uncertainty was  $\pm 1\%$  for  $\text{Ti}^{4+}$  at%, and  $\pm 15\%$  for both the  $\text{Ti}^{3+}$  at% and  $\text{Ti}^{3+}/\text{Ti}^{\text{Total}}$  ratio

a significantly higher defect density in the HDS- $\text{TiO}_2$  compared to NS- $\text{TiO}_2$ . The CVD samples were exposed to atmosphere and have a very low defect density. Further details are discussed in the ESI.†

**Ru 3d/C 1s region – clusters.** The main Ru 3d and C 1s peaks overlap in the same XPS region and were fitted together. No carbon was present in the stoichiometry of the substrate or clusters, excepting for ligated  $\text{Ru}_3(\text{CO})_{12}$ , and thus all carbon present was contamination on the surface or in the bulk structure of  $\text{TiO}_2$ . Three carbon peaks were used in the fitting, assigned to adventitious C–C at 285.0 eV; C–O ligands and contamination at  $287.0 \text{ eV} \pm 0.2 \text{ eV}$ ; and COOH at  $289.4 \text{ eV} \pm 0.2 \text{ eV}$ . These are consistent to previously reported assignments for carbon contamination on  $\text{SiO}_2$  substrates.<sup>68</sup> The COOH peak was often completely removed upon heating. Fig. 4 shows an example of the peak fitting for the Ru 3d and C 1s region of a cluster-loaded sample, and Fig. 5 shows XPS results for Ru clusters on  $\text{SiO}_2$  and  $\text{TiO}_2$  after deposition of the  $\text{Ru}_3$  clusters and specific treatments. A summary of all Ru 3d/C 1s XPS measurements with BEs, at%, and Ru surface coverage is shown in Table 3. A Ru 3d spectrum of a metallic Ru reference sample is also shown in the ESI,† where the  $\text{Ru } 3d_{5/2}$  peak is located at  $279.7 \text{ eV} \pm 0.2 \text{ eV}$  which is comparable to the BE reported by Morgan<sup>69</sup> for metallic Ru;  $279.75 \text{ eV}$ .

Based on the ratio of CO 1s at% to Ru 3d at%, the ratio of CO ligands to Ru atoms per cluster for the  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-}\text{TiO}_2$  sample was calculated to be  $\sim 1.3$  after the cluster deposition (at% results for this are presented in the ESI†). This suggests an approximate average formula of  $\text{Ru}_3(\text{CO})_4$ , indicating some ligands are lost during the CVD process. However, the atomic ratio should be treated as an estimation because it may be affected by any adventitious carbon adsorbed during the CVD process. The number of CO ligands remaining after CVD depositions will be analysed in more detail in a subsequent publication.

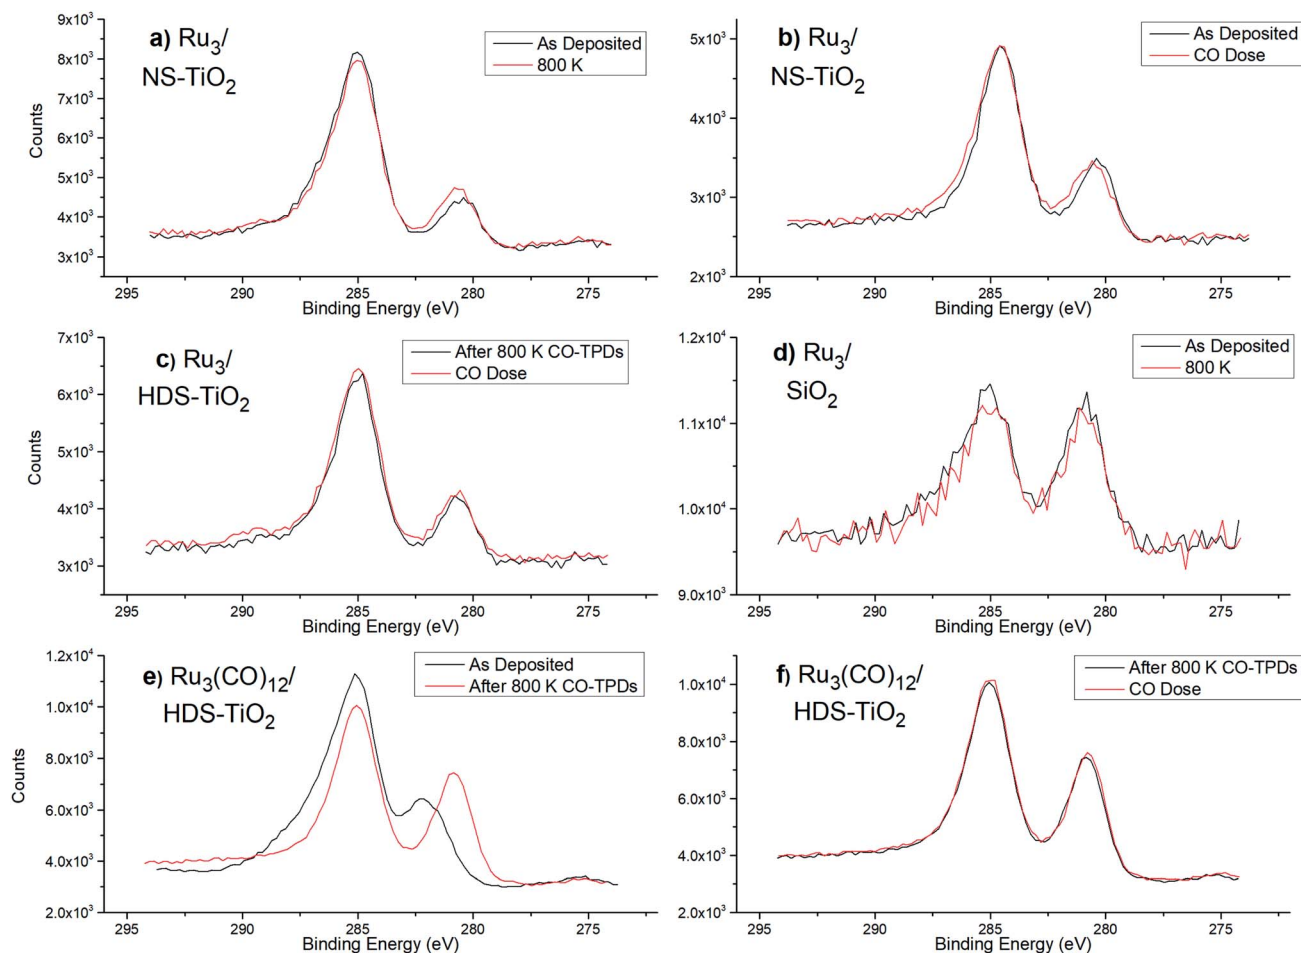

The surface coverage was greater for  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-}\text{TiO}_2$  than for all CS-deposited samples; for example, it is  $\sim 3$  times greater than  $\text{Ru}_3/\text{HDS-}\text{TiO}_2$ . However, all samples had only a fraction of a monolayer (ML) coverage ( $10.7\%$  ML maximum). Due to the low coverages, it was assumed any cluster–cluster interactions were negligible and the differences in cluster loading would not have significantly affected the properties of the clusters when making comparisons between samples.

For  $\text{Ru}_3/\text{SiO}_2$  the Ru  $3d_{5/2}$  BE was at  $280.7 \text{ eV} \pm 0.2 \text{ eV}$ , and there was no peak shifting due to heating to 800 K, indicating there was no detectable change in oxidation state (see Table 3). For as-deposited  $\text{Ru}_3/\text{NS-}\text{TiO}_2$ , the Ru  $3d_{5/2}$  peak is found at  $280.3 \pm 0.2 \text{ eV}$ , and after heating to 800 K it is found at  $280.5 \pm 0.2 \text{ eV}$ , thus shifting by  $+0.2 \text{ eV} \pm 0.1 \text{ eV}$  (Table 3). The increase in BE indicated the clusters had become more positively charged, and the BE moved further away from the value for metallic Ru  $3d_{5/2}$  which is  $279.7 \text{ eV} \pm 0.2 \text{ eV}$ . It should be noted that the relative error in peak position for the same sample before and after heating is smaller than the error for the absolute peak position. For  $\text{Ru}_3/\text{NS-}\text{TiO}_2$  the as-deposited Ru  $3d_{5/2}$  peak increases from  $280.2 \text{ eV}$  to  $280.4 \text{ eV}$  after dosing with CO, which indicates Ru–CO bonding is occurring (see Table 3). For  $\text{Ru}_3/\text{HDS-}\text{TiO}_2$  the Ru 3d BE was compared after heating to 800 K, and then dosing with CO ligands. No shift in Ru  $3d_{5/2}$  BE was detected which provides evidence Ru–CO binding sites were not available on this sample (see Table 3). If Ru–CO binding was occurring one would reasonably expect an increase in BE, as was the case for dosing CO onto  $\text{Ru}_3/\text{NS-}\text{TiO}_2$ . This is supported by the earlier CO-TPD results showing that there was no Ru–CO binding sites available for  $\text{Ru}_3/\text{HDS-}\text{TiO}_2$  (Fig. 1d). For  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-}\text{TiO}_2$ , the Ru 3d peak shifted by  $-1.4 \text{ eV} \pm 0.1 \text{ eV}$  to a BE of  $280.6 \text{ eV} \pm 0.2 \text{ eV}$  after heating, due to the loss of CO ligands (see Table 3). When

**Fig. 4** Example fitting for the Ru 3d/C 1s region; measurement of  $\text{Ru}_3/\text{HDS-}\text{TiO}_2$  after heating to 800 K.

**Fig. 5** XPS spectra of Ru 3d/C 1s region for bare  $\text{Ru}_3$  (a–d) and  $\text{Ru}_3(\text{CO})_{12}$  (e–f) on different substrates. Different surface treatments are being compared with XPS, and some spectra are repetitive. The lower BE peaks at 280.2–282.0 eV are from Ru 3d<sub>5/2</sub> and are the peak of interest to determine peak shifting. (a)  $\text{Ru}_3/\text{NS-TiO}_2$  – as-deposited, and after heating to 800 K. (b)  $\text{Ru}_3/\text{NS-TiO}_2$  – as-deposited, and after CO dose. (c)  $\text{Ru}_3/\text{HDS-TiO}_2$  – after CO-TPD to 800 K, and after CO dose. (d)  $\text{Ru}_3/\text{SiO}_2$  – as-deposited, and after heating to 800 K. (e)  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-TiO}_2$  – as-deposited, and after CO-TPD to 800 K. (f)  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-TiO}_2$  – after CO-TPD to 800 K, and after CO dose (performed in series with the measurement in (e)).

dosing CO onto the clusters after the 800 K heating, there was no detectable shift in the Ru 3d BE (see Table 3), indicating after heating the Ru–CO sites are also blocked for  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-TiO}_2$ .

This is supported by the earlier CO-TPD data which shows no characteristic Ru–CO desorption peaks for  $\text{Ru}_3(\text{CO})_{12}/\text{HDS-TiO}_2$  after the 1<sup>st</sup> CO-TPD cycle (Fig. 2).

**Table 3** Comparison of XPS results for different treatments of bare  $\text{Ru}_3$  and  $\text{Ru}_3(\text{CO})_{12}$  clusters on different substrates. Data is from peak fitting of the XPS spectra in Fig. 5. Ru 3d<sub>5/2</sub> BE, Ru at%, and Ru surface coverage are shown. Each row features XPS measurements before and after a sample treatment step, which have been separated into “Method 1” and “Method 2” (the method number only indicates the order of applying a treatment). Where none is shown for a method, this means the sample was as-deposited. Ru at% values are from method 1. For samples with an “800 K + CO Dose” method, the sample was cooled to 180 K before dosing. Both  $\text{Ru}_3(\text{CO})_{12}$  measurements were performed on a single sample. The uncertainty in BEs was  $\pm 0.2$  eV, while for BE differences the uncertainty was  $\pm 0.1$  eV. Ru at% was  $\pm 4\%$ . The absolute error in the surface coverage was  $\sim 100\%$  while the relative uncertainty was based on the Ru at% and was  $\pm 4\%$

## Discussion

As a brief summary of the results (*vide supra*), the adsorption of CO to CS-deposited Ru<sub>3</sub> clusters was completely blocked when clusters were deposited onto LDS-TiO<sub>2</sub> or HDS-TiO<sub>2</sub>, but this was not the case for SiO<sub>2</sub> or NS-TiO<sub>2</sub>. After Ru<sub>3</sub>/SiO<sub>2</sub> was heated to 800 K for a TPD cycle there was a decrease in temperature and size for the high temperature peak in the CO-TPD spectrum, while for Ru<sub>3</sub>/NS-TiO<sub>2</sub> heating caused the complete loss of the high temperature CO desorption peak. In XPS the Ru 3d BE for Ru<sub>3</sub>/NS-TiO<sub>2</sub> shifted to slightly higher energies after heating to 800 K, which is associated with a change in oxidation state of the clusters. The higher energy BE after heating to 800 K is shared in position by both Ru<sub>3</sub> and Ru<sub>3</sub>(CO)<sub>12</sub> on HDS-TiO<sub>2</sub>.

### Cluster agglomeration for Ru<sub>3</sub>/SiO<sub>2</sub>

For the Ru<sub>3</sub>/SiO<sub>2</sub> sample the decrease in temperature and size for the high temperature CO-TPD peak (Fig. 1a) was also associated with a decrease in total CO desorbing. This decrease cannot be explained by the clusters detaching or travelling into the substrate. First, once the clusters have adsorbed they are not likely to detach due to heating to 800 K because the bulk Ru boiling point is 4423 K.<sup>70</sup> Second, the clusters are unlikely to travel into the substrate because SiO<sub>2</sub> is fairly inert and does not interact strongly with supported clusters<sup>30</sup> or typically form an SMSI with supported metals at these temperatures and conditions.<sup>67</sup> This decrease in CO desorption peak size is therefore attributed to cluster agglomeration. When clusters form larger aggregates the ratio of surface atoms to internal atoms for the clusters is reduced, thereby reducing the total number of CO binding sites on Ru clusters and agglomerated Ru clusters available in the system. A decrease in CO peak size due to cluster agglomeration has similarly been seen in other CO-TPD studies, such as studies by Anderson and co-workers on CS-deposited Pt<sub>7</sub>/alumina and various sized Pt<sub>n</sub>/silica;<sup>71,72</sup> in these studies the CO-TPD spectra changed in shape with repeated TPD cycles to 700 K, where the higher temperature binding site similarly decreased in peak size and temperature. The agglomeration of Ru on SiO<sub>2</sub> was not surprising and is most likely due to the weak cluster–surface interaction between Ru and SiO<sub>2</sub>; previous studies have also shown agglomeration of small clusters on SiO<sub>2</sub> at temperatures below 800 K.<sup>63,73</sup>

In addition to aggregation of the Ru clusters, there is also most likely a change in either the cluster structure (beyond agglomeration) or cluster–surface interaction with repeated CO-TPD cycles; this is evidenced by the peak CO desorption temperature decreasing with each CO-TPD cycle, meaning CO is adsorbing less strongly to the clusters after agglomeration. This is also supported by earlier studies by Anderson and co-workers,<sup>59,71,72</sup> who have shown that for both Pt<sub>n</sub>/alumina ( $2 \leq n \leq 18$ ) and Pt<sub>n</sub>/silica ( $n = 4, 7, 12, 24$ ), the intensity of the high temperature CO-TPD peak increased as cluster size increased, but that repeated CO-TPD cycles caused the peak decrease in intensity and shift to lower temperatures. This provided evidence in the case of small Pt clusters that agglomeration

produces different structures than those produced by deposition of larger size-selected clusters.

By making reasonable assumptions, the increase in cluster size over the four CO-TPD cycles for Ru<sub>3</sub>/SiO<sub>2</sub> was estimated. The 4<sup>th</sup> cycle had 0.3 CO molecules desorbing per Ru atom compared to 0.6 CO per Ru atom in the 1<sup>st</sup> cycle (see Fig. 1a). Total CO desorption is proportional to the number of available CO binding sites. The simplest case to assume employs a model which disregards the individual atoms forming the clusters, instead considering hemispherical clusters pinned to the substrate where the number of binding sites is assumed to be proportional to the surface area (SA). If the bottom half of a hemispherical cluster is bound to the substrate and not available for binding to CO, then the available SA of the clusters would be given by eqn (1) for the surface area of a hemisphere.

$$SA_{(\text{hemisphere})} = 2\pi r^2 \quad (1)$$

Utilising the number of CO desorbing per Ru atom in each cycle, and the assumption that available binding sites are proportional to the available SA, the increase in cluster radius is calculated as per eqn (2) and (3). Subscripts correspond to the SA or radius of clusters in the 1<sup>st</sup> or 4<sup>th</sup> cycle.

$$\frac{0.6 \text{ molecules per atom}}{0.3 \text{ molecules per atom}} = \frac{SA_{(1\text{st})}}{SA_{(4\text{th})}} \quad (2)$$

By substituting in the relationship between SA and radius for each cycle from eqn (1) and simplifying the expression, the change in radius can be estimated.

$$r_{(4\text{th})} = 1.4 \times r_{(1\text{st})} \quad (3)$$

The Ru cluster radius increases by an estimated factor of 1.4 after 4<sup>th</sup> CO-TPD cycles. Given that there would be a range of aggregated cluster sizes, this should be treated as an average size. The diameter of supported Ru<sub>3</sub> is estimated to be 0.265 nm based on the interatomic Ru–Ru distance (bond length),<sup>74</sup> and the clusters therefore increase to an average diameter of 0.37 nm after the 4<sup>th</sup> CO-TPD cycle. The assumptions made in this calculation are rather simplified and must be taken with caution. The assumption of a hemispherical cluster is a rather simple model and likely deviates from the true structure of the supported clusters and also ignores the finite size of the atoms forming the clusters. The calculation also ignores any effects of the cluster structure and size, or the number of binding sites available per SA. For example, another possibility to describe the reduction in CO bond sites is a change from a Ru<sub>3</sub> cluster adsorbed flat on the surface into a 3-dimensional Ru<sub>6</sub> cluster (two Ru<sub>3</sub> clusters on top of each other) that prevents the lower 3 Ru atoms from being exposed to incoming CO.

### Assigning binding sites to CO-TPD features

In the CO-TPD spectra, differences in temperatures for CO desorption could be due to the CO binding to chemically different parts of the cluster (*i.e.* a different binding site) or due to differing cluster–substrate interactions affecting the cluster–

CO binding. The shape of the CO desorption trace between successive CO-TPD cycles can provide information about the location of the Ru–CO binding sites on the clusters. This has been attempted in similar experiments including a study by Labich *et al.*<sup>75</sup> of Rh particles supported on TiO<sub>2</sub>/Mg where an on-top position (away from the substrate, highest temperature) and two-fold coordinated bridge position (cluster–substrate bridging, medium temperature), as well as a third high-coverage state (low temperature) were identified. This study did not have sufficient TPD resolution to identify exact peak positions for the desorption features, but highlights the fact that when on a substrate, cluster–substrate  $\mu_2$  bridging bonds are also a possibility. This was also shown by Lee *et al.*<sup>76</sup> for Au<sub>3</sub> clusters on TiO<sub>2</sub>(110), who argued that CO was bound to the cluster–substrate interface when dosed under UHV because the low energy ion scattering spectroscopy (LEIS) signal for Au was not attenuated by CO adsorption. Regarding the nature of Ru–CO bonds, White *et al.*<sup>77</sup> suggested *via* a DFT study that the optimised structure for Ru<sub>3</sub>(CO)<sub>1</sub> features a 1.50 eV terminal  $\mu_1$  bond (CO bound to one Ru atom) while Ru<sub>3</sub>(CO)<sub>2</sub> features an additional bridging  $\mu_2$  bond (CO bound to two Ru atoms) with a higher average Ru–CO bond energy of 1.79 eV. This calculation was performed in the gas phase and although not directly comparable to supported clusters it importantly indicates that  $\mu_1$  and  $\mu_2$  bonding are possible.

The peaks will first be assigned for the Ru<sub>3</sub>/SiO<sub>2</sub> sample, which is treated as the baseline for comparisons. As mentioned in the ESI,<sup>†</sup> the accuracy of the absolute TPD intensity calibration is estimated to be ~50%. Fig. 1a shows that in the 1<sup>st</sup> cycle there was an average of 0.6 CO adsorbed per Ru atom, or 1.7 CO per Ru<sub>3</sub> cluster. Given the ~50% estimated accuracy, it is likely that most clusters had 2 CO per cluster after dosing. The clusters were agglomerated on SiO<sub>2</sub> with each successive CO-TPD cycle, and the main 560 K CO desorption site decreased in size successively while the smaller 260 K desorption feature increased in size after one cycle and then stabilized. As the clusters agglomerate, the total number of CO “edge sites” available where the cluster meets the substrate is expected to decrease. Understanding this helps to assign the two main features in Fig. 1a. The 560 K peak is most likely from a  $\mu_2$  cluster–substrate bridging site on the cluster edges; this is supported because the CO-TPD peak size decreases, due to a decrease in the number of edge sites that would occur on agglomeration (as discussed above), and because the higher binding energy of the site supports the likelihood of CO bonding to both the cluster and substrate. This peak also decreases in temperature, which provides evidence that the adsorption energy of CO to the cluster–substrate bridging sites decreases as clusters agglomerated, which would be related to a change in cluster charge density. The 260 K feature is most likely from an on-top binding site with  $\mu_1$  and/or  $\mu_2$  Ru–Ru bonding. The increase in the 260 K peak size after the 1<sup>st</sup> cycle may indicate that some amount of agglomeration promoted the number of on-top sites compared to edge sites. Regarding the CO-TPD samples on TiO<sub>2</sub> substrates, for Ru<sub>3</sub>/NS-TiO<sub>2</sub> the CO-TPD spectrum (Fig. 1b) is very similar to Ru<sub>3</sub>/SiO<sub>2</sub> in the 1<sup>st</sup> cycle. The assignment of peaks is therefore the same as for Ru<sub>3</sub>/

SiO<sub>2</sub> but with the peaks shifted in temperature. For bare Ru<sub>3</sub> on sputtered TiO<sub>2</sub> surfaces (Fig. 1c and d), no Ru–CO peaks are observed and there are no CO binding sites to assign.

For the ligated sample, Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>, the high temperature peak in the 1<sup>st</sup> cycle at 600 K appears to be a shifted version of the same feature as the high temperature peak for Ru<sub>3</sub>/NS-TiO<sub>2</sub>, and is assigned to cluster–substrate bridging sites. As previously discussed, this peak is wider in temperature than for the large desorption peak of either Ru<sub>3</sub>/NS-TiO<sub>2</sub> or Ru<sub>3</sub>/SiO<sub>2</sub>, which may indicate a wider range of binding energies for bridging sites in this sample, possibly as a result of the larger number of CO molecules per Ru atom. The peak at 300 K (Fig. 2) is assigned to on-top CO with  $\mu_1$  and/or  $\mu_2$  bonding, the same as for the other samples. The 1<sup>st</sup> cycle CO-TPD spectrum of Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> (Fig. 2) is similar to what Zhao *et al.*<sup>19</sup> previously measured for Ru<sub>3</sub>(CO)<sub>12</sub> on TiO<sub>2</sub>(110) when deposited by CVD at 300 K. However, a key difference is the peaks for Zhao *et al.* were higher at ~400 K and ~650 K, and the higher peak had an extra low-temperature shoulder not seen in Fig. 2. It is likely these differences are related to differences in cluster–surface interaction between the TiO<sub>2</sub>(110) used in that study and HDS-TiO<sub>2</sub> used in this study. Zhao *et al.*<sup>19</sup> did not assign binding sites to the CO-TPD spectra, however they interestingly discovered that the large, broad high temperature CO desorption feature was not present when Ru<sub>3</sub>(CO)<sub>12</sub> clusters were deposited by CVD onto a substrate at 100 K (instead of 300 K); the spectra instead had 5 smaller, narrow features.<sup>19</sup> This further supports the notion that the high temperature peak is related to cluster–substrate bridging, because this kind of binding would most likely be promoted when depositing onto a higher temperature substrate which can more easily interact with the clusters.

### Oxidation of Ru clusters

The Ru 3d BE for Ru<sub>3</sub>/NS-TiO<sub>2</sub> shifted higher to 280.5 eV  $\pm$  0.2 eV after heating (Table 3), and is comparable to studies in the literature<sup>18,19</sup> where O<sub>2</sub> was dosed onto Ru<sub>3</sub>(CO)<sub>12</sub> on TiO<sub>2</sub>(110) with heating to intentionally form oxidised clusters. In these cases, similar BE shifts were measured and absolute values for Ru 3d<sub>5/2</sub> were reported as 280.6 eV by Zhao *et al.*<sup>19</sup> and 280.8 eV by Rizzi *et al.*<sup>18</sup> The similarity between these and the present study provides context for the previously discussed loss of the main 560 K CO desorption peak for Ru<sub>3</sub>/NS-TiO<sub>2</sub> after heating to 800 K (Fig. 1b). The XPS peak shifting and CO-TPD results both point towards the oxidation of the Ru clusters, presumably due to an interaction with the oxygen in the supporting TiO<sub>2</sub> (O<sub>2</sub> was not dosed onto the clusters). The blocked CO-TPD peak is assigned to cluster–substrate bridging sites, and thus oxygen is either binding to these sites or sterically hindering the access of CO to the sites. The shifted Ru 3d<sub>5/2</sub> XPS peak is thus assigned to a partially oxidised form of the clusters. The increase in oxidation state can also be a reason for making Ru less attractive for binding to CO ligands. It should be noted that bulk Ru shows a BE shift of 1.6 eV upon oxidation<sup>69</sup> and that the BEs reported in the literature for oxidised Ru clusters are lower than those typically reported for oxidised bulk

Ru such as RuO<sub>2</sub>.<sup>69</sup> Thus, it is difficult to determine the exact oxidation state for Ru clusters on Ru<sub>3</sub>/NS-TiO<sub>2</sub>.

As-deposited XPS was not measured for Ru<sub>3</sub>/HDS-TiO<sub>2</sub> but at 800 K. However the BE for Ru 3d<sub>5/2</sub> at 800 K was 280.5 eV ± 0.2 eV, identical to that of Ru<sub>3</sub>/NS-TiO<sub>2</sub> (Table 3). Thus, the clusters are most likely oxidised by the TiO<sub>2</sub> surface upon heating to 800 K on HDS-TiO<sub>2</sub> in the same way as NS-TiO<sub>2</sub>. The BE for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-RF-TiO<sub>2</sub> after heating to 800 K is also the same as both Ru<sub>3</sub>/NS-TiO<sub>2</sub> and Ru<sub>3</sub>/HDS-TiO<sub>2</sub> within the experimental uncertainty, indicating that the initially-ligated clusters are also partially oxidised by the TiO<sub>2</sub> substrate once their ligands had been removed by heating. The CO-TPD results for Ru<sub>3</sub>/SiO<sub>2</sub> do not indicate any change in oxidation state of the clusters due to heating. It is also worth noting that in the case of Ru the cluster size does not seem to influence the BE, and thus the agglomeration discussed above on SiO<sub>2</sub> did not result in a change in BE, which is different to other metals like gold.<sup>31,78–83</sup> The lack of change in Ru oxidation state on SiO<sub>2</sub> is most likely due to the fact that it is a non-reducible oxide, while TiO<sub>2</sub> is a reducible oxide.<sup>65</sup> The removal of O<sup>2-</sup> from non-reducible oxides such as SiO<sub>2</sub> is energetically unfavourable and these oxides are more stoichiometrically stable and less reactive.<sup>65,66</sup> Evidence of the substrate-dependent oxidation of clusters has been shown in other studies, and oxidation is typical of the SMSI for clusters on metal-oxide supports.<sup>33,84,85</sup>

It is likely that the mechanism of cluster oxidation on TiO<sub>2</sub> is related to the minimisation of surface energy, where there is an energetic benefit for the system from the oxidation of Ru. The surface free energy of Ru at 298 K has been determined experimentally to be 3.409 J m<sup>-2</sup>,<sup>86</sup> while the surface free energy of RuO<sub>2</sub> was calculated in a separate DFT study as 1.1 J m<sup>-2</sup> for RuO<sub>2</sub>(110) and 1.4 J m<sup>-2</sup> for RuO<sub>2</sub>(100).<sup>87</sup> These two studies used different calculation methods and are not quantitatively comparable for determining the precise change in surface free energy, however the lower surface free energy of RuO<sub>2</sub> than Ru provides evidence for the surface-energy minimisation benefit of Ru oxidation. The reduction of surface free energy due to oxidation has been shown more explicitly using calculations for other transition metals.<sup>88</sup> This mechanism can also be considered in terms of the negative enthalpy of formation for oxidised Ru; the energy of formation of transition metal oxides is typically negative, meaning there is an energetic benefit for oxidation and the clusters would lose energy to their surroundings when an oxide is formed.<sup>89,90</sup> Both the surface energy and the enthalpy considerations have the same meaning.

Heating is required for Ru cluster oxidation on NS-TiO<sub>2</sub>. The as-deposited Ru<sub>3</sub> clusters on NS-TiO<sub>2</sub> showed the lowest oxidation state based on the XPS results, but the oxidation state increased upon heating to 800 K, even after the temperature was reduced. It is probable that for oxidation the transport of O<sup>2-</sup> anions on the substrate must be activated by heating such that they are mobilized and can be transported to the clusters; the idea of bulk TiO<sub>2</sub> defects becoming mobile at elevated temperatures and interacting with supported metals has been suggested previously.<sup>30,33,91</sup>

Zhao *et al.*<sup>19</sup> have previously deposited Ru<sub>3</sub>(CO)<sub>12</sub> by CVD onto TiO<sub>2</sub>(110). After heating and ligand removal the authors

found that the Ru 3d<sub>5/2</sub> peak was located at 279.9 eV, which is comparable to bulk Ru. They found by dosing 400 L O<sub>2</sub> under UHV at 600 K that the Ru peaks shifted higher to 280.6 eV, which they associated with oxidation of the clusters. The necessity for dosing O<sub>2</sub> contrasts with our results on NS-TiO<sub>2</sub> where the clusters were oxidised after only heating to 800 K under UHV. This serves to demonstrate the fact that the SMSI interaction depends greatly on the combination of cluster and substrate, even including different forms of the same material such as TiO<sub>2</sub>(100) in the work of Zhao *et al.*<sup>19</sup> and RF-deposited TiO<sub>2</sub> in this study. Zhao *et al.* estimated that the cluster coverage was 5% to 25% of a monolayer, which is comparable to this study, so surface coverage cannot be the reason for the difference in results.<sup>19</sup> It is most likely that the different outcome is related to the differences between RF-deposited TiO<sub>2</sub> and single crystal TiO<sub>2</sub>(110) substrates; it is possible that TiO<sub>2</sub>(110) is not as easily reducible, or that the surface energy is lower meaning there is less of a driving force for cluster oxidation in terms of surface energy minimization.

### Complete blocking of Ru–CO binding sites

The blocking or changing of some Ru–CO sites seen in the CO-TPD data have been above attributed to both agglomeration and oxidation. However, for Ru<sub>3</sub> on LDS-TiO<sub>2</sub> and HDS-TiO<sub>2</sub> all Ru–CO binding sites are completely blocked such that no CO is able to adsorb to the clusters when dosed under UHV. The Ru–CO blocking cannot be associated with agglomeration only as this would result in CO-TPD spectra like that of Ru<sub>3</sub>/SiO<sub>2</sub> (Fig. 1a), or oxidation only as this would result in CO-TPD spectra like that of Ru<sub>3</sub>/NS-TiO<sub>2</sub> (Fig. 1b). For Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>, the Ru–CO sites were present in the 1<sup>st</sup> CO-TPD cycle (before the ligands were desorbed) but were completely blocked in the 2<sup>nd</sup> and 3<sup>rd</sup> cycles after heating to 800 K. This result also contrasts the previously mentioned study by Zhao *et al.*<sup>19</sup> where XPS peak shifting was used to show Ru–CO binding was not blocked for Ru<sub>3</sub>(CO)<sub>12</sub> on non-sputtered TiO<sub>2</sub>(110) even when heated to 700 K.

For cases where Ru–CO sites are completely blocked there seems to be another reason for the complete loss of Ru–CO sites besides agglomeration or oxidation. The fact that Ru–CO sites were only completely blocked if RF-TiO<sub>2</sub> was sputter treated, in addition to the differences between depositions onto RF-deposited TiO<sub>2</sub> in this study and TiO<sub>2</sub>(110) in other studies,<sup>19</sup> raises a question about the mechanism of site-blocking. Encapsulation is another phenomenon which can occur for metals supported on a reducible oxide like TiO<sub>2</sub>. This involves the mass transport of substrate material to the top of the clusters, effectively covering them. This has been shown in the literature for several types of clusters on TiO<sub>2</sub> substrates, including the study by Fu *et al.*<sup>33</sup> of 1.5 nm Pd clusters grown on TiO<sub>2</sub>(110) as well as many other examples over the past few decades.<sup>32,34,55,75,92–96</sup> Encapsulation is related to the formation of an SMSI state, and there are various proposed reaction mechanisms for encapsulation in the literature, including thermodynamic drive to minimize the total surface energy of the system.<sup>33,75,92,93,96,97</sup> This mechanism is most likely to occur when

the surface energy of the metal is greater than the surface energy of the supporting oxide layer,<sup>33,75,93,97</sup> which is the case for Ru and TiO<sub>2</sub>; as indicated above, the surface energy of Ru is 3.409 J m<sup>-2</sup> and TiO<sub>2</sub>(110) has been calculated to be 1.78 J m<sup>-2</sup>.<sup>64,98</sup>

Given the propensity of TiO<sub>2</sub> to encapsulate surface adsorbates, it is possible that the complete loss of Ru–CO binding sites for Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub> is due to cluster encapsulation by the substrate material, possibly in combination with other phenomena such as oxidation and/or agglomeration. However, the occurrence of encapsulation is not entirely clear because the data does not directly show the encapsulation, only the indirect blocking of Ru–CO sites. From previous literature, varying conditions have been reported to induce cluster encapsulation which typically require high temperature reduction of the oxide substrate under UHV<sup>32–34,64,75,92–96,99,100</sup> or H<sub>2</sub>.<sup>101–105</sup> A notable similarity of the results here to encapsulation occurring in previous studies for Pd and Rh clusters on TiO<sub>2</sub>(110) is that sputtering of the substrate prior to cluster deposition was shown to be required for encapsulation.<sup>33,34</sup> In the present study, Ru–CO binding sites were only completely blocked for Ru<sub>3</sub> on sputtered TiO<sub>2</sub>, providing evidence that surface roughness and/or oxygen deficiency play a role in the state of Ru clusters on the surface. However, a key difference is that in the current study Ru–CO blocking occurs in as-deposited Ru<sub>3</sub>/HDS-TiO<sub>2</sub> with no heating required.<sup>33,34</sup> Thus, this may point towards a different site-blocking mechanism which is unique for the RF-deposited TiO<sub>2</sub> substrate. Other causes for the site blocking may be sub-surface defects caused by sputter treatment<sup>34</sup> which attract the clusters below the surface, or subsurface oxygen being more readily available for the Ru<sub>3</sub> than surface oxygen and the subsurface oxygen similarly attracting the clusters. To the best of our knowledge there have been no previous measurements for the encapsulation of size-selected Ru clusters on TiO<sub>2</sub> in the literature, although some encapsulation studies using similar Ru materials have been conducted.<sup>55,106</sup> Further insight into the mechanisms of interactions of Ru clusters with TiO<sub>2</sub> will be shown in a subsequent publication. It should be noted that the present work does not allow determining the change of the Ru cluster size due to the heating procedures applied. This will be subject to a subsequent publication.

The blocking of cluster–CO binding sites is not generally desired for catalytic purposes because CO adsorption capacity is reduced, which is the case for some samples in this study as well as other reports in the literature.<sup>33,34,75</sup> As such the results discussed can provide a framework for how to achieve Ru clusters on TiO<sub>2</sub> supports with available Ru–CO binding sites for the catalysis of reactions such as CO hydrogenation. While it is possible that conserving Ru–CO binding sites is important for catalytic activity, there have been cases which showed that if a covering layer is thin enough some combinations of cluster and covering layer can have an electronic structure which is suitable for catalysis without direct reactant–cluster contact.<sup>107–109</sup> In these cases, there can be extra benefits for catalysis such as increasing resistance to cluster agglomeration,<sup>107,108</sup> increasing catalytic reaction selectivity,<sup>109</sup> or improving catalytic activity by hindering back reactions which

remove reaction products.<sup>108</sup> As such, catalysis measurements are necessary for experimental verification of this framework.

## Conclusions

For Ru<sub>3</sub> CS-deposited onto SiO<sub>2</sub>, heating the clusters to 800 K caused cluster agglomeration. Conversely, for Ru<sub>3</sub> CS-deposited onto NS-TiO<sub>2</sub>, the clusters remained on the surface but were oxidised by the substrate when heated to 800 K, resulting in the loss of the main CO binding site. This indicated oxygen either bound to the same sites as CO or bound in such a way that CO was sterically hindered, or Ru was less attractive for binding to CO due to an increase in oxidation state. When the TiO<sub>2</sub> substrate was Ar<sup>+</sup> sputter treated before CS-depositions the Ru–CO binding sites on the clusters were completely blocked by the substrate as-deposited. For Ru<sub>3</sub>(CO)<sub>12</sub>/HDS-TiO<sub>2</sub>, the clusters retained their Ru–CO sites as-deposited but after heating to 800 K the ligands were removed, and the Ru–CO sites were completely blocked. It is possible given the lack of Ru–CO binding sites that the catalytic abilities of the small Ru clusters will be reduced when supported on sputtered TiO<sub>2</sub>.

We have developed a set of deposition criteria for Ru<sub>3</sub> clusters to retain their Ru–CO binding sites when supported on RF-deposited TiO<sub>2</sub>. For CS depositions the Ru–CO sites will be blocked if the substrate is sputter treated prior to deposition, but when depositing Ru<sub>3</sub>(CO)<sub>12</sub> by CVD the CO ligands are retained on a sputtered substrate. In both cases heating to 800 K will cause cluster oxidation (a partial loss of CO sites) and/or complete Ru–CO blocking. The mechanism for complete Ru–CO blocking on sputtered TiO<sub>2</sub> could not be precisely determined from the presented results, but comparisons to similar studies of metal/TiO<sub>2</sub>(100) interfaces point towards an interpretation that the clusters were encapsulated by a layer of substrate material. A key difference to previous studies was that no heating was required for Ru–CO blocking to occur, possibly pointing to a unique mechanism for site blocking by RF-deposited TiO<sub>2</sub>.
