From shaping to functionalization of microdroplets and particles

Ryungeun Song,^a Seongsu Cho,^a Seonghun Shin,^a Hyejeong Kim^{*b}
and Jinkee Lee ^{*ac}

The structure of microdroplet and microparticle is a critical factor in their functionality, which determines the distribution and sequence of physicochemical reactions. Therefore, the technology of precisely tailoring their shape is requisite for implementing the user demand functions in various applications. This review highlights various methodologies for droplet shaping, classified into passive and active approaches based on whether additional body forces are applied to droplets to manipulate their functions and fabricate them into microparticles. The passive approaches cover batch emulsification, solvent evaporation and diffusion, micromolding, and microfluidic methods. In active approaches, the external forces, such as electrical and magnetic fields or optical lithography, are applied to microdroplets. Special attention is also given to latest technologies using microdroplets and microparticles, especially in the fields of biological, optical, robotic, and environmental applications. Finally, this review aims to address the advantages and disadvantages of the introduced approaches and suggests the direction for further development in this field.

1. Introduction

Microdroplets are 1–1000 μm in size and can be transformed into emulsions and microparticles according to their composite materials and their thermodynamic status (Fig. 1, inner core).^{1–6} Since microdroplets possess a wide range of structural and functional abilities, they are important for numerous applications in fields such as biomedical, food, pharmaceutical, environmental, robotics, and energy.^{7–13}

Emulsions are thermodynamically stable dispersions of liquid mixtures consisting of at least two immiscible liquids, such as oil and water.^{14,15} The emulsions are designated as A/B emulsions, indicating that phase A is covered by phase B (*i.e.* W/O emulsion means that the aqueous phase (W) is covered with the oil phase (O), and *vice versa*).¹⁶ The complexity of the emulsions increases due to their unique and various geometries such as Janus, Cerberus, or multilayer emulsion forms, and also by their composition, *e.g.* containing polymers, nanoparticles, biomolecules, or using mixtures of surfactants.^{6,17–19}

Microparticles are solid or gel particles composed of various natural or synthetic substances, such as polymers, lipids, or ceramics.^{8,20–22} Colloidal nano/microparticles are also used to generate colloidosome microparticles in the form of

microcapsules in which colloidal particles are tightly packed as the building blocks for the shell.^{23–27} The utilization of microdroplets as templates allows the production of versatile microparticles with their shapes largely relying on those of the

droplets.²⁸ The precisely controlled emulsion templates are physically or chemically treated for solidification, for example, *via* gelation or crystallization.^{29–32} Beyond the materials used, the structure and the shape also determine the properties of the microparticles. With the recent mature development of micro-fabrication techniques, microparticles are produced in a variety of shapes.

In general, the overall physicochemical properties of the microdroplets are largely governed by both their structures and component materials. Therefore, the consistent and controllable creation of the unique structures of microdroplets is desired in order to meet the ever-increasing demands of microdroplets in various applications.³³ This review mainly focuses on introducing the methodologies to generate microdroplets and transforming them into various functional shapes of emulsions or microparticles. The methods are classified into passive and active approaches based on whether additional body forces, such as electrical, magnetic, optical, and mechanical controls, are applied to droplets for their generation or shaping (Fig. 1, outer shell). To explain the explicit principles of each method, we focus more on introducing various morphologies of microdroplets that are manipulated by appropriate methods. The following contents are the latest applications for well-tailored emulsions or microparticles that have been widely applied, especially in the fields of biological, optical, robotics, and environmental applications (Fig. 1, middle shell).

2. Passive methods

Passive methods to manipulate the shaping of the microdroplets rely only on the interfacial forces on the interfaces of the immiscible liquids according to the thermodynamic principles of minimizing interfacial energy. To guide the direction of interfacial forces, well-tailored containers, surfactants or evaporation are used. Here, representative passive methods for manipulating the microdroplet shapes to make emulsions and microparticles using batch emulsification, solvent evaporation and diffusion, micromolding methods, and microfluidic methods are introduced.

2.1 Batch emulsification

The typical strategy for fabricating microdroplets on a batch-scale is the simple pipetting or vortexing of immiscible liquids, leading to emulsifying one phase into the other. The resulting topologies of the emulsified microdroplets are shaped based on the free energy balance between the liquids. The batch emulsification provides superiority in the easy and mass production of microdroplets, as compared to other relatively complex manufacturing methods such as microfluidics and micromolding.^{34–36}

Various shapes and complexities of the droplets have been designed by manipulating the chemical composition, volume ratio, as well as the number of the mixed solutions.^{37–39} One-step vortex mixing, the simplest type of emulsification on a batch-scale, was introduced to produce Janus emulsions by Friberg *et al.* and Guo *et al.* (Fig. 2A).^{40,41} The Janus emulsion was made

by emulsifying two immiscible oils, a vegetable oil (VO) and a silicone oil (SO), in an aqueous phase (W), so that each droplet consisted of two oils against the minor fraction of aqueous solution.⁴⁰ The configuration of the emulsions distinctly varied with the weight fraction of the aqueous solution to the total weight of the solution. When a fraction of aqueous solution exceeded 0.3, the simple Janus emulsions of (VO + SO)/W were predominant in the solution, while when the fraction was 0.1, most of the droplets were in forms of double Janus emulsions of (VO + SO)/W/VO, or triple Janus emulsions of (VO + SO)/W/VO/SO. This simple vortex mixing method was further developed to produce finely designed Janus emulsions.⁴² They quantitatively investigated the effect of the contact angle and the location of the contact plane between the phases on droplet morphology. The contact angle is related to the interfacial tension equilibrium at the contact line between the phases, and the location of the contact plane was determined by the volume ratio of VO/SO within individual droplets. By precisely adjusting the volume ratio of two oils and surfactant concentration, the anisotropic geometry, such as snowman and dumbbell shapes, and the size of Janus droplets could be designed.^{37–39,41,42}

The Cerberus droplets were produced by mixing three mutually immiscible oils with surfactants in aqueous solution (Fig. 2B(i)). Compared to Janus droplets, the Cerberus droplets provide an additional free dimension, allowing for more complex anisotropic geometries. The Cerberus droplets with various shapes, including linear-singlet and engulfed-linear, were obtained by varying the composition, volume ratio, and emulsification energy (Fig. 2(ii)). By polymerizing a specific component of the Cerberus droplets, anisotropic particles consisting of single, binary, and ternary components were produced with diverse morphologies (Fig. 2B(iii)).³⁴ For instance, by selectively polymerizing the Cerberus droplets consisting of two photocurable oils, *i.e.* ethoxylated trimethylolpropane triacrylate and methacryl oxypropyl dimethylsiloxane, and incurable fluorocarbon oil, microparticles with crescent moon, sphere-in-lens, and sandwich-Janus morphologies were obtained with homogeneous or multiple distinct chemical compositions.

In order to fine-tune the structure of droplets that were already formed, some researchers programmed the thermodynamic properties of the phases. Swager *et al.* explored the geometry alternation of the droplets in response to the temperature changes, which induced the phase separation of liquids, providing a simple and scalable approach of compartmentalization.³⁶ When vortexing at a temperature above the consolute temperature ($T_c = 22.65^\circ\text{C}$), above which phase separation could not occur, hexane and perfluorohexane were miscible and emulsified in an aqueous solution of Zonyl FS-300, which is a nonionic fluorosurfactant (Fig. 2C(i, ii)).⁴³ When cooling below T_c , the phase separation of hexane and perfluorohexane occurred and yielded double-emulsion droplets (Fig. 2C(iii, iv)). A similar phase transformation strategy of fluorocarbon was employed by Borden *et al.* to reversibly generate the disc-in-sphere geometry of emulsion droplets.⁴⁴ The perfluoropentane (C_5F_{12})/perfluorododecane ($\text{C}_{12}\text{F}_{26}$) liquid mixture was emulsified at a temperature higher than the melting temperature of C_5F_{12} .

When cooled to room temperature (25 $^{\circ}\text{C}$), C_5F_{12} was solidified to form solid disc structures, thereby generating endoskeletal droplets with disc-in-sphere structures (Fig. 2D(i, ii)). The disc shape of the inner core arose from the asymmetric growth of crystalline C_5F_{12} , where the interfacial transport (removal of latent heat and solute attachment) was faster in the radial direction than in the axial direction.

2.2 Solvent evaporation and diffusion method for the shaping of nano/microparticles

The solvent evaporation method is a versatile and facile technique for producing well-structured nano/micro-scale particles through the self-assembly of block copolymers (BCPs).^{45–48} A water-immiscible volatile solvent with BCPs is used as the dispersed phase, which is then emulsified with the aqueous phase containing a surfactant in order to form emulsion droplets. The subsequent removal of the solvent by evaporation or diffusion into the aqueous continuous phase converts emulsion droplets into polymeric particles.

The self-assembly of BCPs confined in a tiny droplet of hundreds of nanometers generated particles with a periodic structure.^{49–52} Jeon *et al.* investigated the interface-driven

morphological evolution of a diblock copolymer of polystyrene-*block*-polybutadiene (PS-*b*-PB) enclosed in O/W emulsion droplets with polystyrene-*block*-poly(ethylene oxide) (PS-*b*-PEO) and poly-butadiene-*block*-poly(ethylene oxide) (PB-*b*-PEO) as surfactants.⁵³ The emulsion droplets were solidified by the evaporation of the solvent, yielding PS-*b*-PB particles with unique external shapes and internal morphologies, which differed depending on the type of surfactant (Fig. 3A). When only PS-*b*-PEO surfactant was present, onion-like lamellar structured particles were formed, while with the mixed surfactants of PS-*b*-PEO and PB-*b*-PEO, prolate particles were formed due to the neutralization of the interfacial affinity for BCPs as well as the surfactant rearrangement at the interface.

Aside from the surfactant effect, the addition of polymer-coated surfactant nanoparticles also leads to dramatic changes in the shape of the particles.^{51,52} The nanoparticles modulate the interfacial interactions between the emulsion droplets containing BCPs and the surrounding amphiphilic surfactant. Meanwhile, by the selective crosslinking of the dispersed phase of self-assembled BCPs and the subsequent disintegration of the uncrosslinked phase, the complex structured particles, *e.g.* cylinders, Janus, ring, and disc structures, were fabricated from

the pre-formed BCP assemblies.^{49,54,55} Deng *et al.* produced polystyrene-*b*-poly(4-vinyl pyridine) (PS-*b*-P4VP) particles that were hydrogen-bonded with 3-*n*-pentadecylphenol (PDP), as the pre-formed BCP assemblies (Fig. 3B).⁴⁹ Subsequent disassembly of the BCP particles by breaking the hydrogen bond disintegrated the particles to produce individual components. The amount of PDP greatly influenced the structural change. When PDP was not included, a symmetrical copolymer of PS-*b*-P4VP was formed, which had ellipsoids with a stacked lamellar structure (Fig. 3B(i)). By disassembling the stacked PS-*b*-P4VP lamellar ellipsoids in ethanol, which is a good solvent for P4VP but not for PS blocks, nano-disc particles were obtained. The introduction of PDP into PS-*b*-P4VP induced the internal morphological transition to bud-like particles with stacking cup structures, and disassembling the stacked cups derived isolated particles with individual nano-cups (Fig. 3B(ii)). When PS-*b*-P4VP was self-assembled under strong confinement conditions, typically, where the particle size was less than 100 nm, colloidal molecules with various bulging 3D structures, *e.g.*, snowmen, dumbbells, triangles, tetrahedral, and raspberries, were synthesized (Fig. 3C).^{56,57} Bulges regularly protruded from the particle surface and the number of bulges increased depending on the particle size.

When the size of the emulsion droplet was increased to the microscale, polymer microparticles with controllable surface textures were produced by the interfacial instabilities of emulsion droplets.^{47,58} Emulsion droplets of solvent containing hydrophobic polymers or BCPs, such as polystyrene (PS) or PS-*b*-poly(methyl methacrylate), and fatty alcohol co-surfactants such as *n*-hexadecanol (HD) and *n*-cetyl alcohol (CA), were generated. The continuous phase was an aqueous solution with surfactant. As the organic solvent diffused and evaporated through the aqueous phase, a reduction in the interfacial area of shrinking emulsion droplets triggered interfacial instabilities to form wrinkled surfaces (Fig. 3D(i)). The surface textures of the particles could be precisely adjusted from smooth to rough textures by varying the surfactant concentration or the rate of solvent evaporation. For example, as the contents of CA increased from 0.1 to 3 mg mL⁻¹, the surface roughness of the particles gradually increased from slight to enhanced wrinkles (Fig. 3D(ii)).

The solvent evaporation method was also utilized to fabricate polymersomes which are vesicles surrounded by membrane walls composed of lamellae of BCPs.⁵⁹ A double emulsion, W/O/W droplets with a core-shell structure, was typically prepared with BCPs dissolved in the middle oil

phase.^{22,60,61} Evaporation of the solvent oil then led to the assembly of BCPs into monolayers at the oil–water interfaces, accordingly forming the polymer bilayers, polymersomes (Fig. 3E(i, ii)).^{60,61} By preparing the double emulsions with different numbers of inner aqueous droplets for the templates, non-spherical polymersomes could be produced, which encapsulated multiple compartments (Fig. 3E(iii)).⁶²

2.3 Micromolding methods for structured microparticle generation

In the conventional micromolding technique, a curable fluid is filled into shaped micromolds and it becomes solid particles with replicated shape *via* polymerization, thereby creating the specific three-dimensional microstructures in a simple,

scalable, precise and controllable manner.^{63–65} DeSimone *et al.* pioneered a technique, known as particle replication in a non-wetting template (PRINT), to produce monodisperse particles while simultaneously controlling the structure and function of the particles.^{66–68} They fabricated a perfluoropolyether (PFPE) mold with negative micro/nano features to imprint it on a liquid precursor compound. This mold was not wet with organic material, allowing liquid precursor entrapped within the mold features to be isolated and solidified into the target shape (Fig. 4A). The PRINT technology has evolved into an automated roll-to-roll system for the continuous and mass production of the particles.⁶⁹

In contrast to the studies in which particles formed replicated shapes of the mold, Choi *et al.* attempted to synthesize various shapes of particles with spherical, convex, concave, and

Fig. 4 Micromolding methods for structured microparticle generation. Janus forms, which differed from the original shapes of the molds by utilizing surface-tension-induced flow.^{65,70,71} Poly(dimethylsiloxane) (PDMS)-based micromolds fabricated from standard soft lithography were filled with photocurable poly(ethyleneglycol)-diacrylate (PEG-DA) solution. Once the wetting fluid (mineral oil) containing a photoinitiator was applied on top, the curvature of the PEG-DA solution was formed due to the interfacial tension between the wetting fluid and the photocurable fluid; thereafter, the photocurable solution polymerized to a uniform 3D curvature (*i.e.* concave or convex) and monodisperse spheres (Fig. 4B(i)).⁷² The curvature of the wetting fluid formed on the edge of the mold induced the pressure difference to cause the photocurable fluid to move toward the center of the mold and consequently formed a spherical droplet (Fig. 4B(ii)). With a similar strategy, Jung *et al.* demonstrated the fabrication of chemically functional and monodisperse hydrogel microspheres with a macroporous core-shell structure.⁷³ Highly uniform poly(ethyleneglycol)-based microspheres containing an aminopolysaccharide chitosan were fabricated utilizing surface-tension-induced droplet formation followed by polymerization-induced phase separation.

Choi *et al.* further reported the controlled fabrication of complex 3D shapes of microparticles based on the swelling of the mold and the capillarity between various wetting fluids (fluorinated oil, paraffin oil, PDMS 20 cP, and PDMS 5 cP) and the photocurable solution.⁷¹ When the PDMS-based mold was exposed to the wetting fluid, the mold swelled and this led to the spatial deformation of the inner photocurable solution. The solution was transformed into its final shape by the capillary force between the solution and wetting fluid and then solidified *via* ultraviolet (UV)-induced polymerization, whereby polymer particles with permanent structures were obtained.^{2,71} Multi-compartment microparticles with nonsphere/nonsphere and sphere/nonsphere configurations were fabricated by sequentially combining the above manufacturing processes. Fig. 4C(i)–(iv) show the concave-flat, microspheres enclosed in cuboid, concave-sphere/nonsphere, and tri-compartment microparticles (possessing spherical, concave, and convex shapes within a single particle), respectively.

On the other hand, microparticles with higher-order complex geometry could be produced by the layer-by-layer combination of the imprinted particles, named the stamped assembly of polymer layers (SEAL) method. McHugh *et al.* produced high-resolution microparticles by SEAL with a variety of materials, including biodegradable poly(lactic-co-glycolic acid) (PLGA).^{21,74} PDMS was used as an inverse elastomeric mold derived from a silicon wafer mold with complementary patterns etched by the microfabrication technique (Fig. 4D(i)). The PLGA was heated and pressed into the PDMS molds to produce the micro-components of interest, and then delaminated onto a separate surface such as a glass substrate. Subsequent layers for the final structure were assembled with micro-alignment through a layer-by-layer sintering process. In this way, SEAL facilitated the formation of large arrays of microstructures, including a 3D star, a two-layered table, and a three-layered chair (Fig. 4D(ii, iii and iv)). The core-shell particles

embedding the drug solution were also created by using the same SEAL strategy. The thermoplastic polymer containers were fabricated from the mold, filled with drug, and then sealed with polymer lids (Fig. 4E).

2.4 Microfluidic methods for complex structured microdroplet formation

Microfluidic systems offer a versatile route to produce highly monodisperse emulsions with unprecedented accuracy.^{75,76} Microfluidic droplet generator devices manipulate the discrete and small volumes (micro to femto liter) of immiscible fluids in a laminar flow regime. For generating microdroplets, an inner fluid, called the dispersed phase, is introduced into another immiscible fluid, named the continuous phase, thereby leading to a breakup of the inner dispersed phase into monodisperse droplets. The dripping of the inner fluid is a resultant of competing stresses between surface tension, which reduces the interfacial area, and viscous drag force, which drags the interface segment.⁷⁷

The glass capillary microfluidic device, which has been widely used, was first introduced by Weitz *et al.* in 2007.⁷⁸ Glass exhibits high strength and rigidity, high chemical stability, and transparency that facilitates internal flow.⁷⁹ The glass capillaries are heated and pulled into a fine tip, and aligned to a fluid path. In a coaxial flow device, a round capillary is aligned into a square one in which the continuous and dispersed phases flow in the same direction.⁷⁶ As the fluids flow, monodisperse droplets are periodically formed at the tip of the capillary orifice. In an alternate geometry of a flow-focusing device, the continuous and dispersed phases are introduced from the opposite side of the capillaries. The inner fluid is hydrodynamically focused by the outer fluid and ruptured into tiny droplets at the narrow-tapered orifice. The co-flow and flow-focusing geometries can be combined and repeated in a manner for producing multiple emulsions (Fig. 5A).^{75,76,80}

PDMS-based microfluidic devices mostly have the planar flow-focusing configuration mounted on a glass substrate (Fig. 5B).⁸¹ PDMS is by far the most widely used material for the microfluidic devices due to its advantages of transparency, flexibility, biocompatibility, and ease of mass-production.⁸² In addition, lithography techniques (soft-lithography and photolithography) allow for the fabrication of highly complex flow channels with high resolution down to $\sim 1\ \mu\text{m}$, allowing multi-functions to be realized in the microdevice. Despite these advantages, the lithographic technique still requires specialized equipment, expensive base materials, and considerable expertise.⁸³ As an alternate low-cost and simple method, for instance, acrylic-based microfluidics or paper-based microfluidics have been introduced (Fig. 5C and D).^{83,84} In this sense, Song *et al.* recently introduced a 3D printed modular microfluidic system for droplet generation (Fig. 5E).⁸⁵ The microfluidic designs were printed directly with a transparent UV-curable polymer by a high-precision 3D printer. Once properly cured, the modules were assembled with their unique connector design in a leak-free manner with minimal hydraulic resistance (Fig. 5E(i)). Since each individual module can be designed and assembled

for a specific purpose, this modular system has a high degree of flexibility for broader applications. They demonstrated that these integrated modules could produce and manipulate emulsion droplets ranging from single-phase to dual-core multiphase droplets (Fig. 5E(ii)).

Unlike the above examples in which additional flow-inducing pumps are required, Maeda *et al.* introduced a centrifuge-based droplet shooting device (Fig. 5F).⁸⁶ A typical tabletop centrifuge and a microtube, where a multi-barrelled capillary channel was built-in, were needed for particle synthesis. During centrifugation, the solution filled in each capillary barrel was pumped out due to centrifugal force, and formed pendant droplets at the tip of the capillary. The droplets detached from the orifice when centrifugal force surpassed the counteracting drawing force of interfacial tension.

2.5 Complex structured microdroplets and microparticles formed by microfluidics

Versatile designs of microfluidic devices enable the production of microdroplets with highly diverse structures where the number, content, volume ratio and size of the encapsulated droplets can be controlled.^{76,80,86–88} Wang *et al.* constructed a microfluidic device by the on-demand arrangement of three basic building blocks: (i) a droplet maker for generating droplets, (ii) a connector for merging droplets from different

droplet makers, and (iii) a liquid extractor for removing redundant fluid from the continuous phase.⁸⁷ This hierarchical microfluidic device enabled the generation of various high-order multicomponent multiple emulsions, such as quadruple-component double emulsions, quintuple-component double emulsions, quintuple-component triple emulsions, and even sextuple-component triple emulsions (Fig. 6A). Similarly, by using a multi-barrelled capillary for inner core fluid, particles possessing axisymmetric three-, four-, and six-compartment bodies were obtained (Fig. 6B).⁸⁶ The pendant droplets from each capillary, which contained sodium alginate solutions, were immediately gelated in a CaCl_2 solution reservoir so that the multi-compartment particles retained axially symmetric geometries with clear compartmental separations. Meanwhile, the hollow microcapsules with two different sides (Janus shells) could also be formed from the double emulsion templates (Fig. 6C).⁸⁹ Two co-flowing poly(*N*-isopropylacrylamide) (pNIPAm) photocurable streams, each of a different color, were used to encase the kerosene oil droplet and were emulsified with paraffin oil (Fig. 6C(i)). The curing of the pNIPAm droplets with UV polymerization and the removal of the inner kerosene oil phase by washing with isopropanol yielded the hollow microcapsules with two distinguishable halves (Fig. 6C(ii, iii)).

Copyright 2012 and 2014 Wiley-VCH. Copyright 2012 Nature Research.

In addition to the aforementioned spherical droplets, it is also possible to create non-spherical droplets with microfluidics. Zhao *et al.* employed a capillary microfluidic device composed of four inner capillaries, one middle and one outer capillary for the generation of elongated rod-like double emulsion templates consisting of multiple colloidal photonic crystal or magnetic-labeled ETPTA cores and a PEG hydrogel shell (Fig. 6D(i)).³⁰ The four-core double emulsion template was compressed by the outer capillary to form an elongated shape arrayed with four photonic crystal cores, followed by UV polymerization (Fig. 6D(ii)). Because the photonic crystal cores possessed distinct and extremely stable reflection wavelengths, the polymerized microparticles were applied as a barcode system. The non-spherical droplets were also generated by using the Janus droplet templates where the interfacial forces of the three liquid phases were precisely controlled.^{17,32} Guzowski

et al. examined the microdroplets made up of multiple Janus droplets, *i.e.*, an arbitrarily long chain of immiscible droplet segments (Fig. 6E).¹⁷ When droplets of two immiscible liquids were brought into contact with a third host liquid, three equilibrium topologies appeared, depending on the interfacial tensions between the three liquid phases, *i.e.*, non-engulfing, complete engulfing, and partial engulfing configurations (Fig. 6E(i)). The multiple Janus droplets could be generated by supplying partially engulfed two-liquid phases one after the other, carefully preventing the coalescence of the segments (Fig. 6E(ii)). In these droplet chains, the individual segments were bound by three interfaces: one with the external phase and two with the adjacent segments of the other phase. Accordingly, the segments formed interchangeable biconvex and biconcave particles. The synthesized biconvex and biconcave particles of less than 100 μm in diameter could be used as optical

microlenses. Nisisako *et al.* also showed the fabrication of biconcave polymer microlenses from ternary emulsion droplets (Fig. 6F).³² Monodisperse ternary emulsion droplets were produced, which contained a photocurable phase of a 1,6-hexanediol diacrylate (HDDA) and two non-curable segments of SO. In the ternary droplet templates (SO-HDDA-SO of the three-phase parallel stream), only the photocurable HDDA phase was selectively polymerized and SO phases were removed, whereby polymeric microparticles with two concave surfaces were formed. The radius of curvature of the lenses could be varied by controlling the flow rate ratios of the three phases within a microfluidic droplet generation device.

3. Active methods

Active methods utilize external energy input such as electric, magnetic, optic, and mechanical controls to modulate the microdroplet shape. The additional energy input modifies the force balance at the interface and thus manipulates interfacial instabilities.

3.1 Electrical method for manipulating microdroplets

When an electric field of strength E_0 is applied to the liquid droplet submerged in another low-conductive immiscible liquid, free charge in both liquid phases accumulates at the interface between the two immiscible fluids, inducing electrical stress and electro-hydrodynamic flow around the droplet. The

electrical stress causes the electro-hydrodynamic deformation of the droplet, which was theoretically explained by Taylor with a 'leaky dielectric model'.⁹⁰ This model scales the electrical stress under a DC electric field applied to the droplet as $f_E \sim \Omega(R,S)Ca_E$, where $R = \sigma_{in}/\sigma_{out}$ and $S = \epsilon_{in}/\epsilon_{out}$ represent electrical conductivity (σ) and the permittivity (ϵ) ratio of the droplet (in) and the outside liquid (out), respectively. The electric capillary number ($Ca_E = \epsilon_{out}E_0^2a/\gamma$) is the ratio of electric force to interfacial force, where a is the droplet radius and γ is the interfacial tension. The droplet deformation type is classified according to the ratio of R and S . For instance, a castor oil (CO)/silicone oil (SO) droplet is deformed into the prolate (PR) shape when $R/S > 1$, and into the oblate (OB) shape when $(R/S < 1)$ (Fig. 7A).^{91–93}

The deformation of a multi-phase emulsion droplet could be described in the same way as that of a single emulsion droplet. For example, under a weak electric field, the spherical double emulsion droplet is deformed into PR-PR, PR-OB, OB-PR, and OB-OB (inner–outer interface; PR stands for prolate and OB stands for oblate) according to the R/S across each interface.^{94–97} When the electric field strength increases, the emulsion droplet becomes unstable and eventually breaks up, which has been studied for various applications.^{98–100} Abbasi *et al.* reported the various breakup modes of double emulsion droplets, CO/SO/CO and W/SO/CO, under a DC electric field (Fig. 7B).^{101,102} In this system, the volume ratio of the core and shell (β), electric capillary number (Ca_E), and interfacial tension (γ) decided the breakup modes of the core droplet, and depending on the

mode, the broken double emulsion droplet turned into an asymmetric Janus droplet or ternary droplet when removing the electric field. They plotted these results and their theoretical criteria for changing from mode I to II in a β vs. Ca_E parametric space.

Particle-covered droplets, called a colloidosome or Pickering emulsion, are one of the typical templates for making functional particles. Initially, Singh and Auory used an AC electric field to bind or remove particles from the droplet interface.^{103,104} Dommersnes *et al.* reported that particles anchored at the interface were structured in the form of a belt (non-conductive particles) or chain (conductive particles) under the DC electric field.¹⁰⁵ This work was extended to study the effect of electric conductivity, size, and coverage of particles on the degree of deformation and shape of droplets (Fig. 7C).¹⁰⁶ A SO/CO droplet without particles, and a droplet covered with particles in low coverage (~ 0.1 area fraction) were similarly deformed into an oblate shape. On the other hand, at high particle coverage (over 0.4 area fraction), the droplet was deformed in an oblate shape (non-conductive particle) or a prolate shape (conductive particle), as the particles had more influence on the droplet deformation.^{92,107–109}

Under an electric field, two droplets attract each other by electrostatic forces and subsequently merge into one droplet, which is commonly referred to as electro-coalescence.^{110–112} Rozynek *et al.* coalesced the Pickering droplets *via* an electric field to produce well-tailored Janus and patchy capsules (Fig. 7D).^{113–115} When applying the DC electric field to the two droplets covered with particles, the non-conductive particles were actively structured in a belt shape on the droplet interface. Then two droplets with belt-like structures attracted each other and coalesced to form a densely packed Janus droplet. In the same manner, an asymmetric Janus capsule was made by adjusting the size of each droplet and particle concentration, and a multipatchy capsule was produced by repeating electro-coalescence.

Other methods of producing functional droplets or particles using an electric field include electro-spraying or jetting, which are electro-hydrodynamic atomization methods where micro/nano-size droplets are massively produced by electrical stress at the tip of the nozzle. For the production of multifunctional particles or the material encapsulation, a co-axial electro-jetting method has been reported, which supply multiple compartments with one nozzle.^{116,117} The effect of the concentration and flow rate of the polymer solution on the morphology of biphasic particles during the electro-hydrodynamic co-jetting process was investigated (Fig. 7E).^{118,119} Disc-shaped particles were generated from low concentration solutions (up to 3.4 wt% of poly(lactide-co-glycolide) solution), whereas the spherical particles were produced from higher concentration solutions. The rod-shaped particles were made only under specific conditions with a solution concentration of 3.4 wt% and a flow rate of $\sim 0.45 \text{ mL h}^{-1}$.

3.2 Magnetic method for manipulating microdroplets

A magnetic force acts locally on the magnetic reactive materials, and this force can be applied to various applications, such as in drug delivery,¹²⁰ micro-swimmers,¹²¹ and oil/water separation,¹²²

where particles or structures have to be individually manipulated. A ferrofluid, widely used as a material for magnetic droplets, is a stable colloidal suspension composed of ferro- or ferrimagnetic nanoparticles (such as iron oxide nanoparticles) that are dispersed in a carrier liquid (organic solvent or water).¹²³ This liquid exhibits a reversible shape change as it is magnetized and demagnetized with or without a magnetic field. When a uniform magnetic field (H) is applied to a spherical ferrofluid droplet suspended in a non-magnetizable immiscible fluid, the droplet is elongated in the direction of the field (prolate shape) (Fig. 8A).^{124–126} This phenomenon is equivalent to the aforementioned deformation of the conductive droplet suspended in a low-conductive liquid by the electric field. Landau and Lifshitz derived an analytical model for the aspect ratio of deformed droplets under a low magnetic field as a function of magnetic bond number ($Bo_m = \mu_{out} H^2 a / \gamma$, where H and μ are the magnetic field strength and magnetic permeability, respectively), which indicates the ratio of the magnetic force to the interfacial force between the droplet and the carrier liquid.¹²⁷ Afkhami *et al.* revealed that the aspect ratio of the droplet gradually increased with Bo_m , corresponding to the analytical model at low magnetic field, while the deformation of the droplet deviated at high magnetic field as the interfacial tension varied with the magnetic force.¹²⁴

Zhu *et al.* studied the deformation of an aqueous sessile ferrofluid droplet on a hydrophobic substrate by a uniform magnetic field applied in a direction parallel to the substrate surface (Fig. 8B).¹²⁸ A comparison of experimental and numerical results showed that the non-linear elongation of the ferrofluid droplet in the direction of the field occurred due to the non-linear magnetization of the ferrofluid known as Langevin's magnetization law.¹²⁹ On the other hand, Timonen *et al.* applied a vertical magnetic field to a superhydrophobic surface on which a ferrofluid sessile droplet was placed, and observed the deformation of the droplet into a spiked cone shape due to the magnetic field gradient in the vertical direction (dH/dz) acting on the droplet.¹³⁰ Vieu *et al.* expressed this phenomenon in a theoretical manner.¹³¹ When the magnetic field strength was further increased, the ferrofluid droplet split into two smaller droplets at the critical field strength (Fig. 8C). However, the deformation of ferrofluid droplets induced by the magnetic field could not retain their shape when the field was withdrawn because of the nanoparticles' superparamagnetism. To fabricate the supraparticles with permanent unique shapes, Hu *et al.* proposed a method of irreversibly deforming aqueous ferrofluid droplets using an evaporation-guided colloidal assembly with an external magnetic field.¹³² They observed the differently shaped particles by controlling the magnetic field strength and the concentration of Fe_3O_4 /polystyrene (mgPS) nanoparticles in the ferrofluid as depicted in Fig. 8D(i). Binary supraparticles were produced by drying a co-suspension of mgPS nanoparticles with titanium dioxide or polystyrene nanoparticles (Fig. 8D(ii)).

To diversify the structure of the droplets into more complex morphologies, Fan *et al.* tuned the magnetic field distribution *via* the shape or arrangement of permanent- or electro-magnets (Fig. 8E).¹³³ This technique enabled the simultaneous control of the morphology and the spatiotemporal position of the

ferrofluid droplet as a miniature soft robot for liquid cargo, channel valves, and so on.

In a microfluidic system, the ferrofluid is used as a dispersed phase to produce droplets whose size or morphology is precisely manipulated. The direction of the magnetic field determined by the position of the magnet is an important parameter to control the size and frequency of the generated droplet.^{134–136} For example, a magnet placed upstream of a T-shaped droplet generator delayed the breakup and increased the size of the droplet by pulling the ferrofluid. Conversely, a magnet downstream accelerated the breakup and reduced the size of the droplet.¹³⁷ Varma *et al.* applied the magnetic field after droplet generation to fabricate a magnetic Janus droplet (MJD).¹³⁸ When the Fe_3O_4 nanoparticles-laden droplet passed the magnetic field perpendicular to the flow direction, the magnetic nanoparticles were concentrated at the rear part of the droplet to form the MJD, followed by the UV polymerization for particle synthesis (Fig. 8F).

3.3 An optical method for fabricating complex-shaped microparticles

The aforementioned methods for the formation of microparticles using droplets as their template limit the shape of the particles to spherical shapes due to the interfacial tension, which instigates the droplet to maintain their spherical shape. To overcome this limitation, Dendukuri *et al.* introduced a one-step particle synthesis method called continuous-flow lithography (CFL) by combining the microscope projection

photolithography with PDMS-based microfluidic devices.¹³⁹ In CFL, a single-phase photocurable oligomer stream was exposed to a UV light pulse to produce functional particles with mask-defined shapes, such as triangular, rectangular, or hexagonal shapes with sharp edges. In the UV light, the non-polymerized lubricating layer of oligomers resulting from oxygen-aided inhibition near the PDMS walls allowed for polymerized particles to be flushed out by the stream. This method was improved to produce amphiphilic, nonspherical Janus particles by co-flowing immiscible photo-polymeric fluids in microfluidic devices.^{140,141} Fig. 9A demonstrates the synthesis of amphiphilic Janus microparticles using CFL-based polymerization. The mask-defined wedge-shaped particles were formed across two parallel laminar, co-flowing streams containing a hydrophilic oligomer (PEG-DA) and a hydrophobic oligomer (TMPTA).¹⁴⁰ Chung *et al.* purposed an optofluidic maskless lithography technique by replacing the photomask used in CFL with the programmable two-dimensional spatial light modulators.¹⁴² However, the use of high flow rates in the CFL limits the throughput of the sufficiently polymerized particles because the particles are smeared due to the finite pulses of UV light. To overcome this problem, Dendukuri *et al.* proposed a technique named stop-flow lithography (SFL), in which the oligomer was exposed to light pulses only when it was stationary.¹⁴³ The process of SFL consisted of three states as shown in Fig. 9B: (i) The flow was stopped by closing the valve; (ii) the array of particles was polymerized from the stationery monomer film by opening the shutter; (iii) polymerized particles were flushed out

A comparison of 10 μm tall particles with three different feature sizes (mask sizes are 6.25, 2.5 and 1.23 μm , respectively) formed using stop-flow lithography (SFL) (iv–vi), and continuous-flow lithography (CFL) (vii–ix); the scale bar is 10 μm . (C) Vertical flow lithography (VFL) for fabricating 3D anisotropic microparticles. By adjusting the combination of flow rate and UV exposure time, various 3D types of anisotropic particles were fabricated. (D) Fabrication of complex 3D-shaped particles with various combinations of photomasks and flow cross-sections formed by inertial flow. of the channel by opening the valve while keeping the shutter closed. A comparison of the particles synthesized using SFL *versus* CFL is shown in Fig. 9B(iv–ix). The particles formed using CFL were blurred beyond recognition, even for the largest particles that had a feature size of 6 μm , while those formed using SFL showed relatively good resolution at 6 μm and 2.5 μm ; even the 1.25 μm feature was visible but not sharp. Studies had also been conducted to expand the materials available for SFL, such as ceramics or metal oxides.^{144–146} Composite particles consisting of photopolymeric material and SiO_2 or Al_2O_3 particles were polymerized through SFL, and they were transformed into inorganic particles through sintering.

Recently, a modified flow lithography technique was proposed for the synthesis of microparticles with 3D anisotropy beyond 2D extruded shapes.^{147–149} Habasaki *et al.* presented vertical flow lithography (VFL), an application of stereo-lithography concepts to conventional flow lithography, which allowed better control over the fabrication of 3D anisotropic microparticles.¹⁵⁰ In VFL, the light exposure and photocurable resin flow directions were aligned to enable the stacking of multiple photopolymerized layers with controlled 2D shape and thickness (Fig. 9C). This technique demonstrated the formation of multilayered, tapered, and angular compartmental microparticles. Paulsen *et al.* combined inertial flow shaping with SFL to generate the complex 3D-shaped polymer particles.¹⁵¹ At finite Reynolds numbers ($\text{Re} = 10\text{--}100$), pillars strategically positioned inside the microchannels created deterministic localized vortices and additive complex flow shapes depending on the pillar size, placement, number of sequential pillars and

flow profiles, as illustrated in Fig. 9D(i). The 3D-shaped particles were created by the combination of geometry-induced flow deformation by fluid inertia and orthogonal masked UV polymerization (Fig. 9D(ii)).

3.4 Other methods

In addition to the aforementioned methods, various other approaches have been studied to shape microdroplets or microparticles. Although not all methods are covered herein, some representative methods are introduced, such as shear flow-driven, mechanical stretching, and gravity force-based methods.

Droplets subjected to shear flow due to the opposite movement of two parallel plates show ellipsoidal deformation inclined in the shear direction (Fig. 10A(i)).¹⁵² Since Taylor introduced the theoretical model,¹⁵³ the shear-driven deformation and inclination of droplets has been described as a function of capillary number ($\text{Ca} = \mu_{\text{out}} G a / \gamma$, where G is the shear rate, and a is the radius of the droplet) and the viscosity ratio of the continuous phase and dispersed phase ($\lambda = \mu_{\text{out}} / \mu_{\text{in}}$).^{154–156} The additional effects of nanoparticles and surfactants on shear-driven deformation were also investigated.^{157,158} For instance, Frijters *et al.* demonstrated the deformation and inclination of colloidal droplets and nanoparticle distribution due to shear flow through the numerical simulations (Fig. 10A(ii)).¹⁵² Alargova *et al.* combined the shear-driven deformation with the solvent evaporation method to fabricate rod-like particles with diameters between 0.5 and 3 μm , and

lengths of tens of micrometers (Fig. 10B).^{159,160} The polymer emulsion droplets (solution of SU-8 in γ -butyrolactone (GBL)) suspended in an organic medium (such as glycerol or its mixtures with alcohols or glycols) were subjected to viscous shear induced by an impeller. During the shear-driven deformation process, the GBL, which is soluble in the organic medium, diffused out of the emulsion droplets and left behind the rod-like solid polymer. This rod-like shape could be solidified by crosslinking with UV light, and also transformed into a banana-shape by applying heat before crosslinking.¹⁶¹

On the other hand, Ho *et al.* applied mechanical stress by stretching the polymer film surrounding the polystyrene (PS) particles to make them into monodisperse ellipsoidal particles.¹⁶² The polymer film containing the particles was fabricated by evaporating a suspension of monodisperse PS particles and polyvinyl alcohol solution. This film was heated rapidly to 200 $^{\circ}\text{C}$ in an oil bath (liquefying of PS particles) and stretched to the predetermined extent in order to convert the spherical

particles into ellipsoidal particles; the film was then cooled (scheme A in Fig. 10C). Champion *et al.* developed a similar method by changing the order of the liquefying and stretching steps (scheme B in Fig. 10C), and demonstrated that particles of various shapes could be generated by these two methods, such as worm-, UFO-, barrel-, and pill-like particles.¹⁶³

Gravitational force is also one of the attractive options for creating asymmetrical shapes of microdroplets. Typically, when the density difference between the liquid and the particle constituting the colloidal droplet is large enough, the particle settles down to form a Janus colloidal droplet as depicted in Fig. 10D.^{164,165} Another approach is to use the phenomenon that appears when a falling droplet impacts on a liquid-free surface. The physics of droplet impact has been studied with various Weber numbers ($We = \rho_d v^2 a / \gamma$, where v is impact velocity) and Bond numbers ($Bo = \rho_d g a^2 / \gamma$, where g is gravitational constant). When a droplet is impacted on the immiscible liquid surface, various modes such as hanging, intermediate, and wrapping are

observed, which are depicted in Fig. 10E(i).^{166–168} Xie *et al.* used the hanging mode to produce multiple Janus droplets by stacking different droplets (Fig. 10E(ii)).¹⁶⁶ When the impact velocity and droplet size were sufficiently small, the droplet hung stably beneath the interface between the air and liquid due to interfacial tension. Also, when a droplet impacted the miscible liquid surface, the droplet penetrated the surface, showing vortex generation (under low *We*) or jet formation (under high *We*).^{169–171} An *et al.* generated the torus-shaped particles in batch using the vortex ring formation phenomena (Fig. 10F).¹⁷² When a droplet passed the surface with a sufficient impact velocity, the droplet dissipated its energy by curling back the edge, resulting in deformation. During the deformation, liquid intermediates appeared with various intriguing non-spherical shapes including teardrops, jellyfish, caps, and donuts. By dripping a gellable nanoclay solution into the crosslinking buffer bath with precise control of the degree of crosslinking, various shapes of nanoclay vortex rings were gelled and formed vortex ring-derived particles. The mass-production of the particles was enabled with well-controlled size and shape by employing an electrospraying technique.

4. Applications of emulsions and microparticles

Various methods have been studied to control the shapes of microdroplets, which allow us to produce monodisperse emulsions or particles with complex structures on the micro/nano-scale in a high-throughput manner. Well-tailored emulsions or microparticles play important roles in fields such as biological, optical, robotic and environmental applications. Here, we cover the representative examples of these applications.

4.1 Biological applications

Microdroplets are optimal templates for the encapsulation of bio-agents^{173–175} or chemicals,^{176–178} thus the solidified polymeric particles or shells are useful as carriers for drug delivery.^{179,180} The polymer carriers could prevent the loss of the drug component until a target position is reached, and release an optimized dose of the drug in a programmed sequence by layered structures.^{181–183} For example, Mou *et al.* fabricated Trojan-horse-like stimuli-responsive microcapsules for the versatile programmed and sequential release of drugs (Fig. 11A).¹⁸⁴ The microcapsules composed of the stimuli-responsive polymers (chitosan, PEG-DA, and pNIPAm) with different triggering mechanisms could controllably load different contents in their separate capsule compartments and release each content in a predefined order and in a different manner. Shao *et al.* did *in vivo* antitumor tests to demonstrate the effectiveness of their near-infrared (NIR) light-triggered microcapsule, which inhibited tumor growth and prevented metastasis by releasing the encapsulated drug *via* NIR laser irradiation (Fig. 11B).¹⁸⁵

In such drug delivery applications, microparticles are ultimately injected into a body and play their role by flowing through blood vessels. In doing so, the size and shape of the

polymer carrier play an important role in the transport and adhesion to the target cell location, since they encounter various tortuous pathways within a body that are difficult to pass through during transportation.^{186–189} For instance, in order to pass through the interendothelial cell slits inside the spleen, the diameter of spherical particles must be less than 200 nm, but red blood cells with diameters of $\sim 10\ \mu\text{m}$, a large size relative to the spleen geometry, can pass through the spleen due to its non-spherical shape and flexibility.^{188,190} The shape of the particles could also affect their ability to release drugs through stable adsorption to the targeted vessel walls or cell membranes. Vahidkhah and Bagchi investigated the effect of particle shape on the margination, near-wall dynamics and adhesion within blood vessels *via* a three-dimensional numerical simulation.¹⁹¹ Their results revealed that the microparticles of different shapes interact differently with red blood cells, leading to different behaviours in the margination and adhesion of the particles, and oblate-shaped particles showed the highest overall particle adhesion efficiency (Fig. 11C).

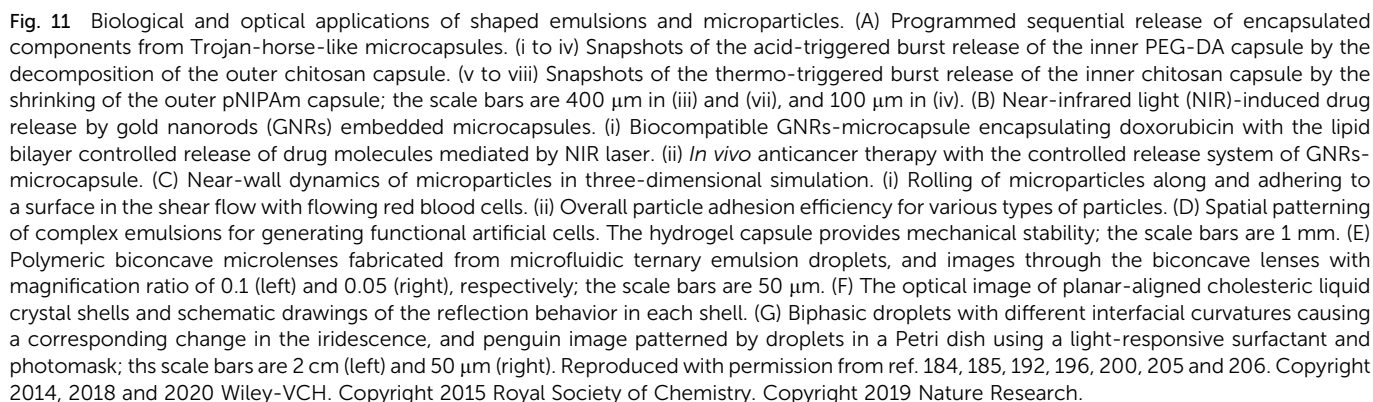

The fields of manufacturing artificial cells and studying interactions of microparticles with real cells have also been emerging. As the techniques for the production of complex microdroplets have advanced, some researchers have tried to fabricate artificial cells that mimic the hierarchical structures of real cells as depicted in Fig. 11D.¹⁹² Cell-laden microdroplet production with microfluidics is another promising application of microdroplets.¹⁹³ In particular, cell-laden microdroplets have been used for research on single-cells,^{194,195} 3D organ/tumors,^{196,197} and stem cell therapy.^{198,199}

4.2 Optical applications

Concave or convex interfaces of Janus or Cerberus emulsion droplets that scatter, diffract or interfere with light are attractive characteristics for optical applications. Nisisako *et al.* produced biconcave polymeric microlenses by first generating a SO-acrylate monomer-SO ternary emulsion droplet with a microfluidic device then removing the SO at both ends (Fig. 11E).²⁰⁰ The magnification ratio (*i.e.* observed image size over real image size) could be adjusted by the volume ratio of the ternary droplet. For example, a magnification ratio of a microlens produced from a droplet with a volume ratio of 2 : 1 : 2 was 0.1, whereas another microlens whose volume ratio was 1 : 3 : 1 showed a magnification ratio of 0.05.

Spherical emulsion droplets or shells composed of cholesteric liquid crystals could also manipulate their optical properties.^{201–204} For instance, microspheres of cholesteric (or chiral nematic) liquid crystals generated and manipulated the diverse photonic patterns due to selective reflection from a helical structure subject to continuously curved boundaries of liquid crystal shells (Fig. 11F).²⁰⁵ On the other hand, Goodling *et al.* also reported that Janus droplets consisting of heptane (refractive index = 1.37) and perfluorohexane (refractive index = 1.27), which are not liquid crystals, could also generate iridescence by total internal reflections and interference at microscale concave interfaces.²⁰⁶ The internal interfacial curvature of the Janus droplet caused a corresponding change

materials are necessary. A common way to make an anisotropic micromotor is to make Janus microparticles that contain catalytic materials, such as Pt, Ag, and TiO_2 , on one side of the microparticles, which are capable of performing tasks of inducing chemical reaction.^{214,215} Depending on the size of the microparticle, the driving mechanism of the propulsion can be varied; (i) the bubble propulsion on a scale of tens of micrometers, (ii) the diffusion and electrochemical driven propulsion on a scale of a few micrometers, and (iii) fast rotational diffusion without directionality on a submicrometer scale (Fig. 12A).²¹⁵ As an example of bubble propulsion swimming, Chen *et al.* introduced the multifunctional micromotor using Janus emulsion templates incorporating Ag nanoparticles and Fe_3O_4 magnetic nanoparticles into each part, where TiO_2 nanoparticles were also deposited on the surface of the

To induce the directional movement of micromotors, precisely engineered anisotropies in 3D structures or in

micromotor (Fig. 12B).²¹⁶ For the Janus micromotor, the bubble was generated under the catalysis of Ag nanoparticles and the micromotor was propelled as the bubbles continually left the concave surface. The propulsion of the motors could also be controlled by the magnetic force, which was controlled on demand *via* spatially changing the orientation of the magnetic field.²¹² Zou *et al.* also presented polymer micromotors with two distinct cores of Pt and Fe₃O₄ nanoparticle-dispersed hydrogels (Fig. 12C).²¹⁷ When exposed to a H₂O₂ medium, the Pt cores provided propulsion by expelling bubbles produced from the catalytic decomposition of H₂O₂, while the Fe₃O₄ cores were impacted by the magnetic guidance. Benefiting from the close cooperation of these two cores, the micromotors achieved powerful propulsion and recyclability for the delivery of micro/macro-scale objects. To demonstrate the delivery of the macro-scale objects, the ring shape of the PDMS film, named 'spaceship', was made where the micromotors were encapsulated. Depending on the direction of the magnetic fields (dashed lines) the micromotors could move directionally to deliver the object with a powerful propulsive force.

4.4 Environmental applications

Microparticles are also applied in dealing with pollution by taking advantage of their controllable structures, properties and motion. For instance, the directional movement of micromotors powered by the other external stimuli, in particular by

magnetic forces, provides a definite trajectory with a high speed. This advantage has been utilized for water purification with anisotropic or Janus microparticles.^{12,218} Sun *et al.* reported a magnetic micro-submarine based on sunflower pollen grains for simultaneously removing oil and microplastic pollutants.¹² The hollow structure of the micro-submarine allowed propelling under or above the water, depending on whether it was filled with water or oil inside (Fig. 12D(i)). The micro-submarine could deliver oil droplets 37 times larger than its own volume and effectively adsorbed floating oil *via* capillarity. Depending on the external magnetic field, the cooperative behavior of assembled micro-submarines achieved the transport of microplastics and oil droplets (Fig. 12D(ii)). Moreover, the colloidal surfactants made of amphiphilic Janus microparticles were utilized as an effective remedy for oil spill accidents (Fig. 12E).²¹⁹ Particularly, the various methods of making colloidal surfactants with biocompatible materials have been introduced.^{220–222} Thus, biocompatible and less toxic colloidal surfactants could be able to replace conventional chemical surfactants and achieve water purification in an environmentally friendly manner.

Hydrogel microcapsules composed of photocatalytic nanoparticles exhibit unique properties, including permeation, purification, and the catalytic reaction of molecular species.²²³ Photocatalytic TiO₂ and ZnO nanoparticles encapsulated in the poly(methacrylic acid) microcapsules were used to remove

Fig. 12 Applications of microparticles in robotics and environmental fields. (A) Size-dependent motility scenarios of self-propelled micromotors. (B) Movement control of the micromotor containing Ag, TiO₂, and Fe₃O₄ nanoparticles; the scale bars are 60 μm. (C) Self-propulsion of the multifunctional micromotors embedding Pt and Fe₃O₄ nanoparticles directionally delivering a macroscale spaceship with magnetic guidance; the scale bar is 2 cm. (D) (i) The hollow structure of the microsubmarine, which propels under or above water depending on the fillings inside, and their movement are controlled *via* magnetic field. (ii) Removal of large oil droplet by the assembling of microsubmarines; the scale bar is 100 μm. (E) Dispersion of oil contaminants in seawater using a colloidal surfactant. (F) (i) TiO₂ nanoparticles encapsulated in poly(anhydride) microcapsule. (ii) Cleaning of methylene blue solution in the flow microreactor while exposing to UV light. Reproduced with permission from ref. 12, 215–217, 219 and 223. Copyright 2016 and 2018 American Chemical Society. Copyright 2017 and 2020 Royal Society of Chemistry. Copyright 2019 and 2020 Elsevier.

organic pollutants. Due to the high surface area of photocatalytic nanomaterials and the adsorption properties of the hydrogel shell itself, the microcapsule effectively removed methylene blue organic material (Fig. 12F(i)). Flow micro-reactors based on the hydrogel capsules enabled the direct adsorption, degradation and separation of pollutants (Fig. 12F(ii)).

5. Conclusion and outlook

In this review, various passive and active strategies for generating and functionalizing microdroplets in various forms, and their corresponding applications, are introduced. The passive methods, such as batch emulsification, solvent evaporation and microfluidic systems, are advantageous for the relatively large-scale production of the microdroplets, since their shapes are predominantly determined by internal thermodynamics and chemical phenomena. On the other hand, the active method deforms the shape of the microdroplets by applying an external force such as an electric or a magnetic force, which is advantageous for generating droplets of more complex shapes. Well-engineered emulsions and microparticles fabricated from microdroplets using these strategies have great potential in areas such as energy, optics, and robotics.

The technical limitations of the passive and active production method, or a lack of understanding of the mechanism, limit the available shapes of the droplets or the materials to be used. In the passive method, the shape of the droplet is very sensitive to factors such as the solution concentration or added materials in working solutions, so the shape should be delicately manipulated to obtain the target shape. Although the active method allows the formation of more complex shapes of the droplets, it also has limitations with regard to the applicable materials, since only those materials that match the applied external force can be chosen (e.g., ferrofluid for the magnetic method). Due to the high dependency on UV-polymerization in converting the microdroplet templates into microparticles, the selectability of materials is also limited. Therefore, in order to break through these hurdles, the research on new microdroplets with unconventional shapes and also the mechanisms underlying their formation should be continued.

The limitations mentioned above would be the reasons why it is difficult to find commercialized products despite the magnitude of research being conducted on various types of functional microdroplets. Thus, the remaining important challenge associated with the functional microdroplets is to develop the usefulness of these microdroplets into actual practical applications. For instance, research on the application of microdroplet systems to drug delivery upon target release has been continuously explored for the past decades, but it is still rare to see the commercialized products in the medical field. The technology for releasing the materials to the desired area has already been extensively investigated, and now it is necessary to broaden the perspective, such as manufacturing biocompatible materials, collecting the vehicle once used, or reusing it. On the other hand, most of the self-propelled micromotors are based on the metal materials, which use

toxic H_2O_2 as a chemical fuel, thereby limiting their actual use in environmental applications. The future motors need to add a new aspect to convert the materials into bioorganic materials that use non-toxic chemical fuels, which could provide high potential for biological or environmental uses.

Another important challenge is to scale up the production of microdroplets. While there have been significant advances in structure-handling strategies, attempts to mass-produce, assemble, and induce the clustering movement of microdroplets remain limited to date. This may be the reason most microparticles are applied in biomedical fields dealing with phenomena on a relatively small scale in a variety of forms. On the other hand, concerns are lacking in the larger scale areas, such as energy, the environment, and the robotics field, and accordingly, practical applications have not yet been achieved. For instance, even though self-propelled microparticles have been developed for oil or microplastic removal, it is not enough to remove a large amount of oil leaking from the actual environment, and the swimmers themselves can become pollutants even after capturing the oil, so the technology for collecting them must also be properly developed. From this point of view, the direction of future research should go toward the mass-production of the microdroplets with high reliability, uniformity, and fast production on a macro-scale, that is, from hundreds of thousands to even more than trillions of droplets. Only then can it be practically applied to fields with high added value in the future, such as environmental or energy issues. To this end, the manufacturing technology on the micron-scale also needs to be further developed.

After a better understanding of the above aspects, actual industrial technologies could be more accurately derived and practically implemented in the future. Although more challenging problems remain, based on the already developed technologies and understanding of basic research, the microdroplets will evolve in a direction that is helpful to humanity.
