Review of emerging nanotechnology in bone regeneration: progress, challenges, and perspectives

Hadi Hajiali, ^{*a} Liliang Ouyang, ^{b,c} Virginia Llopis-Hernandez, ^d Oana Dobre ^d and Felicity R. A. J. Rose ^{*a}

The application of nanotechnology to regenerative medicine has increased over recent decades. The development of materials that can influence biology at the nanoscale has gained interest as our understanding of the interactions between cells and biomaterials at the nanoscale has grown. Materials that are either nanostructured or influence the nanostructure of the cellular microenvironment have been developed and shown to have advantages over their microscale counterparts. There are several reviews which have been published that discuss how nanomaterials have been used in regenerative medicine, particularly in bone regeneration. Most of these studies have explored this concept in specific areas, such as the application of glass-based nanocomposites, nanotechnology for targeted drug delivery to stimulate bone repair, and the progress in nanotechnology for the treatment of osteoporosis. In this review paper, the impact of nanotechnology in biomaterials development for bone regeneration will be discussed highlighting specifically, nanostructured materials that influence mechanical properties, biocompatibility, and osteoinductivity.

Introduction

Nanotechnology as an applicable tool for regenerative medicine has gained interest as our understanding of the interactions between cells and biomaterials at the nanoscale has grown. Materials that are either nanostructured or influence the nanostructure of the cellular microenvironment have been studied and demonstrated to have advantages over their microscale counterparts.¹ We focus here on the application of nanotechnology for bone tissue regeneration as this is an extensive field of study with an ongoing need for efficacious, novel treatments as bone regeneration therapies. This review will consider the many related research papers published in recent years with the common aim of realising the potential that nanotechnology provides to develop new strategies in bone regeneration.

Loss of bone as a result of non-healing fractures following trauma, disease such as osteoporosis, and as a result of

tumours affect millions of people globally, and that is one of the leading causes of disability worldwide.² Current materials used in the clinic include metals, ceramics, polymers and their composites and despite their long history and widespread use, they have drawbacks including low biocompatibility, poor bone formation, and a mismatch of mechanical properties with the surrounding native bone. Regenerative medicine has become an attractive field of study particularly based on the increasing demand for new solutions to treat significant tissue loss. This field of study has developed new treatments which involve the use of cells, growth factors, and biomaterials either alone or in combination for any tissue type, including bone.³ Many research projects have focussed on the development of advanced biomaterials that accelerate and promote bone regrowth in defect sites including, more recently, the use of nanomaterials.⁴

The field of nanotechnology and the application of nanomaterials to regenerative medicine have significantly advanced in recent years. There are several reviews studies which have been published to demonstrate how nanomaterials have been used in medicine^{1,5–7} particularly in bone regeneration.^{8–17} Most of these papers have reviewed specific areas; for instance, Boccaccini *et al.* reviewed the application of glass-based nanocomposites in bone regeneration,⁹ Gu *et al.* studied the application of nanotechnology in the targeted drug delivery for bone regeneration,¹¹ the progress in nanotechnology for the

treatment of osteoporosis was evaluated in another review paper,¹⁵ and Wang *et al.*, in their review study, investigated the interaction of nanomaterials with growth factors and cells for bone repair.¹⁶

Properties of nanostructured biomaterials should be extensively studied for successful bone regeneration. It has been known that the mechanical properties, biocompatibility, and osteoinductivity of biomaterials are important criteria to influence bone regeneration.^{18,19} The bone formation response can also be changed by altering the mechanical environment.²⁰ In addition, the biocompatibility of biomaterials play an important role in their performance for bone healing, and their osteoinductivity would be the most important property of bio-

materials which induces new bone formation.²¹ Therefore, we consider how nanotechnology has been applied to modify tissue engineering scaffolds for bone in three key areas; mechanical properties, biocompatibility, and osteoinductivity, in this paper (Fig. 1). Furthermore, the current challenges and future directions are discussed.

Mechanical properties

Progress

Mechanical forces can play important roles in bone reconstruction and formation.^{20,22} Bone cells are responsive to local

Hadi Hajiali

Dr Hadi Hajiali is a Research Fellow within the Division of Regenerative Medicine and Cellular Therapies at the University of Nottingham (2017-present). He completed his PhD in Bioengineering (Bionanotechnology) at the University of Genoa and Italian Institute of Technology in 2017. Furthermore, he joined Harvard Medical School to improve his knowledge and skill in bionanotechnology and tissue engineering for one year in 2016. He has been involved with many research projects and has published several papers in the field of regenerative medicine over the past decade. His research interests focus on tissue engineering, stem cell technologies, and advanced nano-structured biomaterials.

Liliang Ouyang

Dr Liliang Ouyang is an Assistant Professor in the Department of Mechanical Engineering at Tsinghua University (2020-present). He obtained a Ph.D. degree in Materials Science and Engineering at Tsinghua University (2017), a postdoctoral training in Materials at Imperial College London (2017–2020), and a visiting research training in Bioengineering at the University of Pennsylvania (2015–2016). His research interests include the design, fabrication, and application of complex biomaterial and cellular systems, with a central focus on the development of 3D bioprinting and advanced biofabrication technologies for tissue engineering.

mechanical stresses supplied during motion. These stresses can contribute to changes in cellular metabolism and influence bone remodelling by inducing signalling and biochemical cascades.²⁰ Furthermore, it has been shown that biomaterials with an insufficient mechanical strength or with a higher mechanical strength than native bone can lead to bone repair failure and bone loss that might be as a result of weak interfacial bonding or stress shielding.²¹ Therefore, the mechanical properties of biomaterials for bone repair have to be considered extensively.

There are many papers in the literature that have demonstrated how the mechanical properties of biomaterials can be modified by the application of nanotechnology. The results of recent studies are summarised in Table 1. Bone matrix, a natural nanocomposite structure, consists of two major phases at the nanoscale including organic (collagen) and inorganic (Hydroxyapatite (HAP)). There is a range of mechanical properties depending on the type of bone with the elastic modulus varying from 1 to 20 GPa, and the compressive strength ranging from 1 to 100 MPa dependent on its porosity, composition and structure.^{23,24} Various effects of nanomaterials on the mechanical properties of these nanocomposites have been reported and is dependent upon the nanoparticle dispersion state, surface area, polydispersity, and organo-modification to improve interface interaction between phases.²⁵ Studies have shown how incorporation of nanosized materials, including HAP and bioglass(BG), can improve their mechanical properties compared to their micro-sized equivalents.^{26–29} We have also showed that the elastic modulus of porous scaffolds can be enhanced by the addition of nano BG to the polymeric matrix.³⁰ The chemical and thermal analysis in our study demonstrated a favourable interaction between polymer and bioglass nanoparticles which enhanced the interaction of the two phases at the interface³¹ and conse-

quently enhanced stiffness. It has also been shown that the homogeneously dispersed nanoparticles are also effective in increasing the stiffness of synthetic polymer-based materials.²⁵

Challenge

Despite the fact that there have been many attempts to fabricate scaffolds with appropriate mechanical properties, porous scaffolds that mechanically behave similarly to bone are yet to be reported (Fig. 2A). Although some dense nanocomposites have been developed that exhibit an elastic modulus and strength in the range of cancellous bone, regrowth of bone cannot be expected in such non-porous structures and these do not allow for tissue infiltration. It has been demonstrated that interconnected porous scaffold networks that enable the transport of nutrients, removal of wastes, and facilitate proliferation, migration of cells, and vascular ingrowth are essential for bone tissue engineering.³⁴

Although scaffolds with enhanced mechanical properties, through the incorporation of nanomaterials, have been reported by numerous researchers, our fundamental knowledge of the “nano effect” in terms of mechanical properties is not fully developed (Fig. 2B and C). Challenges in the visualisation at the nanoscale hinders our understanding of the extent and properties of the interphase region. The properties of the interphase layer in nanocomposites has therefore been mostly investigated by indirect methods such as thermal analysis.³⁵ Furthermore, a variety of analytical and computational models have been developed to analyse and predict the mechanical behaviours of nanomaterials and nanocomposites,³⁶ but the complexity of generating experimental data, the lack of knowledge about the interphase region, and the high computational costs have limited the development of

Virginia Llopis-Hernandez

Dr Virginia Llopis-Hernandez is a Postdoctoral Researcher at King's College (2021-present). During her PhD in Biomedical Biotechnology at the UPV (obtained in 2017 with European mention and honours) she developed a biomaterial for bone regeneration and studied how MSCs respond to efficient presentation of growth factors. She did several internships, including at the University of Glasgow, University of Florida and a

Marie-Curie-IAPP Program Secondment. She has done a postdoc with Prof Matthew Dalby (University of Glasgow) where she gained multiple experience in MSCs metabolism. She is currently at the King's College London with Prof Maddy Parsons, understanding how receptors contribute to sensing in tissue.

Oana Dobre

Dr Oana Dobre is Research Associate in the Department of Biomedical Engineering at Glasgow University (2017-present). From August 2015 to April 2017, she has been working as a Research Assistant in the laboratory of Dr Joe Swift within the Wellcome Trust Centre for Cell-Matrix Research, University of Manchester. She did her PhD in the Tribology group, Mechanical Engineering department at Imperial College London (2016)

sponsored by Bosch Belgium. Her research interests include the development of 3D in vitro culture systems such as hydrogels/bioinks to efficiently present growth factors in a controlled manner in order to promote tissue regeneration.

models that can precisely predict the properties of the various types of nanocomposites.

The interactions between cells and their pericellular environment when growing within scaffolds of various stiffness remains relatively unexplored (Fig. 2C).³⁷ However, it has been shown that cells can sense the rigidity of the extracellular matrix (ECM) in 2D environments through cell surface receptors such as integrins.³⁸ Integrins can regulate cell migration, proliferation, and differentiation by connecting the intracellular cytoskeleton to the ECM. This activates focal adhesion kinase (FAK) and phosphoinositide 3-kinase (PI3K) signaling pathways to regulate the self-renewal and proliferation of cells, and has been demonstrated with mesenchymal stem cells.³⁹ It is still not clear how the mechanical properties of scaffolds stimulate cells to secrete the proteinaceous pericellular matrix associated with osteogenesis in a 3D environment. Therefore, there are no defined values for the desired elastic modulus and mechanical strength of scaffolds suitable for bone regeneration. The main challenges in the development of scaffolds with defined mechanical properties from nanostructured materials are summarised in Fig. 2B.

Perspective

Innovative fabrication methods, such as 3D printing,⁴⁰ can be utilised to not only design and control scaffold porosity but also to improve mechanical properties through macroscale scaffold structure design. The application of different shapes of nanomaterials, including nanorods^{41,42} and nanowires,⁴³ with homogeneous distribution and high interaction with the matrix interface can also enhance the strength and elastic modulus. Although, there are several ways to re-enforce porous scaffolds improve their mechanical properties, the main question, however, is how important is the initial mechanical similarity between a porous scaffold and bone in the defect site for bone regeneration? (Fig. 2D).

It has been shown that the growth of bone in the implanted porous scaffolds can improve the mechanical properties of the

regenerated bone in the defect site.^{44–47} Another study has suggested that stem cells take part in a bi-directional interaction between the features of their 3D surroundings and their own secreted pericellular matrix and these interplays induce cellular fate.³⁷ Kolambkar *et al.* and Reichert *et al.* demonstrated that incorporation of growth factors in scaffolds with low mechanical strength (such as hydrogels) can induce bone regeneration with the desired resulting stiffness and torsional strength.^{45,47} It has also been illustrated that some gels can mechanically play the same role as autografts after implantation.⁴⁶ These results reduce the importance of the initial similarity of the mechanical properties of the scaffold to native bone. They also suggest the feasibility of developing porous osteoinductive scaffolds, with lower mechanical properties than the surrounding bone, which can stimulate and accelerate new bone formation to such an extent that the new bone can quickly become load bearing.

Biocompatibility

Progress

It has been demonstrated that topographical features at different length scales, ranging from nano- to micrometre, can have significant impact on cell adhesion and morphology. In particular, it has been discussed in the literature that there could be an optimum size range in which cell adhesion would be enhanced most significantly but this is dependent on cell.⁴⁸ We have reviewed previously how cellular focal adhesions interact with various nanotopographies and discussed how these interactions can be controlled to direct stem cell fate.^{49,50} In fact, cell migration, proliferation, and differentiation are all dependent upon adhesion.^{48–51} In normal physiological conditions, tissue re-organisation (*e.g.* during wound healing) is influenced by the bidirectional flow of information exchanged between cells and the ECM and this steers important cell functions such as adhesion, differentiation, and migration.⁵¹ There is opportunity for this phenomenon to be recreated on biomaterials. Because focal adhesions are assembled from the clustering of many integrins (on the nano-scale),⁴⁹ the design of nanostructured materials (including nanomaterials, nanocomposites and nanotopographical features) can preferential guide the formation of focal adhesions and thereby regulate cell fate through changes in both cell biochemistry and cell morphology. Based on this, the application of nanomaterials as scaffolds should serve as an optimised reproducible environment for cell attachment, proliferation and function over other scaffold designs. The results of studies conducted to investigate the biocompatibility of nanomaterials and nanocomposites are summarised in Table 2.

An example is given by the study published by Webster and colleagues which demonstrated that osteoblast adhesion was significantly ($p < 0.01$) greater after 4 h when these cells were cultured on nanophase alumina, titania, and HAP than on microphase formulations of the same ceramics.⁵² Furthermore, another study demonstrated that osteoblast

Prof. Felicity Rose is a Professor of Biomaterials and Tissue Engineering within the School of Pharmacy at the University of Nottingham. She is Head of the Division of Regenerative Medicine and Cellular Therapies and deputy director of the University of Nottingham Biodiscovery Institute (BDI). She has an established and reputation in leading biomaterials development for tissue engineering and regenerative medicine

applications with a focus on the development of new strategies to support bone regeneration.

Table 1 Summary of the influence on the mechanical properties of materials by application of nanotechnology for bone regeneration

Materials	Fabrication method	Porosity	Mechanical properties results	Ref.
Compact human bone	Natural development (nanocomposite of 20% collagen and 69% calcium phosphate)	5–10%	Elastic modulus 17.0–18.9 GPa; compressive strength: 170–193 MPa; tensile strength: 124–174 MPa; bending strength: 160 MPa; shear strength: 54 MPa; fracture toughness: K _{IC} : 2–12 MPa m ^{1/2}	23 and 24
Cancellous human bone		50–95%	Elastic modulus: 1–2 GPa; compressive strength: 1–100 MPa	
PLLA/nHAP (50/50)	Solid–liquid	85–87%	Elastic modulus: 0.014 GPa; compressive strength: 8.67 MPa	29
PLLA/mHAP (50/50)	Phase separation		Elastic modulus: 0.013 GPa; compressive strength: 4.61 MPa	
PLLA	Freeze–dryer		Elastic modulus: 0.0017 GPa; compressive strength: 2.4 MPa	
PA/nHAP (38%–64% nHAP)	Injection moulding	—	Elastic modulus: 3.6–5.6 GPa; compressive strength: 93–117 MPa; tensile strength: 65–87 MPa; bending strength: 77–95 MPa	32
	Injection foaming	71–80%	NA	
n-HAP/PA (6 : 4)	Thermally induced phase inversion	52%–70%	Elastic modulus: 0.29–0.85 GPa; compressive strength: 13.2–33.9 MPa	33
nHAP-zirconia (1.5%)	Pressure-assisted sintering	—	Elastic modulus: 149 GPa; compressive strength: 766 MPa; Bending strength: 243 MPa	26 and 27
Conventional HAP			Elastic modulus: 130 GPa; Compressive strength: 897 MPa; Bending strength: 193 MPa; fracture toughness: K _{IC} : 1.3 MPa m ^{1/2}	
			Elastic modulus: 120 GPa; compressive strength: 120–800 MPa; bending strength: 38–113 MPa; fracture toughness: K _{IC} : 1 MPa m ^{1/2}	
PHB/nBG (10%–30%)	Solvent casting (dense composite)	—	Elastic modulus: 1.15–1.58 GPa	28
PHB/mBG (10%–30%)			Elastic modulus: 0.79–0.83 GPa	
PHB			Elastic modulus: 1.01 GPa	
PHB/nBG (0%–10%)	Salt leaching	59%–85%	Elastic modulus: 0.007–0.048 GPa	30
PLLA: poly-L-lactic acid; HAP: hydroxyapatite; PA: polyamide; PHB: poly (3-hydroxybutyrate); n: nano; m: micro.				

Fig. 2 (A) Elastic modulus/compressive strength of the various type of materials compared to human bone. (B) Associated challenges in terms of assessing the mechanical properties at the nanoscale when developing scaffolds for bone regeneration. (C) Schematic presentation of interactions between cells and their pericellular environment when growing within scaffolds with unknown parameters. (D) Importance of initial similarity of the mechanical property of scaffolds to the bone. Although the goal is that the regenerated bone behaves similarly to the natural bone, there are several studies that have reduced the importance of the initial similarity in the mechanical properties of tissue engineered scaffolds to the bone.

function and cellular activity were promoted on a nanostructured metallic surface in relation to a coarse-grained counterpart.⁵³ Results of Palin and colleague's research also showed that nanostructured surfaces (nanophase titania and PLGA moulds of nanophase titania), without the influence of any other surface properties, improved adhesion and proliferation of osteoblasts.⁵⁴ Xu and co-workers used injectable nano-apatite scaffolds for cell/growth factor delivery for bone regeneration. Created pores within the nano-apatite scaffolds were suitable for cell infiltration. The new scaffolds were biocompatible and promoted the adhesion and growth of osteoblast-like cells. The cells could infiltrate into the matrix pores, create cell-cell junctions, and adhere to the nano-apatite pores' walls.⁵⁵ Moreover, it has been shown that nano-bioglass can induce higher rates of cell proliferation and higher mRNA expression of osteogenic markers compared to micro-bioglass.⁵⁶ Studies from our laboratories also showed that cells attach and proliferate highly on polymer/nBG scaffolds (PHB/nBG), and proved that there may be an optimal nanobioglass concentration for proliferation and osteoconduction.⁵⁷

In another study, the effect of the various sizes of hydroxyapatite (HAP) nanoparticles (20, 40 and 80 nm), prepared as a

film, on the proliferation of two bone-related cells, bone marrow derived mesenchymal stem cells (MSCs) and osteosarcoma cells (U2OS and MG63), were investigated. The results showed enhanced biocompatibility of films containing nanoparticles as compared with rod-like HAP with a length of hundreds of nanometres. The 20 nm nanoparticle films supported higher cell viability and proliferation of MSCs. But when the bone tumour cells were cultured on the HAP nanoparticles, the opposite phenomenon occurred. In fact, the proliferation of U2OS and MG63 cells was inhibited by the presence of the nanoparticles which was inversely proportional to the particle diameter.⁵⁸

Furthermore, it has been demonstrated in a separate study that the orientation of cytoskeletal networks and expression of focal adhesion proteins and subsequently the adhesion, spreading and migration of SaOS-2 human osteoblast-like cells were affected by nano-TiO₂ particles in a size dependent manner.⁶⁷ They investigated the cells exposed to clinically relevant concentrations (0.05, 0.5, 5 mg L⁻¹) of 5 and 40 nm spherical nano-TiO₂. The actin and microtubule cytoskeletal networks were disrupted by treatment with nano-TiO₂ leading to morphological modifications of SaOS-2 cells and the cell

Table 2 Summary of recent studies that assess the biocompatibility of nanostructures for bone regeneration

Materials	Cell type	Tests	Results	Ref.
Nanomaterials				
Nanoapatite	MC3T3-E1 osteoblast-like cells	Cell viability with calcein-AM, ethidium-homodimer-1	No significant difference in cell attachment and proliferation between nanoapatite scaffolds and controls. Cells infiltrate into the macro pores and anchor to the nano-apatite crystals	55
Nanobioglass(nBG)	MG63 osteoblast-like cells	LDH and mitochondrial activity, alkaline phosphatase (ALP) activity	High cytocompatibility of the nBG particles compared with micro BG	59
Nano fluorhydroxyapatite	Extracted osteoblast-like cells from adult rabbit, L929 mouse fibroblast cell line	Haemacytometer	Biocompatibility of fluorhydroxyapatite was higher than hydroxyapatite and fluorapatite	60
Gold nanoparticles-miRNA	Rat BMSCs	Alamar blue as say, ALP activity	High cellular biocompatibility of nanoparticles	61
Whitlockite inorganic nanoparticles (nWH: Ca18Mg2(HPO4)2(PO4)12)	Human tonsil-derived mesenchymal stem cells (hTMSCs)	LIVE/DEAD cell viability kit, click-IT Edu, flow cytometry assay, ALP activity	No significant difference in cell viability and proliferation between hydroxyapatite and WH nanoparticles. Significantly enhanced ALP activity in nWH compared to nHAP	62
Nanocomposites				
Nano hydroxyapatite/silk fibroin	Rat marrow mesenchymal cells	DNA contents, alkaline phosphatase (ALP) activity, the osteocalcin contents	Support cell proliferation, and osteogenic differentiation of the cells	63
Poly(3-hydroxybutyrate)/nHA nanofibers	Rat bone marrow stroma cells	Methylthiazol tetrazolium (MTT) assay, ALP activity	Positive effect on attachment, proliferation, and differentiation of cells	64
Poly(3-hydroxybutyrate)/nBG scaffolds	MG63 osteoblast-like cells	MTT assay, ALP activity	Improve cell proliferation, and induce a high level of ALP activity	57
Gelatin methacrylate/nanosilicates (LAPONITE®) hydrogels	MC3T3 E1-4	Alamar blue assay, ALP activity	Nanocomposites are cytocompatible, enhanced ALP activity	65
Whitlockite/chitosan scaffolds	Human bone derived mesenchymal stem cells (hBMSCs)	Cell counting Kit-8 [CCK-8], ALP activity	Greatest proliferation and significantly higher ALP activity when cells cultured on WH/chitosan membranes compared to HAP/chitosan membranes and control	66

migration was significantly impaired in cells exposed to 5 nm nanoparticles compared to unexposed cells. Therefore, the biocompatibility and cytotoxicity of materials that incorporate nano-particles influences the subsequent cellular response and further studies are required prior to development for clinical application.

Challenge

Despite the progress made so far, there are still some challenges associated with the biocompatibility or cytotoxicity of the various nanotechnologies applied to bone regeneration (Fig. 3A). It is believed that the main mechanism of nanotoxicity is the high level of reactive oxygen species (ROS) produced in the cells,⁶⁸ which might damage cells and cause sequent dysfunctions to the cellular microenvironment through downstream effects, including peroxidising lipids, disrupting DNA and altering gene transcription. Unlike regular chemical toxicants, nanomaterials cannot be fully defined for toxicity by determining their chemical composition and purity. Moreover, it has not been fully understood how and why nanomaterials differ from their bulk counterparts in toxicity, which also adds to the complexity of understanding nanotoxicity.

The cytotoxicity of nanomaterials is synthetically affected by multiple particular characteristics, including chemical composition, size, shape, surface charge, solubility, and dose, which have been well reviewed by some papers.^{68,69} For instance, the size of the nanoparticle (NP) is critical for toxicity and it seems smaller NPs would compromise cell activity more, which is probably because of the increasing reactivity of NPs with decreasing size.⁷⁰ The shape of nanomaterials would also make a difference and spherical NPs are usually easier and faster for endocytosis than tube- or fibre-like NPs.⁷¹ Despite the growing work in nanomaterials toxicity determination, there is still a demand for comprehensive and reliable characterisation of nanomaterials regarding their characteristics indicated above. For example, there are various methods to determine the size of NPs (e.g. dynamic light scattering, scanning electron microscopy, transmission electron microscopy, and atomic force microscopy), but it remains a challenge to unify the measurement because of the disagreement of values given by the different methods due to different principles behind these techniques.⁷² In addition, the measured size during preparation might not represent the actual size on site in application because of possible aggregation/agglomeration and other reactions caused by dispersion within the physico-chemical environment. Such reactions also add to the difficulty of determining the actual effects of shape and surface charge on toxicity.

With respect to conducting biocompatibility assays, both *in vitro* (e.g. live/dead staining, MTT, DLH, and immunochemistry) and *in vivo* (e.g. blood compatibility and pharmacokinetics study) methods have been used. The *in vitro* assay, which is typically based on 2D cultured cells, is usually the first to be conducted because of its ease and quick outcome of the result. *In vitro* assays provide valuable quantitative and

Fig. 3 (A) Route of nanotechnology applications in bone regeneration and the associated challenges in terms of biocompatibility. (B) Translatability of current *in vitro* studies for clinical applications.

specific measurements for evaluating the toxicity of a new nanomaterial, but it cannot elucidate the mechanism of cell damage and death. In addition, *in vitro* results might not represent the *in vivo* outcomes because of their different microenvironments (2D versus 3D) and timescales of toxicity.⁷³

With respect to bioactivity, the inclusion of nanoHAP (n-HAP) within scaffolds has gained much interest. HAP, as a ceramic component of natural bone, is osteoconductive (supporting bone formation) and not osteoinductive (stimulation of osteogenesis).⁷⁴ HAP is able to support bone formation but cannot promote it, and the capability to stimulate osteogenesis is essential for materials to be used in bone regeneration. By implanting scaffolds fabricated from HAP, it cannot be expected that the newly formed bone demonstrates the same natural bone composition and structure, because the HAP is not highly degradable, and even if the cells migrate and grow inside the scaffolds, the arrangement of HAP around cells will be different from what we observe in natural bone. For example, Dasgupta and colleagues developed scaffolds by using gelatin-chitosan (GC) and GC composites containing 30 wt% n-HAP (GCH 30) which demonstrated that GCH 30 showed significant improvement in the compressive strength. MSC proliferation and differentiation on this scaffold observed *in vitro*, compared to the other GC scaffold formulations but when assessed *in vivo*, lacked bone formation following implantation, and no significant difference to the other GC scaffold formulations following 1, 2, 3 months after implantation.⁷⁵ In another study, Kuttapan and colleagues fabricated a composite scaffold of silica coated nanohydroxyapatite (nHAP)-gelatin reinforced with electrospun poly(L-lactic acid) (PLLA) yarns, and also observed poor bone formation in the nanocomposite scaffolds when they were not loaded any growth factors following 4 and 12 weeks implantation *in vivo*.⁷⁶ Nanostructured materials-tissue interactions *in vivo* therefore, are not necessarily predicted by *in vitro* assays due to the various components involved in regeneration that cannot be replicated easily *in vitro*.⁷⁷

Perspective

There is an increasing tendency to introduce ions in n-HAP containing materials to improve the biocompatibility of HAP such as fluoride and magnesium ions. In particular, Whitlockite (WH) is a kind of calcium phosphate existing in natural bone tissue and contains Mg.⁷⁸ Recent results from the incorporation of WH within scaffolds show higher cell proliferation and differentiation compared to scaffolds containing HAP alone. The incorporation of WH, HAP, bioglass or ceramic phase in the fabrication of scaffolds should be considered with respect to their degradability, bioresorbability, and their functionality during and after bone regeneration. We have previously reviewed how calcium and phosphate ion concentrations in the cells and in the ECM can promote and inhibit mineralisation. In addition, there are still several unanswered questions related to calcium phosphate particles that are associated with mineralisation.⁷⁹ On the other hand, some studies have shown that scaffolds containing no ceramic phase, particularly hydrogels with incorporated growth factors, were also able to induce mineralisation.^{80,81} For instance, Yan and colleagues developed a hydrogel system by using hyaluronic acid (HA) and modulating BMP-2 release, and the *in vivo* experiments with these hydrogels clearly illustrated early mineralisation (in just two weeks).⁸¹ We have also demonstrated the application of an Alginate/ECM hydrogel system with incorporated stem cells and growth factors for *in vivo* bone formation in which the bone ECM component showed an increase in mineralisation compared to irradiated Alginate/ECM (U.V. irradiation was performed to inactivate endogenous growth factors within bone ECM).⁸² These studies suggest that if the cellular microenvironments is well designed, not only can the cells fabricate their own ECM-like collagen, but also the ceramic phase can be naturally formed in an appropriate arrangement around the cells, and potentially the bone can be functionally regenerated.

In addition, as mentioned, several unsuccessful animal studies have been reported despite earlier promising *in vitro*

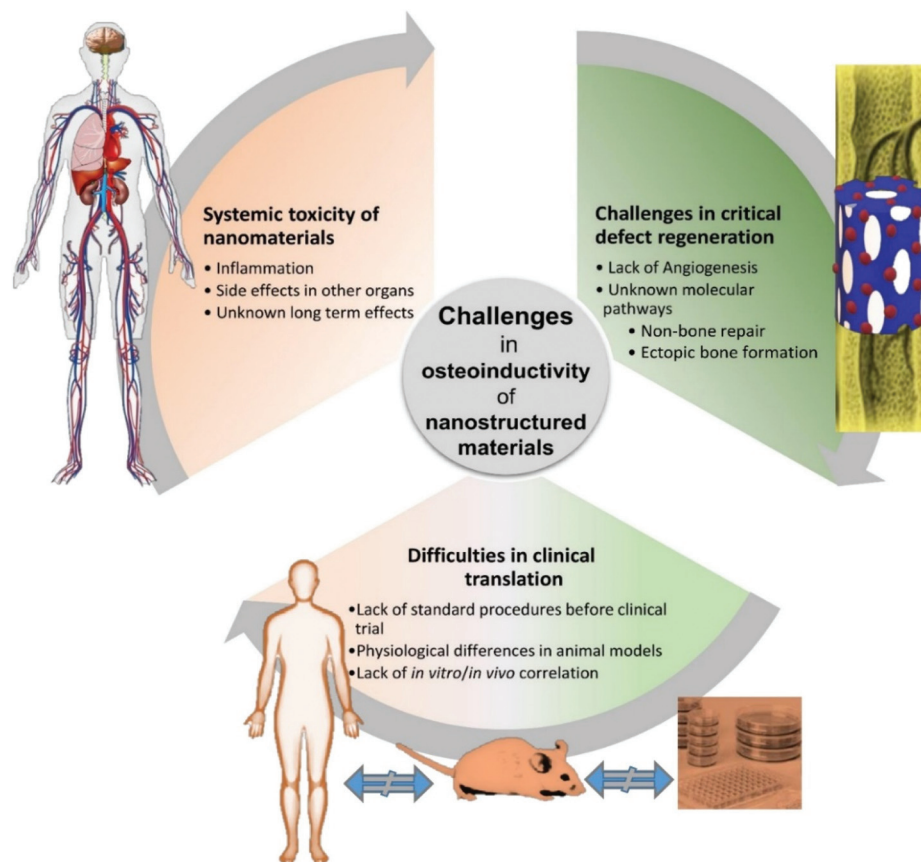

Fig. 4 Associated challenges in terms of osteoinductivity for nanostructured materials in bone regeneration.

data. There is therefore a need to develop better standards for cell characterisation and to design bioreactors which simulate tissue regeneration *in vivo*.⁸³ In this regard, micro and nanofabrication technologies can be useful. The microenvironment can be simulated by the design of advanced microfluidic systems, and scaffolds can be tested and approved in these developed systems before *in vivo* implantation (Fig. 3B).

Though many nanomaterials seem to be nontoxic and even yield beneficial effects for the body, solid risk assessment is still necessary to address the possible concerns of the public and end-users. Regarding the internal challenges above, there is a great demand for establishing standards and guidelines to determine the biocompatibility of nanomaterials and nanotechnologies in biomedical applications, *e.g.* bone regeneration. The ultimate standards should cover all the aspects throughout the pathway from the comprehensive characterisation of nanotechnologies/nanomaterials to reliable toxicity assessment methods. The US National Institute of Standards and Technology (NIST) released the world's first reference material (RM) standards of gold nanoparticles (AuNPs) (10, 30 and 60 nm in diameter) in 2008 and has published some other RMs since then. Nelson *et al.*⁸⁴ tested the genotoxicity of these NPs based on HepG2 cells and concluded that the NIST AuNPs could be potentially used as negative-control nanoparticle RMs

for *in vitro* and *in vivo* genotoxicity studies. More RMs standards should be introduced together with other types of guidelines and protocols.

Osteoinductivity

Progress

Osteoinduction is defined as the ability to stimulate the differentiation of stem cells or osteoprogenitor cells to mature bone-forming cells,^{85,86} and it is the process by which osteogenesis is encouraged. Finally, it is defined as 'action or process of stimulating osteogenesis' agreed in the 2018 Chengdu consensus conference.⁸⁶ It is necessary to conduct an *in vivo* test of any new biomaterial before classifying it as osteoinductive, even if the material had shown great potential *in vitro*. García-Gareta *et al.*⁸⁷ have shown that osteoinductivity is an isolated phenomenon, which is influenced by the chemistry and structure of the biomaterials. Many studies investigating osteoinduction describe bone formation after 8 weeks implantation, but the time after implantation should be in direct correlation with the size of the animal model used due to the fact that bone formation in larger animals is a slower process. There are some studies that have investigated the application of

Table 3 Summary of recent studies in *in vivo* assessment of osteoinductivity of nanostructured biomaterials for bone regeneration

Materials	Animal study	Defect size-time	Controls	Results	Ref.
Nano-hydroxyapatite pullulan/dextran polysaccharide scaffolds	Mice-(subcutaneously) and Goats-(intramuscularly)	4 mm-2, 15, 30, 60 days 10 mm-30 days	Matrix without nHA empty	Nano-hydroxyapatite activates early calcification and osteoid tissue formation in non-osseous and osseous sites	89
	Rats-femoral condyle	6 mm-15, 30, 90 days			
	Goats-mandible	10 mm-30 days			
	Goats-tibial osteotomy	40 mm-30, 180 days			
n-TiO ₂ /poly(ether-ether ketone) (PEEK) cylindrical implants	Dogs-tibia in the proximal diaphyseal region	5 mm-28 days	PEEK	Enhanced bone regeneration around the implants by n-TiO ₂	88
Nano-hydroxyapatite coated β -TCP scaffolds nano-hydroxyapatite coated poly caprolactone(PCL) scaffolds	Rabbits-iliac crest tuber sacrale of each leg	20 mm-90 days	β -TCP PCL	New bone tissue occupying 33% for the nHAP-coated PCL scaffold and 68% for the nHAP-coated β -TCP after a 3-month test	90
Nanodiamond particles-modified poly(l-lactide-co- ϵ -caprolactone) (Poly(LLA-co-CL) scaffolds Moxifloxacin hydrochloride + icariin/PCL nanofibers	Rats-central area of parietal bone Rabbits-middle radius of the right foreleg	5 mm-84 days 10 mm-30, 60, 90 days	Poly(LLA-co-CL) PCL empty	Nanodiamond particles promote osteogenic metabolic activity and finally enhance osteoconductivity Dual drug-loaded nanofibers possess a positive effect in enhancing the quality and quantity of bone formation when compared to the blank and PCL groups	91 92
DNA-loaded nano-calcium phosphate paste	Rabbits-right proximal medial rabbit tibia	8 mm-14, 28, and 84 days	Non-loaded paste	Significantly accelerated bone healing and formation after 4 weeks in the DNA-loaded calcium phosphate group	93

nanotechnology to enhance the osteoinductive properties of new biomaterials *in vivo*; the results of these studies are summarised in Table 3.

Wu *et al.* showed n-TiO₂/polyether ether ketone (PEEK) could enhance bone regeneration around the implant in a canine model (implants were placed in each animal on the medial surface of each tibia in the proximal diaphyseal region).⁸⁸ In another study, it has been shown that nHAP (as a composite of nanohydroxyapatite and pullulan/dextran polysaccharides) activates early calcification and osteoid tissue formation in non-osseous and osseous sites in different animal models such as the femoral condyle of rat, a transversal mandibular defect and a tibial osteotomy in goat.⁸⁹

Novel nanohydroxyapatite sonocoated scaffolds were studied for bone regeneration by Rogowska-Tylman.⁹⁰ A uniform layer of nanohydroxyapatite particles with a thickness within the range of 200 to 300 nm was sonocoated on two types of scaffolds: a porous β -TCP ceramic scaffold and a 3D-printed scaffold made of PCL fibers. *In vivo* tests in rabbits confirmed that the novel coating stimulated new tibial bone tissue formation, occupying 33% of the initial scaffold volume for the nHAP-coated PCL scaffold and 68% for the nHAP-coated β -TCP after 3 months.

M. Gong and colleagues⁹² have developed a core-sheath micro/nano fibre membrane consisting of a polycaprolactone core and gelatine shell loaded with the antibacterial drug moxifloxacin hydrochloride (MOX) and a traditional Chinese medicine called icariin (ICA) as biomimetic artificial periosteum to promote bone regeneration. They tested this material *in vivo*, in a rabbit radius defect model to test the formation of bone. They demonstrated that the dual drug-loaded nanofibers enhanced the quality and quantity of bone formation as well as maturation when compared to control groups.

An injectable DNA-loaded nano-calcium phosphate paste was prepared to be used as a bioactive bone substitution material by Schlickewei and colleagues.⁹³ Calcium phosphate nanoparticles were loaded with BMP-7- and VEGF-A-encoding DNA prior to implantation in a rabbit critical-size tibial bone defect and observed over 2, 4 and 12 weeks following surgery. The calcium phosphate paste without DNA led to regular healing of the critical-size bone defect, but the healing was slower than the DNA-loaded paste. Thus, the *in situ* transfection with BMP-7 and VEGF-A significantly improved the potential of calcium phosphate as a pasty bone substitution material. Over the last decade, several nanotechnologies^{94,95} have been applied to biomaterials fabrication and these approved for use in clinical applications. For example, Vitoss (Orthovita), approved by the FDA in 2000, is a three-dimensional scaffold composed of ultraporous beta-tricalcium phosphate (TCP) NPs (mean size 100 nm). These nanoparticles are used in repairing bone defects by enhancing resorption and stimulating new bone growth. However, in a FDA document published in 2003 related to this product,⁹⁶ Vitoss scaffolds were advised to not be used to treat large defects. In 2008,⁹⁷ they reported the scaffolds functioned as intended in all cases, based on *in vitro* data, although the osteostimulatory nature of

the scaffolds has not yet been correlated to human clinical experience. In addition, a clinical trial also demonstrated that the nanostructured biphasic calcium phosphate is biocompatible and osteoconductive, and that the implants remained *in situ* after 3 and 6 months without complications or loss of the implants and with preservation of the alveolar architecture.⁹⁸ The number available studies regarding *in vivo* new bone formation in human is limited, which gives researchers a limited understanding of the detailed mechanism of bone development in these materials. This section of the review illustrates the lack of studies in this area as well as the need for further *in vivo* and clinical studies on this matter.

Challenge

Nonetheless, the application of nanotechnology to biomaterials development for bone has developed rapidly in recent years, and it has been shown that such materials can stimulate bone formation *in vivo*. However, there are still several challenges in the regeneration of critical sized bone defects (Fig. 4).⁹⁹ The insufficient number of stem cells in the defect site for differentiation to osteocytes, lack of cell penetration and migration to the defect zone, lower levels of vascularisation to supply nutrients and exchange waste materials for the cells could be the factors that impact on inadequate bone regeneration in the critical bone defects.

Angiogenesis and osteogenesis are closely linked and they must be significantly considered for physiological bone function. It is demonstrated that changes in vascular growth can compromise physiological bone formation, for instance, leading to non-union fractures, and osteonecrosis.^{100,101} On the other hand, vascular endothelial growth factor (VEGF) is the main regulator of angiogenesis and has also been reported to inhibit osteoblast differentiation,¹⁰² and VEGF overexpression can also cause bone resorption.¹⁰³ This competition between osteogenesis and angiogenesis inhibits formation of mature blood vessels and interrupts the coupling of angiogenesis and osteogenesis in bone regeneration. Furthermore, non-vascularisation in implanted scaffolds inhibits appropriate bone regeneration in defect sites.⁷⁵ Therefore, the coupling of angiogenesis and osteogenesis is still one of the main challenges in bone regeneration, and both should be investigated when a nanomaterial is suggested for bone tissue engineering.

Animal models are used to study the osteoinductivity of nanostructured materials, however, the *in vivo* interaction of nanomaterials and biological systems are much more complex. In addition, bone regeneration in the commonly used animals for this work (rat, rabbit, sheep) is different compared to man due to species differences in bone regeneration and healing. Despite large investments in tissue engineering, the general success rate of biomaterials in clinical development remains low.⁹⁹ The flawed preclinical research is one of the distinguished explanations, in which the use and outcome of animal models are critical for clinical translations. Hence, a validated and predictive animal model must be selected to address the clinical question. Small animal models are less

expensive and are more straightforward to conduct. However, they do not always represent mechanistic responses compared to humans. For instance, mouse and rats show limited intracortical remodelling and their growth plates remain open. Therefore, the skeletal morphometric and mechanical data can be impacted by these differences.¹⁰⁴

Most nanomaterials, such as gold nanoparticles, are currently being assessed in *in vitro* testing platforms without minimal development towards actual clinical applications.¹⁰⁵ There are a few very important factors relevant to the use of nanoparticles (NPs) for *in vivo* applications, including their size and the stimulation of inflammatory response, together with their osteoinductive properties. If the NPs size is smaller than 10 nm they may be excreted through the kidneys, whereas NPs with sizes between 100 to 200 nm will be cleared by the liver and spleen. Moreover, NPs with sizes from 20 to 100 nm have been shown to diffuse through the endothelium of tumour tissues.⁹⁵ Therefore, particle size plays an important role in materials development for the intended clinical application. Nano-TiO₂ particles can enter the blood circulation and be deposited in the liver, changing biochemical indicators, leading to liver inflammation.¹⁰⁶ It has been shown that long-term inflammation of the liver leads to cell activation, and multiple signalling pathways can promote the ECM deposition, causing liver fibrosis. Recently, the progress on murine liver injury induced by TiO₂ has been investigated. The size of nano-TiO₂, its dosage, exposure time, and surface properties can affect its toxicity. Therefore, the toxic effects of nano-TiO₂ in humans should be investigated in greater depth, and in more in detail for nano-TiO₂ based implants.

Regarding inflammation, some materials are tolerated by the body, such as polycaprolactone (PCL) or inert bioceramics that do not elicit a response from the host immune system.³ In the case of the polyesters, such as PCL, degradation results in acidic compounds that can affect the intracellular pH and alter cellular fate. The degradation of polymeric nanoparticles can induce an inflammatory reaction due to their reduced size and can be rapidly expelled by the body reducing their therapeutic efficacy.¹⁰⁷ However, previous studies have demonstrated encouraging data in controlling inflammation in both *in vitro* and *in vivo* experiments. More extensive investigations should be carried out because the degraded products of the implants can exist for a long period of time in the body and more extensive screening of type, density, and duration of these signals should be conducted to evaluate their effects on macrophages.¹⁰⁸ Finally, the bone engineering community must study the long-term toxicity of nanomaterials to add confidence to their inclusion in the biomedical field.

Perspective

Nanotechnology alone cannot provide a promising approach for bone regeneration. The importance of the application of growth factors such as BMP2, VEGF to enhance osteoinduction and vascularisation is more of concern in the case of critical-sized bone defects.^{76,109,110} VEGF levels must be controlled, because non-physiological doses can inhibit bone formation,

directly influencing osteoblast differentiation and enhancing bone resorption.¹¹¹ Current studies of growth factors' functions should be aimed at further clarifying the molecular crosstalk between osteogenesis and angiogenesis, and the association of their dose in bone formation.¹¹² The controlled release of growth factors and their concentrations are important parameters which should be optimised in bone regeneration.^{109,113,114} We have developed a new nanotechnology method by coating a nanolayer of poly (ethyl acrylate) on material surfaces, including biomaterials, that can increase the bioavailability of fibronectin domains for attachment of cells and growth factors and consequently, improve bone regeneration.^{115–117} In addition, the application of further nanosystem delivery methods for growth factors and other osteoinductive factors such as adenosine¹¹⁸ and ions¹¹⁹ can be explored to support complete bone regeneration. Therefore, it seems that if advanced fabrication methodologies (such as computer-aided design (CAD) and rapid prototyping) and growth factor and metabolite release systems are combined with nanotechnology, we can hopefully tackle the challenges of bone formation in critical-sized bone defects and provide efficacious treatment strategies.

Conclusions

The field of nanotechnology and the application of nanomaterials to regenerative medicine has been a rapidly growing area of research in recent years. In this review paper, the impact of nanotechnology in biomaterials development for bone regeneration has been discussed. The review illustrates that mechanical properties, biocompatibility, and the osteoinductivity of biomaterials can be improved by the application of nanomaterials. However, there are still several challenges that need to be overcome. As this field moves forward, the combination of nanotechnology with factor delivery including growth factors, metabolites and ions will inform biomaterials design with the goal of achieving complete bone regeneration.
