Mixed lead source precursors for producing light absorption layers of perovskite solar cells†

Honggang Xie,^{‡,a} Bo Zheng,^{‡,a} Can Gao,^a Jiannan Xu,^a Jiejing Zhang,^a Chunxiao Gao^b and Xizhe Liu  ^{*,a}

Beside the conventional perovskite precursors with lead halides as lead sources, non-halide lead sources provide additional tools for tuning the properties of perovskite layers, and lead acetate is a promising candidate for non-halide lead sources. In this work, we develop the perovskite precursor with a mixed non-halide lead source by partially replacing lead acetate with lead thiocyanate. Scanning electron microscopy and X-ray diffraction measurements indicate that lead thiocyanate additive can remarkably increase the size of perovskite grains and the crystallization of perovskite layers. And the cross-sectional investigation illustrates that the penetration of perovskite materials into TiO_2 porous layers also can be improved by the lead thiocyanate additive. As a consequence, the recombination process and charge extraction process of devices are improved. By optimizing the quantity of lead thiocyanate, the power conversion efficiency of devices is increased from 14.0% to 17.2%, and the stability of devices is elevated simultaneously.

1. Introduction

In recent years, perovskite solar cells (PSCs) have become a research focus for their excellent photovoltaic performance and simple fabrication procedure.^{1–11} These merits are mainly attributed to the light absorption materials of organic lead halides, which have a perovskite crystal structure of ABX_3 . Previous investigations indicate that the composition of precursor solutions is an important factor to determine the quality of perovskite layers.^{12–14} For one step spin-coating of $\text{CH}_3\text{NH}_3\text{PbI}_3$ layers, two kinds of precursor solutions are developed. One is composed of lead iodide (PbI_2) and methylammonium iodide (MAI) with the same stoichiometric ratio of obtained $\text{CH}_3\text{NH}_3\text{PbI}_3$ layers. For this stoichiometric precursor solution, controlling the morphology of perovskite layers is usually difficult in a one step spin-coating process. Although the solvent engineering method can improve the morphology of these perovskite layers, the usage of antisolvent may lead to environmental problems in industry application. Another non-stoichiometric precursor solution uses non-iodide compounds as the lead source, and methylammonium iodide with three times the stoichiometric ratio is added.⁴ Smooth perovskite

layers with compact structure can be produced with these non-stoichiometric precursor solutions by simple one step spin-coating, which releases excessive compounds in the annealing process.¹⁵

After the pioneering work with lead chloride as non-iodide lead source, the non-stoichiometric precursor with lead acetate ($\text{Pb}(\text{AC})_2$) as a non-halide lead source was developed, which produces ultrasmooth perovskite layers and leads to a power conversion efficiency (PCE) of 15.2%.¹⁶ Although the usage of $\text{Pb}(\text{AC})_2$ improves the morphology of perovskite layers, the PCEs of these devices are still lower than that of devices by solvent engineering method. On the other hand, the stability of PSCs is also important topics for the devices produced by the precursor solutions with $\text{Pb}(\text{AC})_2$ lead sources.^{17,18} Several research works indicate that the small size of grains leads to extensive grain boundaries, which can enhance permeability of oxygen/moisture to induce degradation of perovskite layers. And these grain boundaries also exhibit a high density of defects and result in intensive recombination process.^{19,20}

To improve the photovoltaic performance of devices, several strategies are developed by tuning the composition of $\text{Pb}(\text{AC})_2$ precursors. PCBM is introduced into $\text{Pb}(\text{AC})_2$ precursor as an additional composition for passivating grain boundary.²¹ Zhang *et al.* studies the ability of hypophosphorous acid, which widely exists in the hydroiodic acid solution.²² Several compounds, such as methylammonium bromide,²³ lead chloride²⁴ and lead iodide,²⁵ are also employed in the $\text{Pb}(\text{AC})_2$ precursor. Although $\text{Pb}(\text{AC})_2$ precursor has been investigated by several reports, efficient additive is still desirable for improving the PCE and stability simultaneously. Recently $\text{Pb}(\text{SCN})_2$ is emerged as the

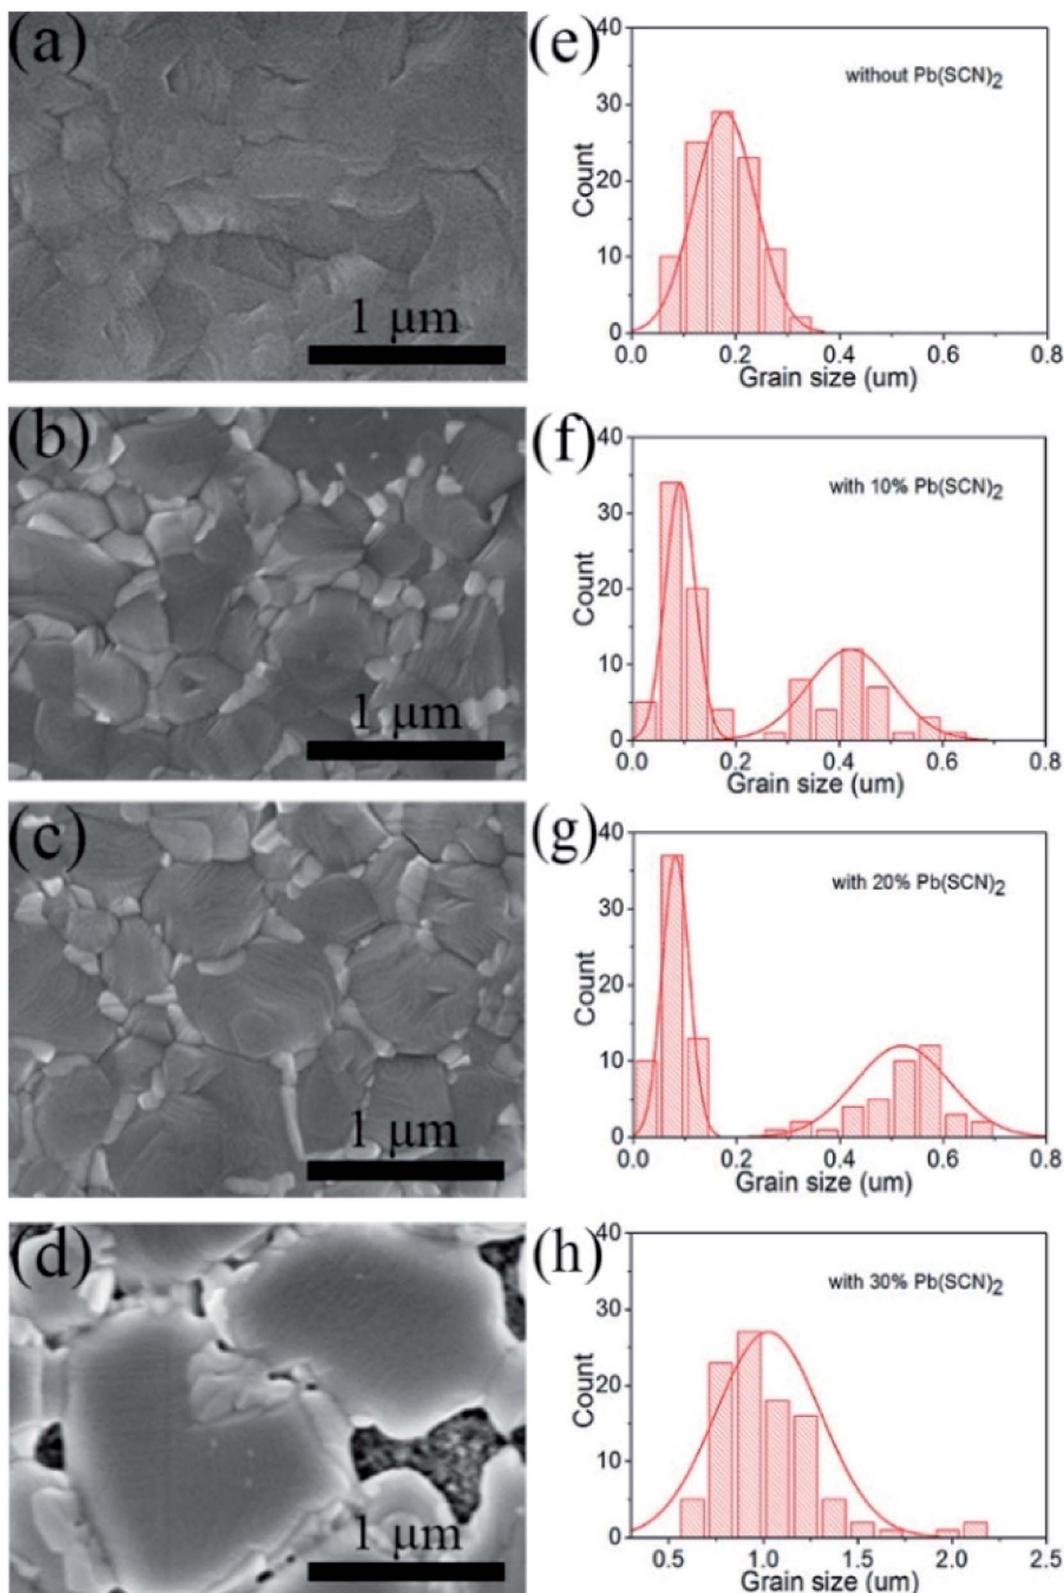

Fig. 1 The surface morphology and grain size distribution of perovskite layers prepared by Pb(AC)₂ precursors without (a and e) and with 10% (b and f), 20% (c and g) and 30% (d and h) Pb(SCN)₂ additives.

additive for perovskite precursor solutions with PbI_2 as the lead source.^{26–28} It is found that adding a small amount of $\text{Pb}(\text{SCN})_2$ into these precursor solutions can significantly enlarge the grain size.^{29,30} And several reports indicate that $\text{Pb}(\text{SCN})_2$ can passivate the defects at grain boundaries, the carrier lifetime is increased consequently.^{31,32} Therefore, $\text{Pb}(\text{SCN})_2$ additive should be a promising candidate for $\text{Pb}(\text{AC})_2$ precursors.

In this work, we fabricated PSCs with $\text{Pb}(\text{AC})_2$ precursors by one step spin-coating without the usage of antisolvent. The function of $\text{Pb}(\text{SCN})_2$ additive was investigated, and the photovoltaic performance and stability of these devices were studied.

2. Experiment

After laser etching, fluorine doped tin oxide (FTO) glass was cleaned with acetone, ethanol and deionized water in ultrasonic bath, sequentially. Compact TiO_2 layers were deposited by spray pyrolysis with $50 \text{ mmol mL}^{-1} \text{ Ti}(\text{OPr})_2(\text{acetylacetone})_2$ in ethanol solution at 450°C . And mesoporous TiO_2 films were deposited on the compact TiO_2 films by spin-coating with the TiO_2 paste solution (18NRT, Dyesol, diluted with six times of ethanol in weight) at 5000 rpm for 30 s . Then these samples were thermal annealing at 80°C , 125°C , 325°C and 500°C for 30 minutes , respectively. $\text{Pb}(\text{AC})_2 \cdot 3\text{H}_2\text{O}$ was dehydrated at 70°C in vacuum drying oven for 12 hours . In the $\text{Pb}(\text{AC})_2$ precursor solution, 3.0 mol L^{-1} MAI and 1.0 mol L^{-1} $\text{Pb}(\text{AC})_2$ are dissolved into *N,N*-dimethylformamide (DMF). For incorporating different quantity of $\text{Pb}(\text{SCN})_2$ (10%, 20% and 30%), 0.1 mol L^{-1} , 0.2 mol L^{-1} and 0.3 mol L^{-1} $\text{Pb}(\text{SCN})_2$ were incorporated into the precursor solutions by replacing $\text{Pb}(\text{AC})_2$, and the total concentration of Pb^{2+} ions is maintained at 1.0 mol L^{-1} . After stirring the precursor solutions at room temperature, the perovskite films were spincoated at 5000 rpm for 30 s and annealed at 100°C for 10 minutes . Then hole transport material (HTM) solution was spincoated on perovskite films at 4000 rpm for 30 s . The HTM solution is composed of 72.3 mg spiro-MeOTAD, $28.5 \mu\text{L}$ 4-*tert*-butylpyridine, $18.5 \mu\text{L}$ lithium bis(trifluoromethanesulfonyl)imide (LiTFSI) solution (520 mg LiTFSI in 1 mL acetonitrile) and 1 mL chlorobenzene. TiO_2 layers were prepared in air condition, then samples were transferred into a N_2 glove box for preparing perovskite layers and HTM layers. After the storage in dry air for 12 hours , Au electrodes were deposited on the HTM layers by thermal evaporation.

SEM images were investigated by FEI-MAGELLAN 400 scanning electron microscope. X-ray diffraction (XRD) patterns were obtained using a Rigaku D/max-2550 X-ray diffractometer. Photocurrent density–photovoltage characteristics were recorded from 1.15 V to 0 V by a CHI660 electrochemical workstation. The active area of solar cells is 0.15 cm^2 defined by a mask. AM1.5 illumination was provided by a 3A class solar simulator (UHE-16, ScienceTech Inc.), which was calibrated to one sun by a KG5 filtered Si reference solar cell (certified by VLSI Standards Inc.). IPCE spectra are measured in the DC mode by a controlled monochromator (BOCIC Inc.) with a 500 W Xe light source (NBet Inc.). The absorption spectra were recorded with a L5S UV-vis spectrophotometer in the wavelength range of $500\text{--}900 \text{ nm}$.

900 nm. Photoluminescence spectra were detected by a CCD detector (PIXIS256BR, Princeton Instruments Inc.), and the excitation wavelength was 532 nm provided by a low noise solid state laser (MLL-III-532). Impedance spectra were measured at 0.7 V bias potential under constant illumination over a frequency range from 1 MHz to 1 Hz by a CHI660 electrochemical workstation. To investigate the humidity stability of devices, unencapsulated perovskite solar cells were maintained under dark at 25°C in the air condition with 50% humidity. A constant temperature and humidity test chamber (LHS-80HC, BLUEPARD) was used for this humidity stability test.

3. Results and discussion

Fig. 1 shows the surface morphology of perovskite layers prepared by $\text{Pb}(\text{AC})_2$ precursors with different quantity of $\text{Pb}(\text{SCN})_2$ additive. For the $\text{Pb}(\text{AC})_2$ precursor solution without $\text{Pb}(\text{SCN})_2$ additive, the perovskite layers are composed of grains with 179 nm in average size (Fig. 1a and e). By adding 10% $\text{Pb}(\text{SCN})_2$ into $\text{Pb}(\text{AC})_2$ precursor solution, the average size of perovskite grains increases to 422 nm (Fig. 1b and f). After

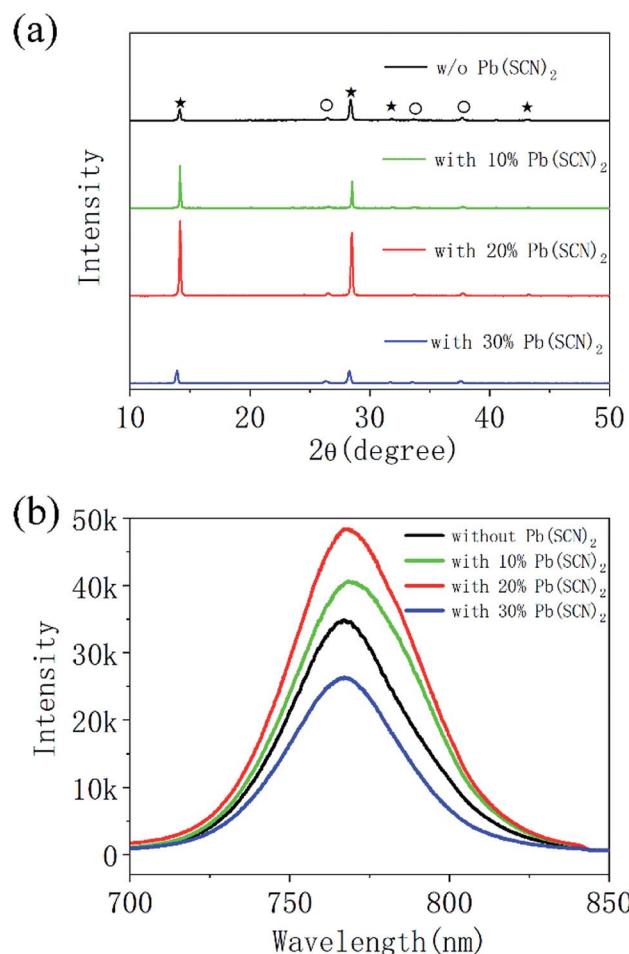

Fig. 2 The XRD patterns (a) and PL spectra (b) of perovskite layers prepared by $\text{Pb}(\text{AC})_2$ precursors without and with different $\text{Pb}(\text{SCN})_2$ additives, the diffraction peaks of $\text{CH}_3\text{NH}_3\text{PbI}_3$ and FTO are labeled with stars and circles, respectively.

further increasing the quantity of $\text{Pb}(\text{SCN})_2$ to 20%, compact perovskite layers with the average grain size of 521 nm can be obtained (Fig. 1c and g). The increase of grain size is likely attributed to the vapor assistant annealing of HSCN and CH_3NH_2 , which is formed by the decomposition of CH_3NH_3^+ cations and SCN^- anions in the heating process.³¹ The large grain size of perovskite layers is beneficial to decrease the scattering of carriers at the grain boundaries.³³ For the $\text{Pb}(\text{AC})_2$ precursor with 30% $\text{Pb}(\text{SCN})_2$ additive in Fig. 1d, the average grain size further increases to 1026 nm (Fig. 1h), but the coverage of perovskite layers on TiO_2 layers is poor. This incomplete coverage usually leads to intensive recombination process in the PSCs. Except the large grains of perovskite layers in Fig. 1b and c, some small grains also exist by the incorporation of $\text{Pb}(\text{SCN})_2$ as shown in Fig. 1f and g. The large perovskite grains are essential for the transport process of photogenerated charge carriers, and the small grains can fill the gaps between large perovskite grains, which guarantees the compact structure of perovskite layers.

X-ray diffraction (XRD) measurements are performed on these four kinds of perovskite layers, which are prepared by $\text{Pb}(\text{AC})_2$ precursors without and with different $\text{Pb}(\text{SCN})_2$ additives. As shown in Fig. 2a, all diffraction peaks can be assigned to FTO substrates and $\text{CH}_3\text{NH}_3\text{PbI}_3$ (MAPbI_3) with perovskite structure. It means that all these four kinds of precursors can prepare MAPbI_3 layers with perovskite structure.²² For the pure $\text{Pb}(\text{AC})_2$ precursors without $\text{Pb}(\text{SCN})_2$ additive, the intensity of diffraction peaks for MAPbI_3 is relatively small. After incorporating 10% and 20% $\text{Pb}(\text{SCN})_2$ into $\text{Pb}(\text{AC})_2$ precursors, the intensity of diffraction peaks continuously increases. This result reflects the improvement of crystallization, which is accordance to the increased size of MAPbI_3 grains in Fig. 1b and c. As shown

in the enlarged XRD pattern of Fig. S1,† 10% and 20% $\text{Pb}(\text{SCN})_2$ additives do not change the degree of diffraction peaks. And 30% $\text{Pb}(\text{SCN})_2$ additive leads to a decrease of 0.26° for the diffraction peak, which reflects the expansion of crystal lattice. Therefore, 10% and 20% $\text{Pb}(\text{SCN})_2$ additives do not change the composition of MAPbI_3 layers, but 30% $\text{Pb}(\text{SCN})_2$ additive is likely to incorporate SCN^- anions into the crystal lattice of MAPbI_3 . The photoluminescence (PL) spectra of perovskite layers without and with different $\text{Pb}(\text{SCN})_2$ additives were measured as shown in Fig. 2b. The intensity of PL peaks can be elevated by incorporating 10% and 20% $\text{Pb}(\text{SCN})_2$ in the precursor solutions. For the excessive $\text{Pb}(\text{SCN})_2$ of 30%, the intensity of PL peaks is even lower than that of MAPbI_3 without $\text{Pb}(\text{SCN})_2$ additive. As the intensity of PL emission reflects the quality of perovskite layers,³⁴ the optimized condition of 20% $\text{Pb}(\text{SCN})_2$ is accordance to the crystallization in XRD measurements.

We fabricate perovskite solar cells based on these four different kinds of perovskite layers, and the cross-sectional SEM images of devices are shown in Fig. 3. Without the incorporation of $\text{Pb}(\text{SCN})_2$ additive (Fig. 3a), the size of perovskite grains is less than the thickness of perovskite layers. Therefore, photogenerated charge carriers suffer from the grain boundary scattering in the transport process. It is also noted that the penetration of MAPbI_3 into TiO_2 porous layers is limited and some small empty holes are existed. This insufficient penetration can degrade the charge transfer process at TiO_2 /perovskite interfaces. After the incorporation of $\text{Pb}(\text{SCN})_2$ as shown in Fig. 3b and c, the size of perovskite grains increases and no grain boundary exists in the depth direction. The SEM images also indicate that $\text{Pb}(\text{SCN})_2$ additive improves the penetration of MAPbI_3 into TiO_2 porous layers. For the perovskite layers with

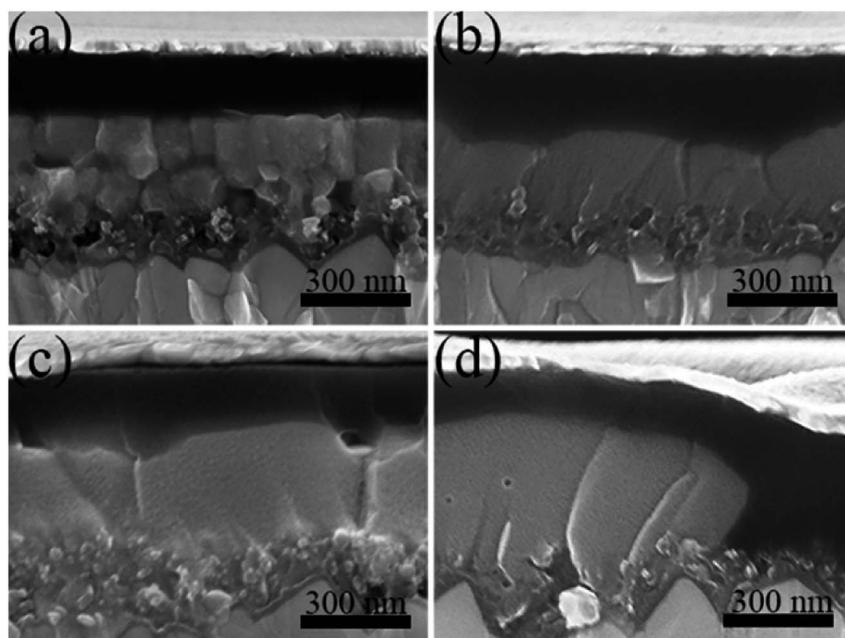

Fig. 3 The cross-sectional SEM images of the devices prepared by $\text{Pb}(\text{AC})_2$ precursors without (a) and with 10% (b), 20% (c) and 30% (d) $\text{Pb}(\text{SCN})_2$ additives.

30% $\text{Pb}(\text{SCN})_2$ additive in Fig. 3d, poor coverage of the perovskite layers leads to the direct contact between Spiro-OMeTAD layers and TiO_2 layers, which can result in the recombination process of devices.

The best performed photocurrent density–photovoltage curves of these different devices are illustrated in Fig. 4a and Table 1. Without the incorporation of $\text{Pb}(\text{SCN})_2$ additive, the device with perovskite layer by pure $\text{Pb}(\text{AC})_2$ precursor gives a PCE of 14.0% under one sun illumination, which has a short circuit current density (J_{sc}) of 20.2 mA cm^{-2} , an open circuit photovoltage (V_{oc}) of 1.044 V and a fill factor (FF) of 0.66. And the PCE of device increases to 15.1% by incorporating 10% $\text{Pb}(\text{SCN})_2$ into the $\text{Pb}(\text{AC})_2$ precursor. For incorporating 20% $\text{Pb}(\text{SCN})_2$ additive, the PCE of device reaches 17.2% with a J_{sc} of 22.1 mA cm^{-2} , a V_{oc} of 1.061 V and a FF of 0.73. The promotion of photovoltaic performance is accordance with the improved quality of perovskite layers by $\text{Pb}(\text{SCN})_2$ additives.³⁵ It indicates that $\text{Pb}(\text{SCN})_2$ additive can improve the $\text{Pb}(\text{AC})_2$ precursor solutions for perovskite solar cells. However, further increasing the quantity of $\text{Pb}(\text{SCN})_2$ to 30% leads to an obvious decrease of device performance, which can be attributed to the incomplete coverage as shown in Fig. 1d. Fig. 4b shows the statistics for

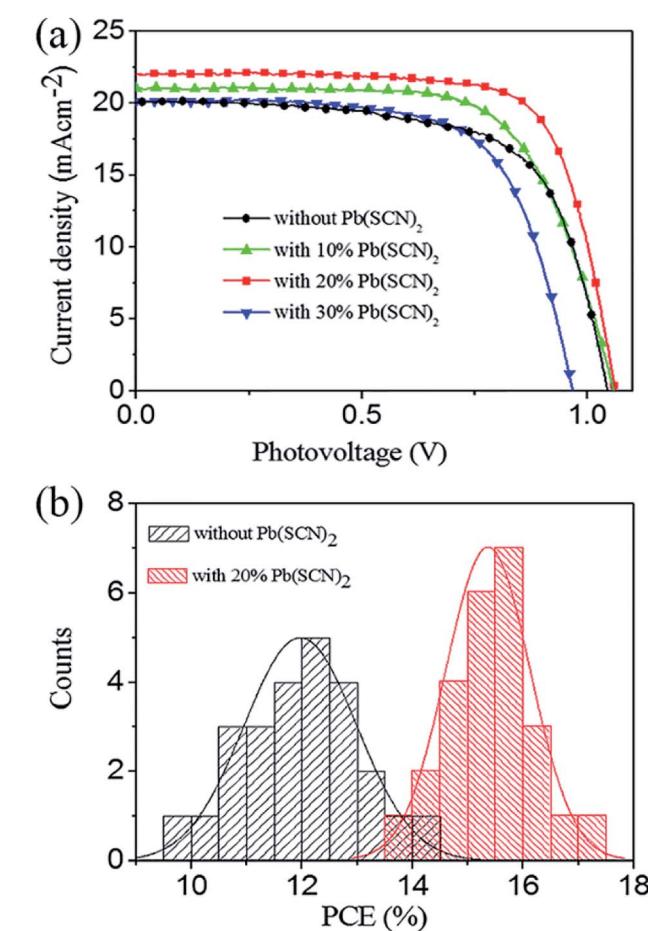

Fig. 4 (a) J – V curves of best performing devices without and with different $\text{Pb}(\text{SCN})_2$ additives, and (b) statistics of PCEs for 25 devices without and with 20% $\text{Pb}(\text{SCN})_2$ additive.

Table 1 The photovoltaic parameters of perovskite solar cells

$\text{Pb}(\text{SCN})_2$	J_{sc} (mA cm^{-2})	V_{oc} (V)	Fill factor	Efficiency (%)
w/o	20.2	1.044	0.66	14.0
10%	21.0	1.058	0.68	15.1
20%	22.1	1.061	0.73	17.2
30%	20.2	0.968	0.68	13.2

PCEs of devices prepared by $\text{Pb}(\text{AC})_2$ precursor without and with 20% $\text{Pb}(\text{SCN})_2$ additive. By adding $\text{Pb}(\text{SCN})_2$, the average PCE of devices can be increased from 12.0% to 15.4%, which confirms the ability of $\text{Pb}(\text{SCN})_2$ additive. To investigate the hysteresis effect of devices, we perform a forward scan from 0 V to 1.15 V right after a reverse scan from 1.15 V to 0 V under one sun illumination. The intensity of hysteresis effect is summarized by the hysteresis index ($(\text{PCE}_{\text{rev}} - \text{PCE}_{\text{forw}})/\text{PCE}_{\text{rev}}$). As shown in Fig. S2,† the device with 20% $\text{Pb}(\text{SCN})_2$ additive has a hysteresis index of 0.082, which is slight lower than that of device without $\text{Pb}(\text{SCN})_2$ additive (0.136). As the high crystallinity of MAPbI_3 layers with 20% $\text{Pb}(\text{SCN})_2$ additive indicates their relative low

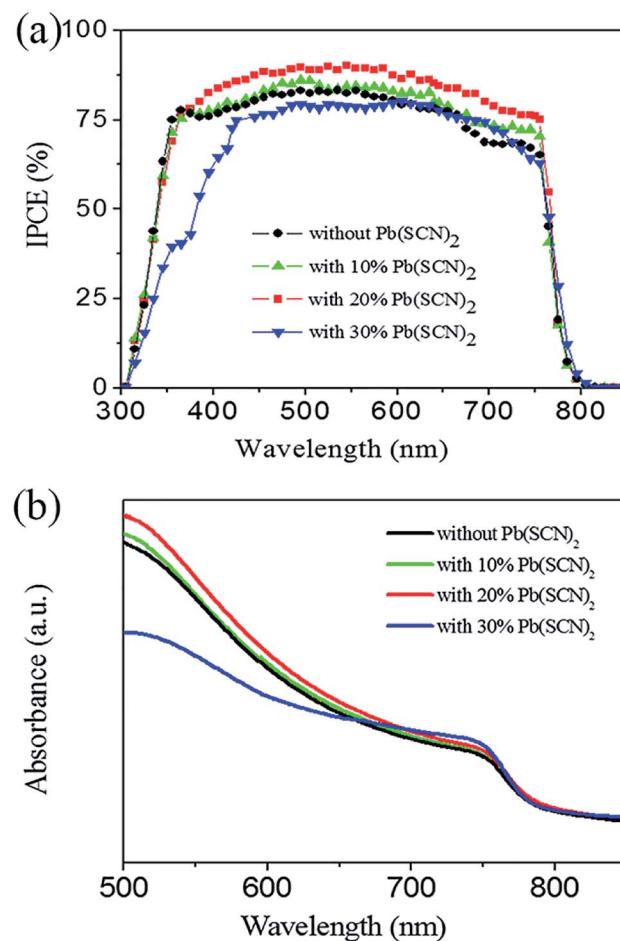

Fig. 5 (a) IPCE spectra of devices and (b) light absorption spectra of perovskite layers prepared by $\text{Pb}(\text{AC})_2$ precursors without and with different $\text{Pb}(\text{SCN})_2$ additives.

density of defects, it reduces the migration path of ions and decreases the hysteresis effect of devices.

We measured the incident photon-to-electron conversion efficiency (IPCE) spectra of these devices as shown in Fig. 5a. By adding 10% and 20% $\text{Pb}(\text{SCN})_2$ into the $\text{Pb}(\text{AC})_2$ precursor, the IPCE values of devices increase evenly in the whole wavelength range with light response. By further increasing the quantity of $\text{Pb}(\text{SCN})_2$ additive to 30%, the IPCE values remarkably decrease, especially at short wavelength range. This tendency of IPCE spectra is accordance with the trend of J_{sc} in Fig. 4a. IPCE values are usually related to the light absorption process and charge collection process of solar cells. Fig. 5b is the light absorption spectra of perovskite layers prepared by different precursor solutions. By adding 30% $\text{Pb}(\text{SCN})_2$ into $\text{Pb}(\text{AC})_2$ precursor solutions, the absorption spectrum has a remarkable decrease at the short wavelength range, which is accordance to the decrease of IPCE values at this wavelength range in Fig. 5a. For the perovskite layers with 10% and 20% $\text{Pb}(\text{SCN})_2$ additive, the absorption spectra of perovskite layers have a minor increase compared with the perovskite layers without $\text{Pb}(\text{SCN})_2$ additive. The improvement of light absorption is beneficial to the utilization of incident solar illumination, but the obvious increase of photovoltaic performance cannot be fully attributed to this light absorption process.

The transport-recombination process of PSCs can be investigated by the impedance spectra. Fig. 6a is the Nyquist plots of devices with different perovskite layers under a bias potential of 0.7 V, and two impedance arcs can be distinguished in these

spectra. Previous reports indicate that the high frequency impedance arc can be attributed to the charge transfer process at the TiO_2 /perovskite interfaces and the low frequency impedance arc can be assigned to the recombination process in the perovskite layers.^{36–38} By fitting the Nyquist plots with equivalent circuit in Fig. 6b, two resistance elements of R_h and R_L can be deduced from high frequency and low frequency impedance arcs respectively. As shown in Table 2, the resistances of recombination process (R_L) increase from $287.1 \Omega \text{ cm}^2$ to $302.9 \Omega \text{ cm}^2$ and $478.4 \Omega \text{ cm}^2$ by adding 10% and 20% $\text{Pb}(\text{SCN})_2$ in the $\text{Pb}(\text{AC})_2$ precursors, but it decreases to $183.3 \Omega \text{ cm}^2$ by further increasing the quantity of $\text{Pb}(\text{SCN})_2$ to 30%. It means that $\text{Pb}(\text{SCN})_2$ additive can reduce the recombination process and 20% $\text{Pb}(\text{SCN})_2$ additive is the optimized condition. The reduced recombination process can promote the photovoltaic performance of PSCs, which is accordance to the tendency of photovoltaic properties in Fig. 4. The slow recombination can be related to the improvement in grain growth and crystallization of perovskite layers. The charge transfer resistance (R_h) can be reduced from $41.6 \Omega \text{ cm}^2$ to $15.7 \Omega \text{ cm}^2$ by incorporating 10% $\text{Pb}(\text{SCN})_2$ additive. This result indicates that the $\text{Pb}(\text{SCN})_2$ additive can improve the charge transfer process at TiO_2 /perovskite interfaces, which likely comes from the promotion of MAPbI_3 penetration into TiO_2 porous layers. As shown in the SEM image of Fig. 3a, small holes exist in the TiO_2 porous layers and the penetration of MAPbI_3 is insufficient. After incorporating 10% and 20% $\text{Pb}(\text{SCN})_2$ additives, these small holes are eliminated and the penetration of MAPbI_3 into TiO_2 porous layers is improved (Fig. 3b and c). The penetration of MAPbI_3 enhances the contact of $\text{TiO}_2/\text{MAPbI}_3$ interfaces, which can lead to the reduced transfer resistance. The improved charge transfer process is beneficial to the extraction of excited electrons and holes. It is noted that further increasing the quantity of $\text{Pb}(\text{SCN})_2$ to 20% results in a slight increase of R_h to $25.2 \Omega \text{ cm}^2$, which is still lower than the R_h of devices without $\text{Pb}(\text{SCN})_2$ additive. Although $\text{Pb}(\text{AC})_2$ precursor with 20% $\text{Pb}(\text{SCN})_2$ additive leads to a slightly larger charge transfer resistance than that of $\text{Pb}(\text{AC})_2$ precursor with 10% $\text{Pb}(\text{SCN})_2$ additive, the devices with 20% $\text{Pb}(\text{SCN})_2$ additive have an obviously large recombination resistance. The balance of these two factors results in the optimized photovoltaics performance at the condition of 20% $\text{Pb}(\text{SCN})_2$ additive. As shown in Table 2, excessive $\text{Pb}(\text{SCN})_2$ additive of 30% leads to a remarkable increase of R_h to $58.8 \Omega \text{ cm}^2$, which degrades the interfacial charge transfer process.

Perovskite materials usually suffer the problem of stability, which leads to the degradation of PSCs. We study the aging performance of unencapsulated devices without and with 20% $\text{Pb}(\text{SCN})_2$ additive under dark in the air condition with 50%

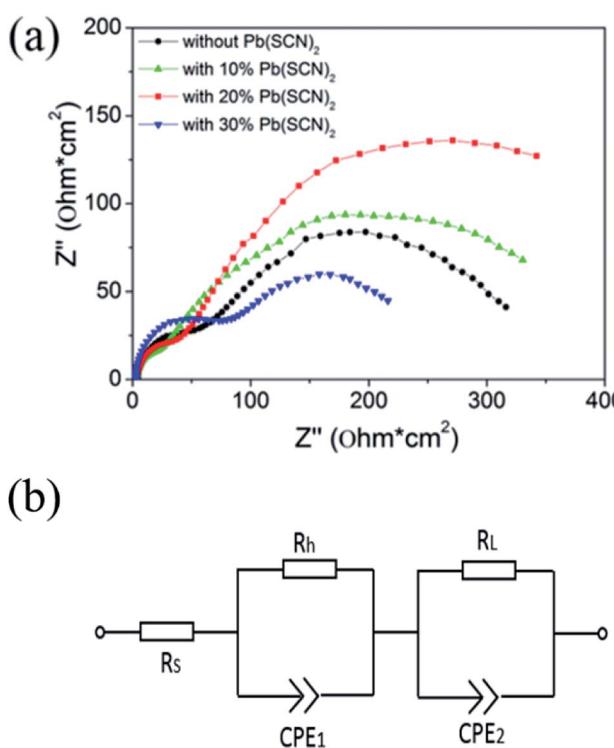

Fig. 6 (a) Nyquist plots of devices without and with different $\text{Pb}(\text{SCN})_2$ additives measured at a bias potential of 0.7 V, and (b) the equivalent circuit for fitting impedance data.

Table 2 The resistance elements extract from impedance spectra

$\text{Pb}(\text{SCN})_2$	0%	10%	20%	30%
$R_h (\Omega \text{ cm}^2)$	41.6	15.7	25.2	58.8
$R_L (\Omega \text{ cm}^2)$	287.1	302.9	478.4	183.3

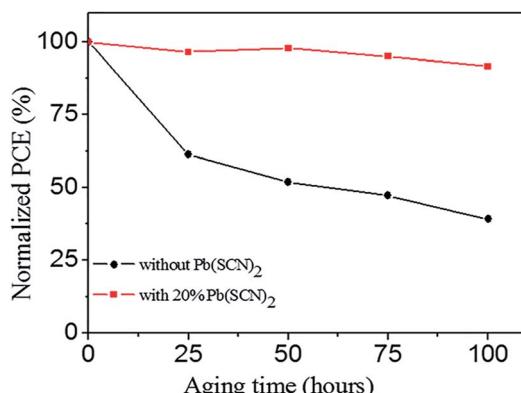

Fig. 7 The degradation of normalized PCEs for the unencapsulated devices without and with 20% Pb(SCN)₂ additive in the air condition with 50% humidity at 25 °C.

humidity at 25 °C. As shown in Fig. 7, the device without Pb(SCN)₂ additive leads to an intensive degradation, only 39.1% of its original PCE is preserved after 100 hours aging. Although Pb(AC)₂ is an effective non-halide lead source for preparing perovskite layers, it may lead to the problem of stability.¹³ After incorporating 20% Pb(SCN)₂ additive into Pb(AC)₂ precursors, the aging performance of PSCs is improved remarkably, and 91.6% of its original PCE is preserved by the 100 hours aging process. The improved stability of devices should be attributed to the promotion of perovskite layers. The large grain size and reduced grain boundaries, which are passivated by the small grains, can reduce permeability of oxygen/moisture for enhancing the stability of these devices.^{19,39} To investigate the thermal stability, we performed thermal aging of MAPbI₃ layers on glass substrates under dark in N₂ atmosphere at 80 °C for 24 hours. After the thermal aging process, the XRD pattern of MAPbI₃ layers without Pb(SCN)₂ additive emerges a diffraction peak at 12.7° (Fig. S3†), which can be assigned to PbI₂. It means that MAPbI₃ partially decomposes in this thermal aging process. By incorporating 20% Pb(SCN)₂ additive, all of the diffraction peaks can be assigned to MAPbI₃ after the thermal aging, and the diffraction peak of PbI₂ is almost undistinguishable. Therefore, Pb(SCN)₂ additive can improve the thermal stability of MAPbI₃ layers produced by Pb(AC)₂ precursors.

4. Conclusion

In summary, we incorporate Pb(SCN)₂ into Pb(AC)₂ precursors as a mixed lead source for preparing MAPbI₃ light absorption layers of PSCs by one step spin-coating. It is found that Pb(SCN)₂ additive can encourage the growth of MAPbI₃ grains and improve the penetration of MAPbI₃ into the TiO₂ porous layers. By optimizing the quantity of Pb(SCN)₂ additive, the PCEs of devices are improved from 14.0% to 17.2%. Further investigation indicates that Pb(SCN)₂ additive can reduce the recombination process and facilitate the interfacial charge transfer process. In addition, Pb(SCN)₂ additive remarkably increases the device stability, which is desirable for the Pb(AC)₂ precursor method.
