Au decorated BiVO₄ inverse opal for efficient visible light driven water oxidation

 Xiaonong Wang,^{ID}*^{ab} Xiaoxia Li^{*ab} and Jingxiang Low^{ID}^c

Photocatalytic water splitting provides an effective way to prepare hydrogen and oxygen. However, the weak light utilization and sluggish kinetics in the oxygen evolution reaction (OER) process substantially retard the photocatalytic efficiency. In this context, modification of the semiconductors to overcome these limits has been the effective strategy for obtaining highly-efficient photocatalytic water oxidation. Here, plasmonic Au has been loaded onto BiVO₄ inverse opal (IO) for photocatalytic water oxidation. It is discovered that the IO structure provides higher specific surface area and favors light absorption on BiVO₄. In the meantime, the plasmonic Au can simultaneously enhance the light-utilization capability and photogenerated charge carrier utilization ability of the BiVO₄ IO. As a result, a high photocurrent density and long photogenerated charge carrier lifetime can be achieved on the optimized Au–BiVO₄ IO, thereby obtaining a superior photocatalytic activity with an oxygen production rate of 9.56 μmol g⁻¹ h⁻¹.

1 Introduction

Over the past century, the development and utilization of solar energy has been one hot topic for tackling the increasingly serious environmental and energy problems due to our dependency on the traditional coal fuel for power generation and supply.^{1–4} In this regard, solar-driven water splitting, which could directly convert and store the incident solar energy into valuable hydrogen and oxygen, has been one of the star-catalytic reactions toward realizing sustainable and green development of human society.^{3,5,6} Therefore, in the past several decades, various semiconductors, such as TiO₂ and WO₃, have been investigated for the photocatalysis.^{7–9} However, their wide bandgap, rapid electron–hole pair recombination and sluggish kinetics in oxygen evolution reaction have substantially retarded the solar conversion efficiency of such a fascinating technology.

Under this circumstance, water oxidation kinetics of the photocatalysts should be optimized and facilitated, accompanying with enhanced light absorption and efficient charge separation to reach highly-efficient photocatalytic water splitting. Recently, BiVO₄, a small bandgap (2.4 eV vs. reversible hydrogen electrode (RHE)) semiconductor with high oxidation ability, has been known as one of potential oxidative

semiconductor for the photocatalytic water splitting.^{10–12} Apart from that, its low cost, high chemical stability and environmental friendliness characteristics have allowed it to be feasible in future large-scale application of photocatalytic water splitting. However, most of the recently reported BiVO₄ owns low photocurrent densities mainly due to the electrons and holes rapid recombination in the bulk or on the surface and weak light utilization capability, which restricts their wide application in photocatalytic water splitting.^{13–16} With these limitations in mind, many effective approaches have been explored, such as morphology control (nano dots, nano leaves),^{17,18} crystal-surface engineering¹⁹ and homo/heterojunction constructing (type II and S scheme heterojunction).^{8,9,14–16}

Fabrication of the BiVO₄ into various morphology with the specific functions has been a simple yet effective strategy for enhancing its physicochemical, especially optical properties.²⁰ For example, Chen *et al.* reported that the BiVO₄ nanoarray structure can endow the BiVO₄ with enormous surface active site and enhanced light absorption capability, thereby improving its photocatalytic performance.²¹ In addition, Ozbay *et al.* introduced the deposition of Au on BiVO₄ nanoarray for enhanced light absorption and high photocurrent generation through the injection of sub-band-gap hot electrons.²² Recently, the inverse opal structure has emerged as a unique morphology for BiVO₄ because it can provide a wide variety of porous structure for the catalytic reaction and allow the multi-scattering of light within its structure for enhancing the light utilization capability of the BiVO₄.^{23,24} Apart from the enhanced light utilization capability, the photogenerated charge carrier separation is another critical issues awaiting to be resolved. Constructing heterostructures by combining noble metal crystal with semiconductor can be a potential answer for this problem,

R. China

due to their higher work function than most of the semiconductors for accepting photogenerated electrons from semiconductors and thus enhancing the photogenerated charge carrier separation efficiency.^{25–29} In addition, plasmonic noble metals, such as Ag and Au, possess unique surface plasmon resonance (SPR) properties, allowing them to simultaneously facilitate the photogenerated charge carrier separation efficiency and provide SPR-induced “hot electron” for the photocatalytic reaction.^{28,30–32} The surface plasmon may improve the photocatalytic activities *via* local electromagnetic field enhancement and resonant energy transfer (RET) mechanisms.³³ Due to the strong local field enhancement, the optical absorption can be adjusted and the spatial distribution of photogenerated electron–hole pairs in semiconductors could be modulated.³⁴ And the metal nanoparticle could also serve as the light capture center, enhancing the photo-electric conversion efficiency. More interestingly, RET process could enhance carrier creation and separation at the energies both above and below the bandgap by surface plasmon dipoles relaxation.³³ By tuning the plasmonic resonant frequency of Au consistent with BiVO₄, the Au surface plasmon resonant energy could directly excite the electrons–holes separation through the near-field electromagnetic interaction. In this work, we report plasmonic Au loaded on BiVO₄ inverse opals (Au–BiVO₄ IO) for the photocatalytic water oxidation. Generally, Au–BiVO₄ IO was prepared by a template-assisted self-assemble method, followed by electron-beam evaporation. Then, the photocatalytic water oxidation of the Au–BiVO₄ IO was studied *via* a photoelectrochemical system under visible light irradiation. Benefiting from the unique features of the IO structure and plasmonic Au, the photocatalytic water oxidation performance of the Au–BiVO₄ IO was higher than that of the BiVO₄ IO. Apart from that, the photocatalytic enhancement mechanism of the plasmonic Au/BiVO₄ IO photocatalyst was proposed and discussed. Such a facile template assisted self-assembly strategy combined with micro-nano fabrication methods for preparation of advanced photocatalyst can shed some light in development of highly efficient visible-light-driven photocatalyst for energy and environmental applications.

2 Experiment procedure

2.1 Chemicals

100 nm, 200 nm and 500 nm monodispersed polystyrene (PS) nanosphere suspensions (2.5 wt% in water, surfactant free) were obtained from Geese (Tianjin) Technology Co., Ltd. Bi(NO₃)₃·5H₂O, NH₄VO₃, ammonia, nitric acid, hydrogen peroxide, ethanol, acetone and microscopic glass slides were purchased from Sinopharm Chemical Reagent Co., Ltd. The water used in the experiments was deionized. All chemicals were used as received without further purification.

2.1.1 Preparation of BiVO₄ sol. 0.05 mol Bi(NO₃)₃·5H₂O was added into 50 ml 4 M nitric acid and marked as solution A. Then, 0.03 mol NH₄VO₃ were added into 50 ml 4 M ammonia and marked as solution B. Subsequently, solution B was dropwise added into the solution A, gradually forming a yellow sol. Finally, the mixture was stirred at 70 °C for 5 h, obtaining BiVO₄ sol.

2.1.2 Preparation of BiVO₄ IO. The glass substrates were ultrasonicated in ethanol, acetone and DI water, and boiled in a solution containing hydrogen peroxide and DI water (3 : 7) for 1 h. Then, these glass substrates were washed with DI water for later use. The monodispersed PS nanosphere suspension was diluted by ethanol (1 : 2 in volume), and ultrasonicated for fine dispersion. The above-treated glass substrates were inserted into the above-prepared BiVO₄ sol, and the PS spheres suspension dropped on the substrate and flowed into the sol–air interface followed by their self-assembly. Finally, BiVO₄ IO can be obtained by annealing at 450 °C in air to remove the spheres.

2.1.3 Preparation of Au nano crystal decorated BiVO₄ IO. The plasmonic Au nanoparticles were loaded onto the BiVO₄ IO *via* the e-beam evaporation system (Shenyang Scientific Instruments, China, DZS-500). The thickness was set to 4 nm and the evaporation rate was maintained at 0.01 nm s^{−1} under the pressure of about 10^{−4} mbar. Finally, the Au–BiVO₄ IO can be obtained.

2.2 Characterization

Scanning electron microscopy (SEM) images and energy-dispersive X-ray spectra (EDS) were taken on a FEI Sirion 200 field-emission scanning electron microscope operated at 5 KV equipped with EDS system (Oxford Instruments). X-ray powder diffraction (XRD) patterns were recorded on a Philips X'Pert Pro Super diffractometer with Cu K α radiation ($\lambda = 1.54178$ Å). UV-vis diffuse reflectance data were recorded in the spectral region of 300–1200 nm with a Shimadzu SolidSpec-3700 spectrophotometer. Nitrogen sorption studies were performed in a Micromeritics ASAP 2020 adsorption apparatus at 77 K (for N₂ sorption) up to 1 bar.

2.3 Photoelectrochemical characterizations

The measurements were carried out on a CHI 660D electrochemical station (Shanghai Chenhua, China) under irradiation of a 300 W Xe lamp (Solaredge 700, China). Visible light (with cut 400 filter) was used as illumination source, with the intensity of 100 mW cm^{−2}. Standard three-electrode setup was used with the fabricated samples as photoelectrode, a Pt foil as counter electrode, and a Ag/AgCl electrode as reference electrode filled in 0.5 M Na₂SO₄ electrolyte. The photocurrent responses of the prepared photoelectrodes (*i.e.*, $I-t$) were operated by measuring the photocurrent densities under chopped light irradiation (light on/off cycles: 10 s) at a bias potential of 0.7 V *vs.* Ag/AgCl for 200 s. The transient open-circuit voltage decay (OCVD, $\frac{dV_{oc}}{dt}$) measurements were taken for 400 s in all, and the light on and off were controlled at 50 s and 200 s from the start, respectively. The average lifetime of the photogenerated carriers (τ_n) were obtained from the OCVD according to eqn (1):

$$\tau_n = -\frac{k_B T}{q} \left(\frac{dV_{oc}}{dt} \right)^{-1} \quad (1)$$

where k_B is the Boltzmann constant, V_{oc} is the transient open-circuit voltage, T is the temperature (in Kelvin), and q is the unsigned charge of an electron.³³

2.4 Photocatalytic water splitting measurements

The photocatalytic H₂O oxidation was measured by a self-made photocatalytic quartz tube. 1.2 g Na₂S₂O₈ dissolved in 15 ml distilled H₂O was used as electron sacrificial agent, and 3 cm² Au/BiVO₄ IO samples with different periods were put in water, followed by Ar pouring 20 min to remove oxygen. The light source and power intensity were the same as those for photocurrent measurements. The photocatalytic reaction was typically performed for 4 h. The amount of O₂ evolved was measured by gas chromatography (GC, 7890A, thermal conductivity detector, TCD, Ar carrier, Agilent).

3 Results and discussion

3.1 Characterization of the photocatalyst

The Au–BiVO₄ IO was first prepared through template-assisted self-assemble method, followed by electron-beam evaporation and the detailed procedures are illustrated in Fig. 1a. Briefly, PS spheres were self-assembled on the interface of BiVO₄ sol and air to form the dense packed monolayer (step 1). With the capillary force, the BiVO₄ sol adsorbed at the bottom of the dense packed monolayer and transferred to the ITO glass (step 2). Followed by annealing process, PS spheres were removed leaving the BiVO₄ IO (step 3). By electron-beam evaporation methods, Au nanoparticles can be loaded onto the BiVO₄ IO, forming the tight connect between them (step 4).

Fig. 1 (a) Schematic illustration for the preparation procedure for Au nanocrystal decorated BiVO₄ IO: step 1, monolayer PS spheres self-assembled on the interface of BiVO₄ sol and air; step 2, transference of hexagon packed PS spheres with the BiVO₄ sol at bottom to ITO glass; step 3, the BiVO₄ IO prepared by annealing process; step 4, Au nano crystal evaporation on BiVO₄ IO; the SEM of (b, f and g) single layer dense packed PS spheres (size 100 nm, 200 nm and 500 nm, separately); the SEM of (c, g and k) BiVO₄ IO (period about 100 nm, 200 nm and 500 nm, separately); the SEM of (d, h and l) dense Au crystal decorated BiVO₄ IO (period about 100 nm, 200 nm and 500 nm, separately); (e) high fold SEM of dense Au crystal decorated BiVO₄ IO (period about 100 nm, Au size about 10 nm); (i) the EDS spectrum of Au–BiVO₄; (m) the XRD patterns of BiVO₄, confirming the monoclinic scheelite BiVO₄.

Then, the morphologies and microstructures of as-constructed monolayer PS spheres (100 nm), BiVO₄ IO and Au crystal decorated BiVO₄ IO were identified through SEM, and the results are exhibited in Fig. 1b–e. As shown in Fig. 1b and c, the single layer PS spheres are dense packed in hexagonal structure and the BiVO₄ nano bowl array inherited the hexagonal structure after removing PS spheres, showing the periodic array. In addition, after introduction of the electron-beam evaporation, the Au nanoparticles with the size of *ca.* 10 nm were found to be densely distributed on the BiVO₄ nano bowl array (see Fig. 1d and e). According to previous studies, such densely packed Au nanoparticles can be beneficial to induce electromagnetic field for enhancing the visible light utilization of the photocatalytic system. To further confirm the distribution of the Au nanoparticles on the BiVO₄, the EDS characterization was performed. As shown in Fig. 1i, the Au, Bi, V and O elements were homogeneously distributed on the samples, confirming the uniform existence of these elements on the prepared samples. Furthermore, the SEM images of reference samples, including 200 nm and 500 nm monolayer PS spheres and the corresponding BiVO₄ nano array, were shown in Fig. 1f–l, suggesting that they own similar structure to the Au–BiVO₄ IO. Moreover, the XRD patterns in Fig. 1m confirms the monoclinic scheelite BiVO₄, consistent with PDF card 83-1697.

It is well-known that the large porous structure can substantially contribute to the enlarged specific surface area and enhanced catalytic sites. In this regard, we evaluate the physical properties of our prepared BiVO₄ IO with different porous sizes of 100, 200 and 500 nm through N₂ adsorption–

desorption isotherm, and the results are shown in Fig. 2a–c. Generally, the specific surface area of the 100 nm, 200 nm and 500 nm BiVO₄ inverse opal (on ITO substrate) was 2.05 m² g⁻¹, 1.263 m² g⁻¹ and 0.736 m² g⁻¹, separately. By excluding the influence of the ITO glass substrate which owns a specific surface area of 12.6 cm² g⁻¹, the actual specific surface area for BiVO₄ inverse opal (100 nm) can be calculated to be 1627 cm⁻² cm⁻² by specific surface area of BiVO₄ inverse opal divided that for ITO glass. Accordingly, the specific surface area for BiVO₄ inverse opal with the porous sizes of 200 nm and 500 nm can be confirmed to be 1000.3 cm⁻² cm⁻² and 584 cm⁻² cm⁻², respectively. Clearly, the BiVO₄ IO demonstrates a very high specific surface area due to its porous structure, which can provide more active sites and effectively enhance the contact of the catalysts with reactants.

3.2 Photoelectrochemical measurements

The photocatalytic water splitting performance of the prepared samples was determined through a PEC system. Prior to the test, the optical properties of the prepared samples were studied. As shown in Fig. 3a, compared with BiVO₄ film, absorption band of BiVO₄ IO exhibited a red shift, suggesting its improved light utilization capability, which was mainly attributed to the slow light effect caused by IO photonic bandgap.^{35,36} Notably, the pure BiVO₄ IO owns noticeable absorption at 600 nm, enhancing the light scattering within its IO structure, which was beneficial for enhancing the light utilization of the photocatalytic system. After introduction of Au nanoparticles, two wide absorbance enhancement can be observed at *ca.* 500

Fig. 2 N₂ adsorption–desorption isotherms of BiVO₄ IO with period of (a) 100 nm, (b) 200 nm and (c) 500 nm.

Fig. 3 Visible light absorption spectra of (a) BiVO₄ film, BiVO₄ IO and (b) BiVO₄ IO, Au-BiVO₄ IO; (c) *I*-*t* curve of three different BiVO₄ IO (period 100 nm, 200 nm and 500 nm, applied potential 0.7 V vs. Ag/AgCl, light on 10 s, light off 10 s); (d) *I*-*t* curve of BiVO₄ IO and Au/BiVO₄ IO (period 100 nm, applied potential 0.7 V vs. Ag/AgCl, light on 10 s, light off 10 s); (e) *I*-*t* curve of BiVO₄ IO and Au/BiVO₄ IO (period 200 nm, applied potential 0.7 V vs. Ag/AgCl, light on 10 s, light off 10 s); (f) *I*-*t* curve of BiVO₄ IO and Au/BiVO₄ IO (period 500 nm, applied potential 0.7 V vs. Ag/AgCl, light on 10 s, light off 10 s); (g) *I*-*V* curve of BiVO₄ IO (period 100 nm, 200 nm and 500 nm, light on 10 s, light off 10 s); (h) *I*-*V* curve of Au-BiVO₄ IO (period 100 nm, 200 nm and 500 nm, light on 10 s, light off 10 s).

and 650 nm, as shown in Fig. 3b. The absorption enhancement at this frequency band should be attributed to the intrinsic absorption of Au nanocrystal and plasmon resonance absorption of dense Au nanoparticles. Furthermore, there is an overlap in the second plasmonic peak of Au nanoparticles with the enhanced light absorption of the IO structure of BiVO₄. Such an overlap can

enhance the light utilization ability of the Au nanoparticles, and thus further boosting the function of SPR effect on the BiVO₄.

To reach the efficient photocatalyst for water splitting, its photocurrent density should be always optimized. In this sense, we determined the photocurrent density-time (*I*-*t*) curve for the different samples through a three-electrode electrochemical

Fig. 4 (a) OCVD curve and (b) average lifetimes of the photogenerated carriers (τ_n) obtained from the OCVD for Au nanocrystal decorated BiVO₄ IO.

system at an applied bias voltage of 0.7 V vs. Ag/AgCl. Generally, the nanoarray structure can realize multiple reflection and scattering of incident light, thereby enhancing the light utilization capability of the photocatalyst toward improved photocurrent density. Therefore, as shown in Fig. 3c, the proper tuned BiVO₄ IO (100 nm) exhibited the highest photocurrent density among all the prepared sample, because the moderate porous structure is beneficial for making full use of large specific surface area and unique light-scattering capability. More importantly, such a superior photocurrent density performance of the BiVO₄ IO can be further improved by introduction of the Au nanoparticles. As shown in Fig. 3d, the photocurrent density of Au-BiVO₄ IO (100 nm) was *ca.* 3 times enhanced in comparison with that of BiVO₄ IO. This result is because the SPR effect of Au nanoparticles can induce a built-in electric field at its contact interface with the BiVO₄, which can facilitate the photogenerated charge carrier migration, and thus further improve the photocurrent generation on the Au-BiVO₄. Apart from that, as shown in Fig. 3d-f, the photocurrent density of Au-BiVO₄ IO (100 nm) was also higher than that of Au-BiVO₄ IO (200 nm) and Au-BiVO₄ IO (500 nm), suggesting that the moderate porous structure can have the highest interaction with the plasmonic effect of Au. In addition, we perform the photocurrent-potential ($I-V$) curves for the above six samples and the results are shown in Fig. 3g and h. Generally, the photocurrent density gradually increases with the increase in applied bias potential, suggesting the high stability of the Au-BiVO₄.

The average charge carrier lifetimes play a dominant role in determining the photocatalytic performance of a material. To further evaluate the influence of enlarged specific surface area and improved light absorption capability on photocatalytic performance of the Au-BiVO₄ IO, we carried out the transient open-circuit voltage decay (OCVD) measurements (Fig. 4a) and calculated the corresponding average carrier lifetimes for the three composite samples (Fig. 4b). Similar to the above results, as shown in Fig. 4b, the Au-BiVO₄ IO (100 nm) demonstrated the longest photogenerated charge carrier lifetime, further confirming that the unique porous structure of inverse opal and plasmonic effect of Au nanoparticles can synergistically enhance the photoconversion efficiency of the Au-BiVO₄ IO (100 nm).

3.3 Photocatalytic water oxidation

After studying the physicochemical and light-responsive properties of the prepared samples, we are in a position to utilize the prepared samples for photocatalytic water splitting. The resultant oxygen production performances of the various prepared samples are shown in Fig. 5a. As expected, the Au-BiVO₄ IO (100 nm) exhibited the highest oxygen production rate among all the prepared samples. Such a superior performance of the Au-BiVO₄ IO (100 nm) is mainly attributed the synergistic effect of the inverse opal structure and the plasmonic effect of Au. In detail, the inverse opal structure can endow the photocatalyst with large specific area and provide enormous surface active sites for the catalytic reaction. In addition, the plasmonic Au can

Fig. 5 (a) O₂ production with the six samples as photocatalysts by visible light illumination (light intensity 100 mW cm⁻², Na₂S₂O₈ as electron sacrificial agent); (b) mechanism on the Au/BiVO₄ IO for photocatalytic water oxidation.

induce an electric field around the BiVO₄ and thus facilitate the photogenerated charge carrier separation efficiency. Most of all, the light-scattering effect of inverse opal structure can guarantee the optimized light utilization of Au, thereby intensifying the SPR effect of Au on enhancing the photocatalytic performance of BiVO₄. As a result, the oxygen evolution rate of the Au–BiVO₄ IO (100 nm) reached 9.56 μmol cm⁻² h⁻¹ through photocatalytic water splitting, which is about 3 times of the pure BiVO₄ IO (100 nm).

Based on the above results and discussion, the mechanism for the enhanced photocatalytic water splitting performance of the Au–BiVO₄ can be illustrated and shown in Fig. 5b. Generally, the prepared BiVO₄ IO owns a porous structure on its surface, which can endow it with large specific surface area and enormous surface active site. In addition, the loading of Au nanoparticles can introduce the SPR effect on the BiVO₄ and induce an electric field at its interface with the BiVO₄ for accelerating the photogenerated charge carrier migration. More importantly, the incorporation of inverse opal structure and plasmonic Au nanoparticles can stimulate a synergistic effect, where the multi-scattering of light within the inverse opal structure can guarantee the optimized light absorption of the Au nanoparticles. Therefore, the SPR effect of the Au nanoparticles can be boosted. For the detailed mechanism of the photocatalytic water splitting on Au–BiVO₄, under light irradiation, the photogenerated electrons on the BiVO₄ can migrate to the Au nanoparticles due to the formation of Schottky barrier attributed to the lower work function of Au. Then, the photogenerated electrons can further migrate to the surface of Au for S₂O₈²⁻ reduction, leaving the photogenerated holes on BiVO₄ for water oxidation. The Schottky junction at the interface would prohibit the electron-holes recombination and promote charge transfer.

4 Conclusion

In summary, a series of BiVO₄ IO and Au decorated BiVO₄ IO were successfully constructed using the colloidal crystal template and electron beam evaporation methods. The SEM and BET results show the BiVO₄ IO with high surface area, and Au nanocrystal was in tight contact with the BiVO₄. The photoelectrochemical results indicated that Au–BiVO₄ IO exhibited optimum photocatalytic activity under visible light irradiation, about 3 times higher than those of BiVO₄. And the excellent water oxidation activity with oxygen of 9.56 μmol cm⁻² h⁻¹ was achieved. The superior photocatalytic activity of Au–BiVO₄ IO can be mainly ascribed to synergetic effect of Schottky junction and RET process, leading to the effective separation the photo-generated electrons and holes for catalytic reaction. Consequently, this work would provide a useful technique for water oxidation under visible light irradiation.
