Recent progress of conductive 3D-printed electrodes based upon polymers/carbon nanomaterials using a fused deposition modelling (FDM) method as emerging electrochemical sensing devices

 Muhamad Huzaifah Omar,^a Khairunisak Abdul Razak,^{bc} Mohd Nadhir Ab Wahab^d and Hairul Hisham Hamzah ^{*a}

3D-printing or additive manufacturing is presently an emerging technology in the fourth industrial revolution that promises to reshape traditional manufacturing processes. The electrochemistry field can undoubtedly take advantage of this technology to fabricate electrodes to create a new generation of electrode sensor devices that could replace conventionally manufactured electrodes; glassy carbon, screen-printed carbon and carbon composite electrodes. In the electrochemistry research area, studies to date show that there is a demand for electrically 3D printable conductive polymer/carbon nanomaterial filaments where these materials can be printed out through an extrusion process based upon the fused deposition modelling (FDM) method. FDM could be used to manufacture novel electrochemical 3D printed electrode sensing devices for electrochemical sensor and biosensor applications. This is due to the FDM method being the most affordable 3D printing technique since conductive and non-conductive thermoplastic filaments are commercially available. Therefore, in this minireview, we focus on only the most outstanding studies that have been published since 2018. We believe this to be a highly-valuable research area to the scientific community, both in academia and

Huzaifah Omar received his first degree in Chemistry with first-class honours in 2020 from the Universiti Sains Malaysia (USM). He is currently pursuing his master research degree under the supervision of Dr Hairul Hisham Hamzah to work on the fabrication and characterisation of the 3D-printed electrodes from 3D printable conductive polymer/carbon nanomaterial filaments for

developing electrochemical biosensors.

Professor Khairunisak Abdul Razak is currently a professor at the School of Materials and Mineral Resources Engineering, USM. She obtained her bachelor degree from the Universiti Kebangsaan Malaysia (UKM) in 1999. In 2007, she received her PhD degree in chemical and materials engineering from the University of Auckland, New Zealand. She was appointed as senior lecturer in 2008, asso-

ciate professor in 2011 and professor in 2017. She was trained in Nanobiotix SA, Paris in 2008 in the field of nanobiotechnology. Her research interest is on sensors, biosensors, electronic ceramic, and nanomaterials for electronic and biomedical applications.

industry, to enable novel ideas, materials, designs and methods relating to electroanalytical sensing devices to be generated. This approach has the potential to create a new generation of electrochemical sensing devices based upon additive manufacturing. This minireview also provides insight into how the research community could improve the electrochemical performance of 3D-printed electrodes to significantly increase the sensitivity of the 3D-printed electrodes as electrode sensing devices.

Introduction

Three-dimensional (3D) printing technology in the electrochemistry research field is a technological advancement from additive manufacturing. The researchers have illustrated many novel electrochemistry applications such as fabricating electrochemical sensor¹ and electrochemical biosensor² electrodes, producing energy storage devices,³ and building chemical reactors⁴ and microfluidic devices.⁵ To date, 3D printing technology has gained popularity among electrochemists to print 3D electrochemical objects. Several advantages compared to traditional manufacturing methods include it being rapid and low cost and eco-friendly, and there being various printing materials that can be used for manufacturing products and that can be printed in multiple shapes and complex geometries. There are numerous types of 3D printing processes, including binder jetting, materials extrusion, materials jetting, powder bed fusion, sheet lamination, photopolymerisation and directed energy deposition.^{6,7}

The most common 3D product used for fundamental and applications electrochemistry is a 3D-printed electrode based upon 3D printable conductive polymers-based carbon nanomaterials. For instance, polymer materials containing carbon nanomaterials such as graphene, carbon black (CB) and carbon nanotubes (CNTs) will exist in thermoplastic filament form. This will be discussed in detail in the next section. Essentially, to print 3D-printed electrodes using those filament materials, a fused deposition modelling (FDM) method based on the extrusion process^{8,9} is used in various 3D-printed electrodes with different design and geometrical shapes. Using the FDM

technique, continuous layers will be deposited by the extruded polymer filament and finally formed the 3D printed electrode products. This method has been discussed in detail in a minireview by Patel and co-workers.¹ In their review, the advantages of using the FDM 3D printing method in the fabrication of 3D-printed electrodes from 3D printable conductive polymer/nanomaterial filaments for electrochemical sensors were discussed. However, in this minireview, we will only focus on the recent progress of the fabricated 3D-printed electrodes using the composite 3D printable conductive carbon nanomaterials with polymers for electrochemical sensors and biosensors.

3D printable conductive polymer/ carbon nanomaterial filaments for fabricating 3D-printed electrodes

Recent studies showed that carbon nanomaterials reinforced with polymeric filaments as feedstocks for the FDM 3D printing method are popular among researchers in 3D printing applications. Graphene, CB, and CNTs are common carbon nanomaterials used as conductive filler materials in past studies.¹⁰⁻¹⁴ The conductive filaments either can be commercially purchased, or can be made in house for further investigations. These materials have obtained high interest among the researchers because of their outstanding properties in making 3D-printed electrodes. For example, graphene has high thermal conductivity and low resistivity,¹³ while CB has higher conductivity, high surface area and stability.¹⁵ Besides, CNTs can accommodate nucleation sites to bind with the reinforcing

Mohd Nadhir Ab Wahab is a senior lecturer at the School of Computer Sciences, Universiti Sains Malaysia (USM). He received his B.Eng. (Hons.) Mechatronics Engineering in 2010 and M.Sc. Mechatronics Engineering in 2012 from the Universiti Malaysia Perlis (UNIMAP). Afterwards, he received his PhD degree in Robotics and Automation System in 2017 from the

University of Salford, UK. His main research interests are mobile robotics, artificial intelligence, computer vision, optimization, navigation, and path planning.

Hairul Hisham Hamzah received his bachelor and master research degrees in 2006 and 2010, respectively, from the Universiti Putra Malaysia (UPM). In 2013, he then pursued his PhD research at the University of Southampton, UK, under the supervision of Professor Philip N. Bartlett. In April 2017, he had successfully defended his PhD thesis. Then, in May 2017, he moved to the University of

Brighton, UK, to take up a position as a postdoctoral research assistant in Professor Bhavik Patel's lab at the School of Pharmacy and Biomolecular Sciences. Currently, he has been a senior lecturer at the School of Chemical Sciences, Universiti Sains Malaysia (USM) since January 2018.

polymer matrix easily.¹³ Various types of polymer materials such as polylactic acid (PLA),¹⁶ acrylonitrile butadiene styrene (ABS),¹⁷ polyimide (PI)¹⁸ and polyurethane¹⁴ have been reinforced with these carbon nanomaterials as 3D printable conductive thermoplastic filaments.

The standard commercially available 3D printable conductive thermoplastic filaments used in printing 3D-printed electrodes used are PLA/graphene, PLA/CB, PLA/CNTs, and ABS/CB. Nevertheless, the primary key aspect that needs consideration before printing the 3D-printed electrodes using thermoplastic 3D printable conductive nanomaterials is percolating structure carbon nanomaterial fillers within the polymer matrix. This factor will influence the flow performance of the printed electrodes, by impeding the current through the non-conductive polymers. This is called the threshold limit, or percolation threshold, governing the electrical conductivity of 3D printable conductive polymers/nanomaterials by their electrical percolation. They require a minimum nanofiller content, where this scientifically refers to volume fraction to convert insulators (polymers) into conductive composite nanomaterial filaments. The minimum volume fraction of carbon nanofillers essentially depends on several factors such as the shape and size distribution of the carbon nanofillers in the polymer matrix, attractive interactions between the polymers and carbon nanofillers in the filament form, and processing methods (dispersion and agglomeration of carbon nanomaterials into the polymer).¹⁹ As discussed by Banks *et al.*,¹⁶ a commercially available PLA/graphene 3D filament only contains 8% of graphene. This is considered a very low active nanofillers that could limit the

electrochemical performance of the printed electrodes as reflected by a shallow percolation threshold, giving a poor electrical percolation after the printing process.

One interesting study on the development of 3D printable thermoplastic filament based-polyimide (TPI) with different CNT contents to investigate its thermal and electrical properties was reported by Wu and co-workers.¹⁸ Their work studied the tensile and bending properties of pure TPI 3D printing specimens printed by the nozzles with different diameters that could replace aerospace metal and structural parts. They varied the contents of CNTs as 1% wt, 3% wt, 5% wt, 7% wt and 9% wt in the TPI matrix as illustrated in Fig. 1A. Using an insulation resistance tester, they found that the conductive resistivity of the TPI/CNTs filament decreases gradually with the increase of the filling ratio of CNTs in the TPI resin matrix, as shown in Fig. 1B. From the conductive resistivity plot, the conductive percolation threshold for the TPI/CNTs 3D filament was found to be 3% wt of CNTs.

In a different study by Bank *et al.*,¹⁶ utilising a PLA polymer as an insulator matrix with varying contents of nanographite (NG) to make conductive 3D printable NG-PLA filaments with different fillings of NG, containing 1, 5, 15, 20, 25, 30 and 40% wt were developed and tested towards their printability to make the 3D-printed electrodes. Then, the physicochemical electrochemical properties of the developed filaments and 3D-printed electrodes were evaluated. The study has found that the loaded NG powder of 20% wt in the PLA exhibits a sufficient percolation over the measured resistivity ($\Omega \text{ cm}^{-1}$) as depicted in Fig. 1C. The authors concluded that PLA/NG filament at

Fig. 1 (A) The developed conductive TPI/CNTs 3D printable filaments with varying percentages of CNTs; 1% wt, 3% wt, 5% wt, 7% wt and 9% wt. (B) Conductive resistivity of TPI/CNTs 3D printable filaments; pure PI and a variety of loaded CNTs; 1% wt, 3% wt, 5% wt, 7% wt and 9% wt. (C) Conductive resistivity of the developed PLA/NG 3D printable filaments, filled with a variety of loaded NG; 1% wt, 5% wt, 15% wt, 20% wt, 25% wt, 30% wt and 40% wt. (D) FDM 3D printing process to print PLA/NG 3D-printed electrodes, utilised for electrochemical characterisation. This figure has been reproduced from ref. 16 and 18 with permission from ELSEVIER, copyright 2019 and 2020, respectively.

20% wt gave a superior conductivity. Thus at 25% of the loaded PLA/NG could be a threshold limit for their developed 3D filament as above 25% wt of NG may impede electrical conductivity of conductive 3D filament by the PLA matrix.

Additionally, the developed 3D filaments are difficult to be printed out using FDM 3D-printer, because the filaments are too brittle due to the lack of the PLA contents that decreased the attractive interaction between the PLA-NG filament. It is interesting to note that the fabricated 3D-printed electrodes in their study (Fig. 1D) were printed from a filament, comprised of 75% PLA and 25% NG, and were applied for the simultaneous detection of lead(II) and cadmium(II) ions. Therefore, they suggested that the volume fraction obtains the best anisotropic conductivity of their 3D printed electrodes, comprising 25% of NG and 75% of PLA. This study has shown a significant improvement in the volume fraction form of the commercially available 3D printable polymer/graphene filaments, where the highest filling of graphene in PLA is only 8%.¹⁶

Effect of printing orientations, chemical treatments, and thermal treatments for electrochemical enhancement of polymer/carbon nanomaterial 3D-printed electrodes

Studies to date show that many articles reported on the activation of the 3D-printed electrodes to enhance the electrodes' electrochemical performances since the as-printed electrodes exhibit insufficient electrochemical activity in their native state. However, recently, Patel *et al.*²⁰ have printed PLA/CB 3D-printed electrodes with different layers of thicknesses; 0.1, 0.2, 0.3 and 0.4 mm, and different printing orientations (vertical and horizontal) as shown in Fig. 2. The main interest of their study was to investigate the effects of different printing layer thickness and orientation on resistivity, and heterogeneous electron transfer rate from the PLA/CB 3D-printed electrodes.

The electrochemical behaviours of the 3D printed electrodes were carried out by using 1 mM of ruthenium hexamine(III) chloride in 0.1 mM potassium chloride (KCl) and 1 mM serotonin (5-HT) in Krebs' buffer solution (pH 7) for cyclic voltammetry (CV) and ferricyanide/ferrocyanide mixture in 1 M KCl for electrochemical impedance spectroscopy (EIS). From the result obtained, thinner PLA/CB 3D-printed electrodes that are printed in vertical orientation have facilitated faster electron transfer reactions and have lowered charge-transfer resistance (R_{ct}) compared to thicker PLA/CB 3D-printed electrodes printed in the horizontal direction. They conclude that the low layer of thickness printed in the vertical printing orientation gave the best electrochemical behaviour to PLA/CB 3D-printed electrodes. The authors advocate that printing in a vertical printed direction gives a lower air voids effect, resulting in lower resistance between filaments during the printing process. The authors also imply that printing in the vertical orientation method is more compact, and ordered PLA/CB structures, than the horizontal printing orientation as the density of CB particles

Fig. 2 Different printing orientations of PLA/CB 3D-printed cone electrodes with different printing thicknesses; 0.1 mm, 0.2 mm, 0.3 mm and 0.4 mm. The PLA/CB 3D-printed electrodes used for electrochemical characterisation. This figure has been retrieved from ref. 20 with permission from ELSEVIER, copyright 2020.

is higher than PLA making CB more oriented to the centre, while PLA pushed to the side. This makes the vertical orientation printing method that prints in parallel and side to side, has more advantage than the horizontal orientation printing method.

As mentioned previously, the 3D-printed electrode surfaces can be chemically activated to enhance the electrochemical activity of the 3D-printed electrodes based-polymer/carbon nanomaterial filaments. To the best of our knowledge, Pumera and co-workers²¹ have been the first group that established a simple activation approach of the PLA/graphene 3D-printed electrodes surfaces with solvent and electrochemical activations. The solvent activation was activated in dimethylformamide (DMF). In contrast, the electrochemical activations were conducted by applying a constant potential at 1.5, 2.0 and 2.5 V vs. Ag/AgCl, using a phosphate buffer solution of pH 7.2, performed at different times from 0 to 250 s *via* chronoamperometric technique. The activated PLA/graphene 3D-printed electrodes were then investigated in $[\text{Fe}(\text{CN})_6]^{-4/-3}$ redox probe after the activation steps. The electrochemical performances of the untreated and treated electrodes were accessed toward the $[\text{Fe}(\text{CN})_6]^{-4/-3}$ ions by comparing the heterogeneous rate constant electron (k_o , cm s^{-1}), calculated using the Nicholson method. Interestingly, they found that the k_o significantly increased from $2.13 \times 10^{-5} \text{ cm s}^{-1}$ (activated in DMF, 10 min) to $2.43 \times 10^{-3} \text{ cm s}^{-1}$ (activated electrochemically at 150 s).

Another intriguing report from Pumera *et al.*²² is using different solvents to activate the PLA/graphene 3D-printed electrodes, demonstrating the effect of polar protic and polar aprotic solvents used to activate electrodes (Fig. 3A) by monitoring the k_o and electrochemical double-layer capacitance. Polar protic solvents consist of deionized water, methanol and ethanol, whilst polar aprotic solvents consist of acetone and DMF tested on the PLA/graphene 3D-printed electrodes during the solvent activation steps. The electrochemical behaviour of the electrodes was investigated in 1 mM $[\text{Fe}(\text{CN})_6]^{-4/-3}$ solution in 0.1 M KCl, while the capacitance behaviour was tested in 1.0 M sodium hydroxide (NaOH). From the results obtained, the solvent-activated PLA/graphene 3D-printed electrodes increased the electroactive surface area of the electrodes. However, polar aprotic solvents (DMF and acetone) have had a major effect on

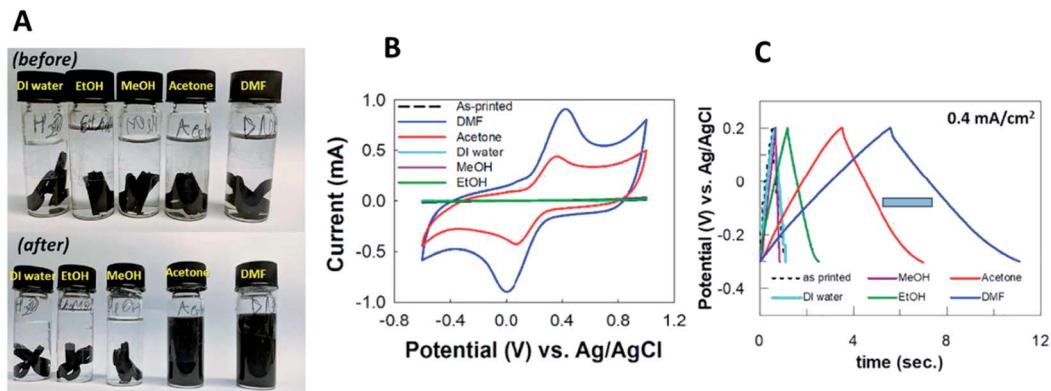

Fig. 3 (A) Chemical solvent treatment for PLA/graphene 3D-printed electrodes in the vials with various solvents before, and after activation steps. The solvents used were DI water, ethanol, methanol, acetone and DMF. (B) CV responses for the activated PLA/graphene 3D-printed electrodes, treated in ethanol, methanol, DI water, acetone and DMF, respectively. (C) Galvanostatic charge–discharge responses from PLA/graphene 3D-printed electrodes in 1.0 M NaOH, activated in different solvents at a constant current of 0.4 mA cm^{-2} . This figure been reproduced from ref. 22 with permission from ELSEVIER, copyright 2019.

the activated PLA/graphene 3D-printed electrodes and showed higher currents in CV peaks for $[\text{Fe}(\text{CN})_6]^{-4/-3}$ when compared to the polar protic solvents, as shown in Fig. 3B. However, they concluded that the obtained k_o via acetone activation is higher than that of the k_o , activated in DMF since the activation of 3D-printed electrodes in acetone made the electrode surface rougher, than the inactivated 3D-printed electrodes in DMF.

Meanwhile, all the electrodes showed pseudo-capacitor behaviour in the capacitance. The areal capacitance produced by the solvent-activated PLA/graphene 3D-printed electrodes were higher than the unactivated 3D-printed electrodes. However, polar aprotic solvents-activated electrodes have superior areal capacitance, compared to polar protic solvents-activated electrodes, as shown by galvanostatic charge-discharge responses in Fig. 3C. Overall, the activated PLA/graphene 3D-printed electrode in DMF provides the best supercapacitor performance compared to other solvents. Nevertheless, the authors have recommended using acetone rather than DMF as an activation, as it is less dangerous, and still gives an excellent activation solvent to be used in the pre-treatment of 3D-printed electrodes.

A different approach, reported by Vaněčková *et al.*²³ discussed PLA/CB 3D-printed electrodes' electrochemical behaviours. The PLA/CB 3D-printed electrodes fabricated by the FDM method and a controlled electrode made from the cut filament were also prepared. Then, the faradaic peak currents, generated from the CVs were compared with theoretical values in order to investigate the relative effective surface area of electrodes. Nevertheless, before the 3D-printed electrode used, the electrodes were activated using a 0.3 M sodium sulphate (Na_2SO_4) as an anode terminal, whereas a thin gold electrode was a cathode terminal in a U-cell. Then, a constant voltage was applied with the range 0–25 V between the two electrodes, where time was set from 0 to 60 s to monitor the electric current. After the electrochemical treatment, the electrode's electrochemical behaviours were studied in 5×10^{-4} M ruthenium(III) acetylacetonate ($\text{Ru}(\text{acac})_3$) in 0.3 M Na_2SO_4 using the CV technique. Both electrodes showed a faradaic response parallel to platinum (Pt)

and GC electrodes. The anodic and cathodic potential peak separation (ΔE_p) values for both electrodes obtained was between 80 to 85 mV. These values are higher than the theoretical value of ΔE_p , which is 57 mV for reversible transfer of one electron reaction. This indicates that the electrode kinetics for the 3D-printed and cut filament electrodes is lower than expected. However, according to the authors, the ΔE_p values obtained are higher than the literature values based on past research using PLA composites which range between 100 to 410 mV. The authors also showed that the 3D-printed and cut filament electrodes have a similar electroactive surface area which means that the electroactive area sites are not altered by the FDM printing method. Thus, the authors suggest that the electron transfer characteristics of the PLA/CB 3D-printed electrode are similar, and comparable to the conventional metallic and carbon electrodes.

Bonacin *et al.*²⁴ reported an interesting report where they investigated different approaches in treating the PLA/graphene nanoribbon 3D-printed electrodes before the use of the 3D-printed electrodes in dopamine detection. The techniques involved electrochemical activation, mechanical polishing using alumina suspension and chemical solvents. The authors treated the 3D-printed electrodes using chronoamperometric technique in the electrochemical activation by applying a constant potential at +1.8 V vs. SCE for 900 s in a phosphate buffer solution, pH 7.4. They then used CV, scanned from 0 V to –1.8 V vs. SCE at a scan rate of 50 mV s^{-1} . In contrast, for mechanical polishing, the 3D-printed electrodes were polished with $0.3 \mu\text{M}$ alumina suspension in a polishing pad, polished in a figure-8 pattern. The polishing durations were varied in 1,0, 3,0, 5,0 and 10 min.

Meanwhile, for chemical solvent activations, four different solvents were employed; DMF, 1 M NaOH, 7.9 mM HNO_3 and 0.5 M H_2SO_4 in different immersion periods of 30, 60 and 180 min. Their study aimed to exfoliate and reduce graphene sheets at the 3D-printed electrode surfaces. This has led to an increase in edges and defects. Subsequently, this elevates electroactive site exposure for redox reactions of ruthenium

Table 1 Chemical solvent, electrochemical and thermally annealing pre-treatments for activation of the polymer/carbon nanomaterial 3D-printed electrode surfaces

Polymer/carbon nanomaterial 3D-printed electrode	Solvent treatment	Electrochemical treatment	Thermal annealing	Aims of the study
PLA/nanocarbon and PLA/carbon black 3D-printed electrodes ²⁷	Immersing the 3D-printed electrodes in different reducing agent solutions (0.1 M) of sodium borohydride (NaBH ₄), ascorbic acid, hydrazine (N ₂ H ₄) in deionized water and lithium aluminium hydride (LiAlH ₄) in tetrahydrofuran (THF) for 24 hours	Applying constant potential of +2.5 V vs. Ag/AgCl in phosphate buffer solution (pH 7.2) for 1000 seconds using chronoamperometric measurement	—	To develop a greener wet-chemical post-treatment for the achievement of electrically active 3D-printed electrode surfaces
PLA/graphene 3D-printed electrode ²⁸	—	—	Thermal annealing with a heating rate of 5 °C min ⁻¹ at 350 °C in the air atmosphere in an electric furnace for 3 h, followed by natural cooling	-To elucidate the effect of inherent impurities in the commercial filament on the capacitive performance of a supercapacitor -To demonstrate that the impurities can be removed <i>via</i> linear sweep voltammetry (LSV) measurement -To develop 3D-printed voltammetric pH electrodesensors using a commercially available PLA/graphene filament by activating inherent oxygen-containing functional groups on the graphene surfaces
PLA/graphene 3D-printed electrode ²⁹	—	-Applying potential from +1.4 and -1.0 V in 0.5 M NaOH for 200 seconds -Applying current at +0.1 mA cm ⁻² in a strongly oxidising electrolyte containing 2 M H ₂ SO ₄ and 1 M KNO ₃ -Conditioning the electrodes in pH ≈ 4 carmody buffer by running 1000 consecutive square wave voltammetry (SWV) runs	—	To exhibit the potential of a 3D-printed electrode in immobilising horseradish peroxidase (HRP) enzyme to create a direct electron transfer enzyme-based biosensors for hydrogen peroxide (H ₂ O ₂) detection To show the potential application of the 3D-printed electrodes as fully additive manufacturing
PLA/graphene 3D-printed electrode ³⁰	Immersing and sonicating the 3D-printed electrodes in DMF for 5 minutes	Applying constant potential of 2 V for 150, 300 and 450 seconds	—	
PLA/carbon black 3D-printed electrode ³¹	—	Applying potential of +1.4 for 200 seconds and -1.0 V for 200 seconds in 0.5 M NaOH	—	

Table 1 (Contd.)

Polymer/carbon nanomaterial 3D-printed electrode	Solvent treatment	Electrochemical treatment	Thermal annealing	Aims of the study
PLA/graphene 3D-printed electrode ³²	—	-Applying potential of +1.8 V in 0.1 M phosphate buffer solution (pH 7.4) for 900 seconds -Applying different potentials starting from 0.0 to -1.0, -1.2, -1.4, -1.6, and -1.8 V for one cycle at a scan rate of 50 mV s ⁻¹ in 0.1 M phosphate buffer solution (pH 7.4)	—	(AM) in a three-electrode system setup (working, counter and pseudo-reference electrodes) To develop low-cost and reproducible 3D-printed electrodes for electrocatalytic detection of dopamine

hexamine. Additionally, these made the approaches improve their 3D-printed electrode in sensing dopamine.

Recently, to avoid lengthy electrochemical pre-treatments and harsh chemical treatments, Pumera and co-workers²⁵ have reported a new approach by a simple physical method based upon thermal annealing of the PLA/graphene 3D-printed electrodes. Essentially, thermal annealing is a physical process that could control surface roughness in materials where the procedure will modify the surface morphology of material with temperature and time. Commonly, it is performed in a vacuum chamber in an inert ambient such as nitrogen or argon with a specific temperature.²⁶ In Pumera and co-workers' approach, thermal annealing for PLA/graphene 3D-printed electrodes was conducted at a temperature over 350 °C with a heating rate of 5 °C min⁻¹ at a pressure of 200 Pa and N₂ gas (6 N) in which the temperature was kept constant for 3 h during the treatment. Then, the electrodes were electrochemically analysed using CV and EIS, respectively. The data obtained from the thermally annealed electrodes were compared with the 3D-printed electrode, activated with DMF solvent. Interestingly, the electrode showed significant enhancement after the thermal annealing gave a significant enhancement in the terms of electrochemical behaviours in which a smaller ΔE_p and faster k_o value with a magnitude of 10⁻⁴ cm s⁻¹ compared to the activated 3D-printed electrode in DMF, which only gave k_o value with a magnitude of 10⁻⁸ cm s⁻¹. From the electrode kinetic data, this study shows that the thermally annealed 3D-printed electrode greatly increased the k_o value by a 9655-fold in comparison to the treated electrode in DMF solution.

This section only discusses the prominent studies that the research community has reported on how the electrochemist could treat the 3D-printed electrode surfaces to significantly improve the performance of the 3D-printed electrodes, fabricated from 3D printable conductive polymer/carbon nanomaterial filaments. Nevertheless, many works have been published to date as summarised in Table 1.

Polymer/carbon nanomaterial 3D-printed electrodes for electrochemical sensors

Fabrication of polymer/carbon nanomaterial 3D printed electrodes for electrochemical sensor applications have also been significantly studied in previous years. The developed electrochemical sensors have been studied as electrochemical sensing devices in many analytes of interests, including in detecting metals ions,^{33,34} picric and ascorbic acids,³⁵ uric acid,³¹ and mycotoxin compound.³⁶ Based on our literature search, at present, as discussed in the previous section before the 3D-printed carbon nanomaterial electrodes were utilised as electrochemical sensor devices, the electrochemical activities of the polymer/carbon nanomaterial 3D-printed electrodes were electrochemically optimised either with the printing orientations or pre-treating the 3D-printed electrode surfaces with chemical substances.

Patel *et al.*³⁷ show for the first time the PLA/CB 3D-printed electrode in a cone geometry, printed in horizontal orientation has been utilised in *ex vivo* experiment over gut tissue of guinea pig to simultaneously monitor the serotonin overflow and muscle contraction as displayed in Fig. 4A and B. Serotonin (5-HT) is one of the neurotransmitter molecules that plays an essential role to modulate the motility of the gastrointestinal tissue. In their work, before they applied the PLA/CB 3D-printed electrodes on the gut tissue samples, the electrodes were tested first on the different concentrations of 5HT in Krebs's buffer solution using chronoamperometric measurements, as shown in Fig. 4C. The fabricated electrode shows that the 3D-printed electrode gave a linear range between 1–10 μM . Interestingly, this range of concentration corresponds with the physiological concentrations of the 5-HT present in the gastrointestinal tissue for 15 min without significant electrode fouling as shown in Fig. 4D and offered a limit of the detection as low as 540 nM. Overall, their work is the first to show that the PLA/CB 3D-printed electrode device can conduct dual measurement of signalling, and contractility. This offers significant scope for clinical application, in particular, to monitor bowel function that could be a direct function of therapeutic management of patients with bowel disorders.³⁸ The most exciting thing about their work is that the 3D-printed electrode was not undergoing any pre-treatment before the electrochemical measurements.

A different conductive thermoplastic carbon nanomaterial, Katic and co-workers,³⁹ have developed PLA/graphene 3D-printed electrodes, using the FDM method to create chemically modified 3D-printed electrode for the detection of H_2O_2 . The electrodes have also been activated by using a similar approach based on their previous study.³² The authors reported that these activated 3D-printed electrodes have had the same electrochemical behaviour as regularly used electrodes, such as gold and GC electrodes. Furthermore, the PLA/graphene 3D-printed electrodes have been modified with Prussian blue (PB) by using the chronoamperometric technique through the electrodeposition method and evaluated for the detection of the H_2O_2 . Then, PB/PLA/graphene modified 3D-printed electrodes have been compared to the unmodified PLA/graphene 3D-printed electrode for the sensing of H_2O_2 . The results showed that only PB modified PLA/graphene 3D-printed electrode could detect H_2O_2 as there were oxidation and reduction peaks shown in the CV. Meanwhile, there were no peaks shown for the unmodified PLA/graphene 3D-printed electrode. The electrochemical response of the PB modified PLA/graphene 3D-printed electrodes for sensing H_2O_2 has been studied using the amperometric technique with a concentration of H_2O_2 from 2.0 μM to 112.0 μM and LOD obtained for the PB modified electrode was 0.44 μM .

Fig. 4 (A and B) Fabricated a cone PLA/CB 3D-printed electrode that mimics faecal pellets to suit guinea pig's anorectal tissue for *ex vivo* experiment. (C) Chronoamperogram for an experimental response of the addition 5-HT in a Krebs buffer solution with different concentrations of the 5-HT (1–10 μM), held at a constant potential of +0.6 V vs. Ag/AgCl. (D) Differential pulse voltammograms (DPVs) of 5 μM 5-HT in a Krebs buffer solution (pH 7.4) before and after *ex vivo* tissue measurement to investigate the electrode's fouling surface. Meanwhile, Pumera *et al.*³⁶ have printed PLA/graphene 3D-printed electrode to detect a mycotoxin of zearalenone (ZEA) compound. Like in their previous work,³⁵ the authors treated the PLA/graphene 3D-printed electrodes before using them as electrodesensors. The authors have tested the ability of PLA/graphene 3D-printed electrodes to detect ZEA. The printed electrodes showed a very well-defined anodic peak in CV analysis compared to GC and edge-plane pyrolytic graphite (EPPG) in which the GC and EPPG produced lower signals in the same analysis as illustrated in Fig. 5A and B. This showcased that the PLA/graphene 3D-printed electrodes can detect ZEA. The PLA/graphene 3D-printed electrodes have shown the capability to detect ZEA at a broad range of concentrations from 10 to 300 μM with a linear correlation value of 0.995, nearly to the ideal value of 1. The 3D printed electrodes also gave the LOD of 0.340 μM and limit of quantification (LOQ) of 1.13 μM when compared to the GC electrode, which had an LOD of 0.0683 μM and LOQ of 0.228 μM . This dictates that the PLA/graphene 3D-printed electrodes had a better capability for ZEA detection.

In contrast to other literature discussed in this section, Rocha *et al.*⁴⁰ utilised PLA/CB filament to fabricate 3D-printed

electrode to detect metal ions in biological specimens. Routinely, activation or pre-treatment steps are needed to obtain more conductive sites of a 3D printed electrode. Thus, the authors have activated the PLA/CB 3D-printed electrode in 0.5 M NaOH. The authors also reported that the surface porosity of the PLA/CB 3D printed electrode increased, through scanning electron microscopy (SEM) analysis after the activation steps, indicating growing CB nanoparticles at the electrode's surface. The activated PLA/CB 3D-printed electrode also had better electrochemical behaviour (higher electroactive surface area and faster electron transfer reactions) than the unactivated PLA/CB 3D-printed electrode. The sensitivity of activated PLA/CB 3D-printed electrode towards metals ions (cadmium ion (Cd^{2+}) and lead ion, (Pb^{2+})) also increased enormously compared to the unactivated PLA/CB 3D-printed electrode. For the metal sensing application, the activated PLA/CB 3D-printed electrodes have been reported to have a wide linear range of 30 $\mu\text{g L}^{-1}$ to 270 $\mu\text{g L}^{-1}$ for both Cd^{2+} and Pb^{2+} ions, given the LOD of 2.9 $\mu\text{g L}^{-1}$ and 2.6 $\mu\text{g L}^{-1}$, and LOQ of 8.9 $\mu\text{g L}^{-1}$ and 7.9 $\mu\text{g L}^{-1}$, respectively. Furthermore, these activated PLA/CB 3D-printed electrodes have been tested in biological samples (urine and saliva). From

the result obtained, the 3D-printed electrodes have shown good accuracy with an acceptable recovery value of 93% to 108% and 96% to 112% for Cd²⁺ and Pb²⁺, respectively. Besides, the authors also carried out an interference study and reported that the activated 3D-printed electrodes are also able to detect other metal ions such as copper(II) ion (Cu²⁺) and mercuric ion (Hg²⁺).

Polymer/carbon nanomaterial 3D-printed electrodes for electrochemical biosensors

Apart from electrochemical sensor applications, currently, there is an increasing trend on how polymers/carbon nanomaterial 3D-printed electrodes could be used to construct electrochemical biosensing electrode substrates. Practically, biomolecules; enzymes, nucleic acids (DNA) and antibodies are immobilised at the electrode substrates as a biosensor probe before using it to sense the specifically targeted analytes. The immobilised biomolecules at the electrode surfaces could be

achieved either using physical adsorption, self-assembly monolayer, polymer coating or covalent immobilisation methods.⁴¹ The targeted analytes could be cancer biomarkers,⁴¹ viruses,⁴² cardiac biomarkers,^{43,44} glucose,⁴⁵ hydrogen peroxide (H₂O₂),⁴⁶ foodborne pathogens⁴⁷ and heavy metal ions.⁴⁸ The common electrode substrates used to construct the immobilised biomolecule probes are GC electrode,⁴⁹ gold electrode,^{50,51} screen-printed carbon electrode (SPCE)^{52,53} and indium tin oxide (ITO) electrode.^{45,54} To the best of our knowledge, only a few articles have been initiated in reporting the accessibility of the conductive thermoplastic carbon nanomaterial 3D-printed electrodes as electrode platforms for electrochemical biosensing purposes.

A fascinating study has been designed by Pumera *et al.*³⁰ where the PLA/graphene 3D-printed electrodes were used to immobilise horseradish peroxidase (HRP) enzyme to construct enzymatic biosensors based on a direct electron transfer enzyme in sensing H₂O₂. Two types of electrodes were then prepared, one with gold nanoparticles (AuNPs) modified PLA/graphene 3D-printed electrode (AuNPs/PLA/graphene) and one

without the modification of AuNPs (PLA/graphene). The HRP enzyme was then immobilised at the surface of both 3D graphene/PLA/AuNPs and 3D graphene/PLA based on physical adsorption (by drop-casting method), incubated overnight at 7 °C, producing 3D-printed electrode biosensors as depicted in Fig. 6. The 3D-printed electrode biosensors were then used to detect H₂O₂, which involved the mechanism of the HRP enzyme electron transfer reaction. The authors have concluded that the mechanism of electron transfer between the HRP and H₂O₂ was based upon direct electron transfer from the HRP enzyme without mediators or binder polymers. It is a fact that the H₂O₂ can be detected when it undergoes a reduction process. This will make the HRP contain a redox iron centre to be oxidised from Fe(III) to Fe(IV) state. The Fe(IV) will then be reduced to its original condition, Fe(III), by applying a negative potential that is almost zero value. The authors also reported that without the HRP enzyme, the PLA/graphene 3D-printed electrodes, with or without AuNPs could not electrocatalyst the H₂O₂, resulting in no detection of H₂O₂. Furthermore, the AuNPs/HRP modified 3D-printed electrode showed slightly better electrocatalytic performance than HRP/modified 3D-printed electrode. The chronoamperometric technique was utilised for the detection of H₂O₂ in PBS buffer (pH 7.2) and human plasma. From the result obtained in the chronoamperometric analyses, HRP modified PLA/graphene 3D-printed electrode had an LOD of 11.1 μM and LOQ of 37.0 μM with the linearity of 0.994. Meanwhile, AuNPs/HRP changed the 3D-printed electrode with slightly lower LOD and LOQ (9.1 μM and 30.4 μM), respectively, with the linearity of 0.996.

In a different study, Muñoz and colleagues⁵⁵ have also studied the PLA/graphene 3D-printed electrodes for glucose biosensing applications, achieved through the mediation of electron transfer by ferrocene-carboxylic acid (FCA) in developing an amperometric biosensor. Initially, the 3D printed electrodes have been activated in DMF for 10 minutes. Afterwards, a drop-casting method was carried out on the PLA/graphene 3D-printed electrodes to fabricate glucose biosensor. The used enzyme probe was glucose oxidase (GOx), immobilised at the surface of the PLA/graphene 3D-printed electrodes based upon physical adsorption. This approach is similar to Pumera and co-workers.³⁹ Then the glutaraldehyde solution was dropped on top of the immobilised GOx layer as a crosslinking polymer matrix to make the immobilised GOx enzyme more stable to entrap at the electrode surface. The PLA/graphene 3D-printed electrode played as a transducer in this glucose biosensor. Additionally, the FCA, which contained a redox iron centre, has been used as a mediator in this glucose biosensor. They proposed that the electrochemical response follows a second-generation glucose biosensor, as illustrated in Fig. 7.

Based on Fig. 7, they suggested that the glucose biosensor detection system follows a second-generation glucose biosensor where the two steps of reactions occurred. In the first step, flavin adenine dinucleotide (FAD) (active centre of the enzyme) acts as an electron mediator for glucose oxidation to gluconolactone, and reduces to flavin adenine dinucleotide (FADH₂). Thus, the FAD is converted to FADH₂, subsequently catalysing glucose oxidation reaction. Then, in the second step, the

Fig. 7 Proposed detection system for immobilised GOx enzyme at the PLA/graphene 3D-printed electrode for glucose detection, mediated by FCA. This figure has been adapted from ref. 55 with permission from ELSEVIER, copyright 2020.

reduced species of the FADH₂ is returned to the FAD species, and the electron involved in this oxidation reaction is transferred to FCA, in which the electrode produced during the oxidation process will reduce Fe(III) to Fe(II). The authors have also optimised the parameters in the fabrication of this glucose biosensor, such as pH value (pH 7) and the enzyme concentrations (6 units per electrode). After the optimisation steps, the fabricated biosensor is tested using the chronoamperometric technique in glucose with a variety concentration from 0 to 6.3 mmol L⁻¹ at a constant potential of +0.4 V. From the result obtained, the biosensor showed linear behaviour with an LOD of 15 μmol L⁻¹ and R² value of 0.998. The PLA/graphene 3D-printed biosensor has also been tested in human plasma for glucose detection. The developed 3D-printed electrode biosensor has shown a satisfactory recovery value of 94 to 104% and was reported stable even after being used in 15 measurements.

Another interesting study of the 3D-printed electrode as an electrochemical biosensor probe was presented by Janegitz *et al.*⁵⁶ to detect catechol through the immobilised tyrosinase enzyme at the 3D-printed electrode surface, as displayed in Fig. 8. In their work, PLA/reduced graphene oxide (RGO) 3D-printed electrodes were fabricated. Before using them as a biosensor probe, the 3D-printed electrodes were activated with solvent treatments. Then the tyrosinase enzyme was immobilised at the electrode surface through the physical absorption method using the drop-casting technique. To obtain stabilised

Fig. 8 The schematic diagram for steps to prepare immobilised tyrosinase enzyme, coated with the DHP film to detect catechol. (A) The mixture of tyrosinase enzyme and DHP solution. (B) Drop-casting method of tyrosinase/DHP solution onto PLA/RGO 3D-printed electrode surface. (C) The immobilised tyrosinase/DHP film was obtained. (D) SWV response for detection of catechol after exposure to immobilised tyrosinase probe. This figure has been adapted from ref. 56 with permission from ELSEVIER, copyright 2020.

immobilised enzyme at the electrode surface, before coating the enzyme, the authors prepared the tyrosinase enzyme solution (25 units in 10 μL) in hexadecyl phosphate (DHP) solution to maintain the immobilised tyrosinase enzyme at the electrode surface within DHP film as depicted in Fig. 8. The square wave voltammetric (SWV) responses for detection catechol were evaluated to obtain a calibration plot in the range of 30–700 $\mu\text{mol L}^{-1}$, giving an LOD detection at 0.26 $\mu\text{mol L}^{-1}$ with R^2 is 0.999.

Bergamini and colleagues⁵⁷ reported a very different study on the application of the 3D-printed electrodes for the biosensing platform on the development of an immunobiosensor for the detection of Hantavirus Araucaria nucleoprotein (Np). The best thing about their developed method is they employed a covalent immobilisation method to attach IgG2B antibody (HAb) onto the 3D printed PLA/carbon black electrodes using *N*-(3-dimethylaminopropyl)-*N'*-ethylcarbodiimidehydrochloride (EDC) and *N*-hydroxysulfosuccinimide sodium salt (NHS) as catalyst reagents. This approach will provide a stable and robust immobilisation of biomolecules at the electrode surface compared to the physical adsorption method. After preparing the immunobiosensor probes, the electrodes were characterised using CV and EIS in a $\text{K}_3[\text{Fe}(\text{CN})_6]$ redox probe solution, as illustrated in Fig. 9. The detection system was analysed by comparing the values of R_{ct} or CV peak currents before and after sensing the immunobiosensor probes to Np virus with a concentration range between 30–240 $\mu\text{g mL}^{-1}$, in which the calibration plot gave an LOD value of 22 $\mu\text{g mL}^{-1}$. Interestingly, the developed immunobiosensor was able to detect Np virus 0.120 mg mL^{-1} in spiked human serum samples (100 \times diluted).

Future outlook

We have discussed polymer/carbon nanomaterial 3D-printed electrodes for electrochemical sensors and electrochemical biosensors based on recent and past studies using the FDM 3D printing method. These 3D printed carbon nanomaterials can be fabricated easily, inexpensive, and straightforwardly to be incorporated with other chemicals for broad electroanalytical applications. Additionally, many published studies have shown that after the electrode treatments, these polymer/carbon nanomaterial 3D-printed electrodes have revealed promising properties such as high anisotropic conductivity, more electroactive sites produced, low resistivity, and high sensitivity in electrochemical sensors and biosensors development. As discussed earlier, the activation steps, whether chemically, electrochemically or thermally, could be employed to increase the electrochemical performance of the 3D-printed electrodes. Thus increasing electrode roughness, and anisotropic conductivity of the treated electrode, resulting in a significant increase in the sensitivity of the 3D printed electrodes. The 3D-printed carbon nanomaterial electrodes are commonly activated in aprotic solvents such as DMF from our literature survey. However, the DMF is a toxic and not eco-friendly chemical. To date, the utilisation of 0.5 M,¹⁶ 1 M,²⁴ or 3 M NaOH⁵⁸ solution as a pre-treatment 3D-printed electrode can also give a similar advantage as DMF. However, there are still some potential approaches that could be attempted to improve the electrochemical performance of the 3D printed electrodes in the future. One of the methods is by electrochemically treating the 3D-printed carbon nanomaterial electrode in acetonitrile (ACN) with 0.1 M tetrabutylammonium tetrafluoroborate (TBATFB) using

Fig. 9 Steps for creating immunobiosensor for covalent immobilisation of IgG2B antibody (HAb) onto PLA/carbon black 3D-printed electrode surface to detect Np virus in the human plasma sample. This figure has been adapted from ref. 57 with permission from ELSEVIER, copyright 2021.

CV, cycled the potential between 0–2.0 V.⁵⁹ This will make the electrode surface rougher, thus, providing more electroactive sites available for redox reactions. In contrast, an enzyme solution could also be used to activate the 3D-printed carbon nanomaterial electrodes.⁶⁰ However, using an enzyme will increase the experiment's cost as the enzyme molecule is very expensive and unstable.

The commonly used conductive thermoplastic carbon nanomaterial filaments are graphene and CB, where both of these filaments are commercially available. However, it would be advantageous if the conductive thermoplastic filaments are made in house by incorporating metal hydroxide, or metal oxide materials to produce conductive thermoplastic nanocomposite filaments. For metal hydroxide, it has been reported that the addition of nickel(II) hydroxide ($\text{Ni}(\text{OH})_2$) microparticles within a PLA/graphene matrix can produce a non-enzymatic 3D-printed electrode for creating a glucose sensor, in which $\text{Ni}(\text{OH})_2$ can act as an electrocatalyst for glucose.^{61–63} By contrast, ought to be interesting if conductive thermoplastic nanocomposite filaments are developed to be utilised in fabricating 3D-printed electrodes for photoelectrochemical sensors,^{64,65} or biosensors^{66,67} without modification of the electrode surfaces. This can be achieved by integrating tungsten trioxide (WO_3),⁶⁸ or titanium dioxide (TiO_2)⁶⁹ particles within polymer/carbon nanomaterial matrixes. This approach would be a very novel idea for developing photoelectrochemical sensors, or biosensors through 3D-printed electrodesensors.

The 3D-printed carbon nanomaterial electrodes' surface can also be modified easily through electrodeposition and chemical deposition methods. These approaches are highly recommended, mainly *via* the electrodeposition method as through the electrodeposition, the metal and metal oxide nanoparticle films such as electrodeposited gold (Au), platinum (Pt), silver (Ag), palladium (Pd), copper (Cu) and zinc oxide (ZnO) nanoparticles could be obtained, and the electrodeposited metal and metal oxide nanoparticle films could be employed broadly to

improve the electrochemical performances of the sensor, and biosensor electrode devices. In a different application, the 3D-printed electrodes can be made as pseudo-reference and counter electrodes,^{31,58} or only as a pseudo-reference electrode⁷⁰ for a three-electrode system set up. Attractively, in the case of the pseudo-reference electrode, it can be generated through electrodeposited, or coated Ag at the 3D-printed electrode surfaces. To date, it has been shown that the developed pseudo-reference electrodes based on 3D-printed electrodes exhibit a similar performance to a commercial Ag/AgCl reference electrode.^{31,70} On the contrary, the 3D-printed electrodes can also be utilised as an auxiliary electrode. Thus, this will replace the use of a conventional Pt electrode, and consequently, reducing the analysis cost. To the best of our knowledge, both types of electrodes were fabricated from conductive PLA/graphene filament,^{58,70} or PLA/CB filament.³¹ Hence, it would be of interest if a variety of thermoplastic carbon nanomaterials such as CNTs, or carbon fibers is used to generate the pseudo-reference and counter electrodes. Then, their electrochemical performance can be evaluated and can also be compared to the previous studies.^{31,58,70}

From the discussion, the current progress of the applications of the conductive polymer/carbon nanomaterial 3D-printed electrodes, produced from the FDM 3D printing method has a big potential to be employed as electrode substrates to immobilise biomolecules (enzymes and antibodies) in developing electrode biosensing devices *via* physical adsorption, entrapment with a polymer matrix or solid-phase synthesis with the presence of the catalyst reagents; EDC and NHS. Most of the published works so far only reported as proof-of-concept on the potentials of the 3D-printed electrodes for electrochemical biosensors. Therefore, in the future, some novel concepts, designs and approaches could be developed by the research community to attain robust immobilised biomolecule films at the electrode surface, high selectivity, and high sensitivity of the 3D printed electrodes for electrochemical biosensing purposes.

For instance, the electrodeposited AuNPs at the 3D-printed carbon nanomaterial electrode could be utilised as a substrate in anchoring various thiol linkers with different lengths and organic functional groups as the specific functional group could be used to covalently bind the enzyme, single-stranded DNA (ssDNA), or antibody molecules. This can be achieved by utilising a self-assembly monolayer method. The 3D-printed carbon nanomaterial electrodes could also be used as electrode substrates for electrografting of primary amine linkers. These linkers play an essential role in obtaining stable monolayer electrografted primary amine linkers^{59,71} that could be used to covalently attach redox probes, enzyme molecules or ssDNA molecules at the electrode surfaces. These modifications are very useful, especially for biosensors applications. The modification of the electrode surfaces is urgently needed for the improvement of the 3D-printed electrode to improve the stability, and selectivity of the biosensor probes in the detection process. The modified 3D-printed electrode could then be applied for the development of biosensors, biofuel cells, and electrocatalysts.

On the other hand, the electrodeposited Au, Pt, Pd, Ag, and Cu nanoparticles at 3D-printed carbon nanomaterial electrodes could be utilised as electrocatalyst platforms to study oxygen reduction reaction (ORR), oxygen evolution reaction, hydrogen evolution reaction and carbon dioxide reduction reaction. This gives a significant potential to develop electrochemical sensors to detect dissolved O₂ and CO₂ molecules in an aqueous solution. In conclusion, thermoplastic 3D printable conductive carbon nanomaterial electrodes have a promising future in electrochemistry and analytical chemistry research. Considering the current on-demand applications of the conductive 3D-printed electrodes in developing electrochemical sensors and biosensors, further studies ought to be carried out with different thermoplastic carbon nanomaterial filaments used in the FDM 3D printing process (e.g., carbon fibers⁷²). More optimization processes over individually adjustable FDM 3D printing parameters such as infill percentage, printing speed and temperature, and surface inclination angle can be explored to obtain the best 3D-printed electrode products in the selected electrochemistry applications by exploring their electrochemical performance.
