Novel potentiometric sensors for determination of ondansetron hydrochloride in pure and dosage form

 Amina M. Abass,^a Sahar S. M. Alabdullah,^{*ab} Omar Salih Hassan^c
 and Ahmed Ahmed^a

A new and sensitive potentiometric method has been developed and characterized for four novel sensors responsive to ondansetron hydrochloride. The potentiometric sensor method includes advancement of ondansetron hydrochloride sensors using a membrane comprised of molybdophosphoric acid (MPA) and ondansetron as an electro-active material in a polyvinylchloride (PVC) matrix membrane plasticized with di-butyl phthalate (DBPH), *ortho*-nitrophenyloctyl ether (*O*-NPOE), di-octyl phthalate (DOPH), or di-butyl phosphate (DBP). The validity of sensors in the present work has been examined, and steady and reproducible responses were obtained over the concentration ranges of 7.3×10^{-5} to 1.0×10^{-2} , 6.6×10^{-6} to 1.0×10^{-2} , 1.0×10^{-5} to 1.0×10^{-2} , and 2.0×10^{-5} to 1.0×10^{-2} M for DBPH-, *O*-NPOE-, DOPH-, and DBP-ondansetron, respectively. The sensors revealed Nernstian gradients of 59.61 ± 0.50 , 57.71 ± 0.23 , 53.01 ± 0.14 , and 53.20 ± 0.35 mV per decade individually with pH ranges of 2.5–5.5 in DBPH and 3.5–5.0 in *O*-NPOE electrodes, and 4.0–5.5 for both individual DOPH and DBP plasticized film-based sensors. The time responses for the sensors were 30, 32, 31, and 29 s for DBPH-, *O*-NPOE-, DOPH-, and DBP-ondansetron, respectively. The developed sensors also exhibited high selectivity towards ondansetron hydrochloride against different interfering species of inorganic particles with long-term stability of approximately 41, 36, 18, and multiple days for the DBPH, *O*-NPOE, DOPH, and DBP electrodes.

1. Introduction

The structure of ondansetron hydrochloride (ODH) is (*RS*)-9-methyl-3-[(2-methyl-1*H*-imidazole-1-yl)methyl]-1,2,3,9-tetrahydro-4*H*-carbazol-4-one hydrochloride dihydrate¹ (Fig. 1), and it is a basic compound with a pK_a of 7.7. It is a specific serotonin 5-HT₃ receptor antagonist that is used to treat nausea and vomiting caused by cancer chemotherapy and radiotherapy. It has also been shown to have neuroleptic and anti-anxiety characteristics.^{2,3} For anti-anxiety, the normal dosage is 8–32 mg per day, and for anxiety disorder, the initial results from clinical recommendations suggested lower levels of 2–4 mg per day.³

Over time, methods have been developed for the determination of ondansetron by liquid chromatography (LC),^{4,5} high-performance liquid chromatography (HPLC),^{6,7} ion-pair chromatography,⁸ liquid chromatography mass spectrometry (LC-MS),^{9,10} capillary zone electrophoresis,^{11,12} flow injection atomic absorption spectroscopy, and ultraviolet (UV)

spectrophotometry.^{13–15} Ninama *et al.* improved and validated a mass spectrometry method for concentrations of 1.00–100.00 ng mL⁻¹ with a lower limit of quantitation (LLOQ) at approximately 1.00 ng mL⁻¹, and shorter stability time for analysis of ondansetron solutions at approximately 7 h 10 min. This process is long and time consuming for routine regulatory analysis of the quality of pharmaceutical dosage forms.¹⁶ However, Farnoush *et al.* introduced a reliable and rapid potentiometric sensor for ondansetron with an acceptable Nernstian slope of 58 ± 0.3 mV, and the author also employed the sensor in ionic liquid solvents, such as 1-butyl-3-methylimidazolium tetrafluoroborate ([BMIM][BF₄]).¹⁷ A further important issue with the use of [BMIM][BF₄] is that the

liquid junction potential (E_j) could possibly accrue when different solutions are used due to different mobility of ions.¹⁸

The drawbacks of the above studies have been the included number of complex processes, limited applications, and required derivatization responses for measuring ondansetron. Another challenge is that there are few existing analytical methods with sensors of sufficient sensitivity that can be used to measure ondansetron in bioequivalence studies.¹⁹ A new approach is therefore required to overcome the weaknesses of published methods and devise accurate and sensitive techniques.

Thus, the overall goal of the current study was to improve a new version of potentiometric polymer matrix membrane sensors so that they were sufficiently accurate to measure trace amounts of ondansetron. The sensors successfully measured ondansetron in a bioequivalence pharmaceutical form, which was achieved using polyvinylchloride (PVC) as a matrix membrane plasticized with electro-active materials acting as ion pair complexes with either dibutyl phthalate, *o*-nitrophenyl octylether, di-octyl phthalate, or di-butyl phosphate in molybdophosphoric acid ondansetron.

2. Experimental

2.1. Chemical preparations

All analytical reagents were prepared in deionised water. Molybdophosphoric acid (MPA) and tetrahydrofuran (THF) were purchased from Aldrich and used without further purification. Polyvinylchloride (PVC) Breon S110/10 was purchased from B.P. Chemical UK, Ltd, whilst *o*-nitrophenyl octyl ether, dibutyl phthalate, di-octyl phthalate, and di-butyl phosphate were purchased from Fluka and BDH. Pure ondansetron hydrochloride was supplied by the State Company of Drug Industries and Medical Appliances (IRAQ-SDI, Samara). The formulated ondansetron hydrochloride tablets used were Zofran, 4 mg, manufactured in Singapore, and Zofran, 8 mg, manufactured in Egypt.

2.2. Instruments and analytical conditions

All electrochemical measurements were carried out at room temperature (25 ± 1 °C) with a digital pH meter (WTW model PH720, Germany) utilizing an MPA-ondansetron PVC matrix membrane sensor with calomel reference electrodes (Gallenkamp, USA). A reference electrode of glass/Ag AgCl was constructed for pH estimates. The ion-selective electrode contained an inner solution of 0.01 M of ondansetron solution.

2.3. Preparation of the PVC sensor membrane

The ion pair system was formed by 100 mL of 1.0×10^{-1} M ODH solution and 100 mL of 1.0×10^{-1} M aqueous MPA. The resulting precipitate was filtered and washed with distilled water, and then left to dry. The film (membrane) was prepared by dissolving 0.170 mg of powdered PVC, 0.40 mg of plasticizer, and 0.040 mg of the ion pair in 7 mL THF. The solvent was added to a Petri dish (7 cm in diameter), and then covered with filter paper and allowed to gradually evaporate at room temperature. A punched-out circular piece of film (membrane)

was connected to a polyethylene tube with a diameter of approximately 8 mm in an electrode construction.^{20,21} A 1.0×10^{-2} M ODH solution was used as the interior solution in the Ag/AgCl reference electrode. The constructed electrode was formulated and soaked for 24 h in 1.0×10^{-2} M ODH solution, with subsequent storage in a similar solution. The electrochemical cell for the ion-selective electrode (ISE) system used in this study is shown in Fig. 2.

2.4. Calibration of the sensors

The standardization of the sensors was tested by immersing the sensor into 50 mL-beakers containing 1.0×10^{-6} to 1.0×10^{-2} M ondansetron solutions. The potential was verified by plotting as a function of the logarithm of the concentration of ondansetron. The associated calibration curve was subsequently used to determine unknown ondansetron concentrations.

2.5. Determination of the selectivity coefficient

The selectivity coefficient ($K_{A,B}^{\text{pot}}$) was determined for the different electrodes by applying the matched potential method (MPM). In the MPM method, different interfering ions are added to a reference solution until the same electrode potential is recorded as that with a particular activity of elementary ions in a separate experiment. The K_{MPM} assumption was measured to calculate the selectivity coefficient for each interference ion from the ratio of the primary ion to interfering ion activity, as indicated in eqn (1) below:

$$K_{\text{MPM}} = \Delta a_2 A / a_1 B \quad (1)$$

where the activity of primary solution a_2 and a_1 is the activity of the reference solution, and aB denotes the interfering concentration that causes the same ΔE .¹⁹

Fig. 2 Ion-selective electrodes in an electro-analytical cell.

3. Results and discussion

3.1. Characterization of the sensor

We devised a specific method of preparing plasticized PVC matrix membrane sensors using MPA-ODH with suitable ionophores. Four types of ion-selective plasticizer membranes were formed to increase the diffusional mobility of the analysts and electroactive complex. A detailed standard protocol was investigated for applying the electrochemical technique to assess the ondansetron sensors. The response to the Nernst equation with respect to the potential-defining spaces in the solution was also considered. In this study, the sensor was activated before use by soaking in ondansetron solution for approximately two days. A series of 7.3×10^{-5} to 1.0×10^{-2} , 6.6×10^{-6} to 1.0×10^{-2} , 1.0×10^{-5} to 1.0×10^{-2} , and 2.0×10^{-5} to 1.0×10^{-2} M solutions for DBPH-, O-NPOE-, DOPH-, and DBP-ondansetron anodes was prepared to study the response of the electrode as a function of nominal Nernstian behavior that remained similar to the standard conditions.¹⁹

The data in Table 1 show an accurate response and high reproducibility for the O-NPOE, DBPH, DOPH, and DBP films. The slope of the graph was 59.61 ± 0.50 for DBPH, while the other slopes slightly decreased to 57.71 ± 0.23 , 53.01 ± 0.14 , and 53.20 ± 0.35 mV per decade for DBPH, DOPH, and DBP, respectively. It is clear that the four types provide a linear response with a satisfactory lifetime. These sensors could, however, provide an analytical signal for measuring ondansetron hydrochloride.

3.2. Effect of time

Time response is an important factor for use in ion-selective electrodes, and it is usually dependent on the time required for the system to reach equilibrium. An interesting observation was the stability of the potential, and chemical equilibrium in 10^{-3} M ondansetron solution resulted in 30, 32, 31, and 29 seconds for sensors O-NPOE, DBPH, DOPH, and DBP, respectively. The response of the electrode can disrupt the non-linearity, and this error could decrease the efficiency of the electrode. In this case, the potential at equilibrium was less stable, and the sensor could display uncertainty in the linear response to the Nernst equation. In some cases, it was found that uncertainty was recorded for potentiometric titration of the order of potential measurements, and these differences were approximately ± 5 mV e.m.f.²⁰ In a study for measuring

Fig. 3 Potentiometric response of ondansetron PVC matrix membrane sensors.

metoclopramide hydrochloride by PVC using a similar apparatus, the authors noted that the PVC membrane produced linear responses to the Nernst equation, while the day-to-day reproducibility of the sensor showed a decrease in the potential measurements of approximately ± 0.5 mV for the same solutions.²⁰

The data in Fig. 3 show that the change in the potential for the four electrodes in different concentrations of ondansetron solutions is in satisfactory agreement with the Nernst equation. However, the four electrodes gave slight deviations in analytical signals above 0.01 M. Previously, it has been shown that accurate measurements above 0.01 M could be clearly obtained when the reaction mixture was heated to 60°C . This was due to reaching the optimum reaction time for the charge-transfer complexation to occur between ondansetron base as an n-electron donor with chloranil as a π -acceptor to produce a colored complex.²¹ However, the quantitation of ODH in all four prepared electrodes at a concentration range lower than 10^{-5} M could not be feasible without a fitting of accumulation of transport ions, which would minimize the ion exchange of the ion-pair with competing endogenous ions.²²

All prepared sensors were in good agreement with the life expectancy values of 41, 36, 18, and 20 days for the O-NPOE-, DBPH-, DOPH-, and DBP-based membrane sensors, respectively. Therefore, in most cases, it is assumed that the differences between the responses of the four membranes are dependent on the filtering of the ion pair from the membranes.⁶

Fig. 4a and b shows the characterization of ondansetron with ion pair and pure drug formulation. The graph is split into two parts, and they indicate wavelength measurements of the ion pair productions. The data are similar to those expected from the previous study showing the functional groups for

ondansetron with an ion pair. The Fourier transform infrared (FTIR) spectroscopy results for ondansetron show intense bands at 3483.41 cm^{-1} , 2910.11 cm^{-1} , and 1638.7 cm^{-1} , which correspond to the presence of the NH group, C–C-aromatic group, and C–C-aliphatic group, respectively.²³

3.3. Effect of pH

The performances of the membranes in electrodes mostly depend on the potentiometric responses. One of the important factors is the presence of hydrogen ion. To further understand the potentiometric responses of the O-NPOE-, DBPH-, DOPH-, and DBP-based membrane sensors, they were tested with the standard addition of 10^{-3} M ondansetron solution in a pH range of 1.2–12.4, as shown in Table 2. An adjustment of pH was achieved using diluted solutions of either sodium hydroxide or hydrochloric acid. Fig. 5 shows that the pH of 2.5–5.5 for DBPH, 3.5–5.5 for NPOE, and 4.0–5.5 for DOPH and DBP did not

significantly affect the sensor response. A much slower response of the membrane was obtained at $\text{pH} < 2.00$. This could be attributed to competitive binding of hydrogen ion at the surface of the membrane, while at $\text{pH} > 6$, the electrode function remained unaltered with a slight change in pH due to progressive precipitation of high alkali solution.²⁴

3.4. Effect of interfering ions

Having shown that the presence of ion pairs in the membrane increases the selectivity of the electrode and enables quantification of the ondansetron solutions, the next step was to examine the influences in different inorganic anions. The selectivity coefficients ($k_{\text{potODH},B}$) are representative of the activity ratio of primary and interfering ions. They are also an essential parameter that refers to the operability of the electrodes, as it is generally known that high selectivity values refer to the high free ions that confer a smaller effect than the other interfering ions in the solution. Table 3 shows that the results are logical given the acceptable selectivity for ondansetron solutions in the presence of numerous inorganic anions.^{25,26}

3.5. Measuring the pharmaceutical form of ondansetron

Tests were performed to ensure that the electrodes were valid for measuring ondansetron. All electrodes underwent the direct, standard (SAM), and multi-standard potentiometric method (SAMS) to determine the concentration of 10^{-4} M and 10^{-3} M ondansetron solutions for all electrodes. These data are shown in Table 6, and in all cases, it was assumed that there was considerably high precision and linearity with a low detection limit for all values obtained using the potentiometric titration method for all plasticizer-based membranes, and they emphasize the improved performances of the electrodes, as summarized in Tables 4–7. The performances of the prepared membrane electrodes were similar to those previously mentioned in the literature. In the same context, a study by Nigović examined the electrochemical behavior of ondansetron on the multi-walled carbon nanotubes of a Nafion polymer composite in a glassy carbon electrode.²⁷ The quantification of

ondansetron concentrations in coated tablets was reported as electrochemical data.

Recovery studies of drugs in serum samples were performed using the standard addition method, with 98.77% recovery of ondansetron as protonated drug molecules on a Nafion surface matrix.²⁷ Another comparable study by Ninama *et al.* measured ODH concentration using the solid-phase extraction chromatography-mass spectrometry method.¹⁶ The work reported that the percent accuracy of samples prepared with different biological matrixes was found to be 91.88%, and wet extract stability was found to be 43 h 30 min at 5 ± 3 °C.¹⁶

For the current method, the recovery measurements for prepared electrodes were approximately 97.90% using the standard addition method. The precision and accuracy of the method expressed as recovery% was found to be approximately 2.1%.⁹ The results obtained were within the acceptable range and were higher than those observed in the biological matrix.¹⁶ The values are also in accordance with the effective accuracy measurements of ODH solutions, as shown in Table 4.

Additional tests were performed after the application of the improved electrodes in pure solutions of ondansetron. The plasticized PVC matrix membranes were used to measure

pharmaceutical preparations, and the data are shown in Table 8. It was noted that all electrodes were able to adequately measure the concentration of ondansetron, and these data indicate that the proposed potentiometric method is applicable for quality control of medicinal preparations.²⁸

4. Conclusion

This work has demonstrated the importance of PVC sensors in potentiometric applications for measurement of ondansetron in two pharmaceutical formulations. The ODH-MPA-DBPH membrane sensor was more optimal than the other prepared

electrodes with respect to Nernstian response, reproducibility, and sensitivity. The results of this investigation enable the direct prediction of ondansetron. Our data indicate that polymeric membrane sensors are unique for characterizations at wide ranges of pH (from 2.5 to 5.5). Our methodology was also found to be an important design process because a selective response toward ondansetron in the presence of all the expected interfering ions was exhibited.
