Tuning MoSO monolayer properties for optoelectronic and spintronic applications: effect of external strain, vacancies and doping†

Duy Khanh Nguyen,^a J. Guerrero-Sanchez,^b Vo Van On,^a J. F. Rivas-Silva,^c R. Ponce-Pérez,^b Gregorio H. Coccoletzi^c and D. M. Hoat^{id}*^{de}

Since the successful synthesis of the MoS₂ monolayer, two-dimensional (2D) Janus materials have attracted huge attention from researchers. In this work, the MoSO monolayer with tunable electronic and magnetic properties is comprehensively investigated using first-principles calculations based on density functional theory (DFT). The pristine MoSO single layer is an indirect gap semiconductor with energy gap of 1.02(1.64) eV as predicted by the PBE(HSE06) functional. This gap feature can be efficiently modified by applying external strain presenting a decrease in its value upon switching the strain from compressive to tensile. In addition, the effects of vacancies and doping at Mo, S, and O sites on the electronic structure and magnetic properties are examined. Results reveal that Mo vacancies, and Al and Ga doping yield magnetic semiconductor 2D materials, where both spin states are semiconductors with significant spin-polarization at the vicinity of the Fermi level. In contrast, single S and O vacancies induce a considerable gap reduction of 52.89% and 58.78%, respectively. Doping the MoSO single layer with F and Cl at both S and O sites will form half-metallic 2D materials, whose band structures are generated by a metallic spin-up state and direct gap semiconductor spin-down state. Consequently, Mo_V, Mo_{Al}, Mo_{Ga}, S_F, S_{Cl}, O_F, and O_{Cl} are magnetic systems, and the magnetism is produced mainly by the Mo transition metal that exhibits either ferromagnetic or antiferromagnetic coupling. Our work may suggest the MoSO Janus monolayer as a prospective candidate for optoelectronic applications, as well as proposing an efficient approach to functionalize it to be employed in optoelectronic and spintronic devices.

1. Introduction

Pushed by the success of graphene,^{1–3} the investigation of two-dimensional (2D) materials at atomic thickness has been continuously increased experimentally and theoretically. Between the materials studied so far, it would be wrong not to mention the transition metal dichalcogenides (TMDs).^{4,5} Being an important member of the TMD family, the MoS₂ monolayer has been extensively investigated. Previously, Yu *et al.*⁶ have

successfully prepared large-area and high quality MoS₂ monolayers and few-layer films using a self-limiting approach, which made possible the fabrication of miniature devices. Large-area synthesis at 200 °C of the high phase purity and crystallinity MoS₂ monolayer has been achieved by Gong *et al.*⁷ using chemical vapour deposition (CVD). The synthesized single layer shows significant fluorescence, however the intensity decreases considerably according to the increase in layer number as a result of the direct–indirect gap transition. It has been demonstrated that the photoluminescence yield of the MoS₂ monolayer can reach high values close to 100% using superacid treatment.^{8,9} Liu *et al.*¹⁰ have shown that the 2D hybrid materials based on the monolayer MoS₂ films are promising photodetectors exhibiting high responsivity near 1.8 × 10⁴ A W^{−1} and ultrahigh detectivity near 7.6 × 10¹³ Jones. The MoS₂ monolayer has been also suggested as an excellent 2D electrocatalyst for application in the hydrogen evolution reaction (HER), showing a Tafel slope of 61 mV per decade and exchange current density of 38.1 μA cm^{−2}.¹¹ Theoretically, first-principles calculations carried out by Yelgel *et al.*¹² yield a direct energy gap of 1.85 eV for the MoS₂ single layer. Besides, the modulation of the fundamental properties of the MoS₂ monolayer has been also

investigated using different methods such as application of external strain,^{13,14} formation of intrinsic defects,^{15,16} and doping,^{17,18} which are efficient in inducing novel properties in the layer.

On the other hand, a new 2D materials family called “Janus” has been developed from 2017 with the successful synthesis of the MoSSe monolayer, which is formed by breaking the out-of-plane mirror symmetry. This is achieved by either replacing the S top-layer in MoS₂ monolayer with Se atoms¹⁹ or Se-layer in MoSe₂ monolayer with S atoms using a controlled sulfurization approach.²⁰ Later, Roberto *et al.*²¹ have carried out the sulfurization of the PtSe₂ single layer on Pt(111) substrate under H₂S atmosphere. Chemical composition analysis has demonstrated the Se-by-S substitution in the topmost layer, indicating the formation of PtSSe Janus monolayer. Theoretically, many 2D TMD Janus materials with good stability and novel properties have been predicted.^{22,23} However, studies have not been only limited to TMDs, but the chemical composition has been extended to other possible combinations. For examples, IIIA-group chalcogenides Janus monolayers have been investigated. Results indicate prospect of their electronic, optical, and piezoelectric properties.^{24–27} Semiconductor layered BiTeCl and BiTeBr compounds with giant Rashba-splitting have been prepared by Debarati *et al.*²⁸ Theoretical calculations yield small energy gaps of 0.83 and 0.80 eV,²⁹ respectively. Besides, a large variety of Janus single layers based on chalcogens and halogens with feature-rich properties have been reported in the computational 2D materials database (C2DB).^{30,31} Janus Ga₂XO structures (X = S, Se, Te) have been designed by Demirtas *et al.*³² using first-principles calculations. Results indicate good dynamical and mechanical stability of Ga₂SO and Ga₂SeO. These possess direct band-gap that can be further tuned by external strain. Demirtas *et al.*³³ have also predicted the Al₂XX' (X/X' = O, S, Se, and Te) with energy gap ranging from 1.07 to 2.74 eV, using first-principles method. Janus In₂XO (X = S, Se, and Te) as potential nanomaterials for applications in optoelectronic and thermal devices have been studied by Vu *et al.*³⁴ In a recent work, we have investigated the PtOX (X = S and Se) monolayers,³⁵ results indicate prospective optoelectronic and thermoelectric features of these 2D materials.

The oxidation of MoS₂ monolayer to form intermediate phase composed of MoS_xO_y has been realized by Xu *et al.*³⁶ through hydrogen peroxide (H₂O₂) treatment. Photoluminescence spectra show an effective band gap modulation induced by the oxidation. Yagmurcukardes *et al.*³⁷ have investigated the MoSO single layer electronic and photonic properties under biaxial strain. A strong out-of-plane piezoelectricity and indirect gap semiconductor are characterized, where the energy gap can be effectively engineered. Using MoSO monolayer as a building block, the Janus-MoSO/MoS₂ heterojunction has been investigated by Wang *et al.*³⁸ Results show an improvement of the optoelectronic performance of the structure based on MoSO monolayer. In this work, we explore the structural, electronic, and magnetic properties of the MoSO Janus monolayer using first-principles calculations. As a first step, the structure is optimized, followed by the test of dynamical and thermal stability. Then, the electronic properties

are studied analyzing the band structure, density of states, and charge density difference. In addition, the effect of external strain, vacancies, and doping at different sites of MoSO single layer will be considered in order to induce novel electronic and magnetic properties. Hereafter, the Mo_V, Mo_{Al}, and Mo_{Ga} terms refer to the MoSO monolayer with a single Mo vacancy, Al doping at Mo site, and Ga doping at Mo site, respectively. Similarly, the structures with a single S(O) vacancy, doped with F, and doped with Cl at S(O) site will be denoted by S_V(O_V), S_F(O_F), and S_{Cl}(O_{Cl}), respectively.

II. Computational details

First-principles calculations in framework of the density functional theory (DFT)³⁹ have been performed using CASTEP computational package⁴⁰ to explore the structural, electronic, and magnetic properties of MoSO Janus monolayer under effect of external strain, vacancy, and doping. The generalized gradient approximation in Perdew–Burke–Ernzerhof form (GGA-PBE)⁴¹ is included in calculation to take into account the effect of exchange-correlation potentials, while the norm-conserving pseudopotential describes the electron-ion interactions. The expansion of plane waves is truncated with a kinetic energy cut-off of 500 eV. The Brillouin zone sampling is done with a *k*-mesh of 20 × 20 × 1 and 6 × 6 × 1 in the pristine primitive cell and supercell cases, respectively. The structures optimization is realized with a force criterion of 0.01 (eV Å^{−1}). Stopping point for self-consistent iterations is set to 10^{−6} eV. In all calculations, a vacuum gap of width 15 (Å) is generated along the direction perpendicular to the layer plane, which is large enough to exclude the interactions of periodic layers.

III. Results and discussion

A. Pristine MoSO monolayer

It is well known that MoS₂ can be found in either 1T or 2H phases, where the later is more common and is considered in this work. Similar to the MoSSe Janus monolayer, the MoSO structure is generated by substituting completely one of the two S-layers by O atoms. This fact breaks the structural mirror-symmetry, reducing the symmetry to *P3m1* space group (no. 156) (see Fig. 1a). According to our calculations, the optimized lattice parameter is 3.05 (Å), which is smaller than that of MoS₂,⁴² as a result of the smaller atomic size of O atom as compared to S atom. The calculated bond lengths are *d*_{Mo–S} = 2.41 and *d*_{Mo–O} = 2.13, and interatomic angle ∠SMoO = 77.33°. In addition, a total thickness of 2.84 (Å) is generated by the buckling heights Δ_{Mo–S} and Δ_{Mo–O} of 1.64 (Å) and 1.20 (Å), respectively. Following the structural optimization, the dynamical and thermal stability of the predicted single layer is examined. Fig. 1b shows the phonon dispersion curves, which are formed by nine phonon modes resulting from the vibrations of three constituent atoms in the primitive cell. From the figure it can be noted no imaginary vibrational frequency, that is all phonon modes are positive, indicating that MoSO Janus single layer is dynamically stable. Further *ab-initio* molecular dynamics (AIMD) simulations have been carried out, results are

Fig. 1 (a) Atomic structure (gray ball: Mo; red ball: O; green ball: S), (b) phonon dispersion curves, and fluctuation of temperature as a function of molecular dynamics simulation steps of MoSO monolayer at (c) 300 K and (d) 1000 K.

displayed in Fig. 1c and d. The recorded snapshots suggest that no structural destruction occurs at room temperature (300 K) and high temperature (1000 K), confirming good structural-thermal stability of the considered pristine Janus monolayer. In addition, we have calculated the formation enthalpy ΔH_f using following formula:

$$\Delta H_f = \frac{E_t - \mu(\text{Mo}) - \mu(\text{S}) - \mu(\text{O})}{3} \quad (1)$$

where E_t denotes the total energy; μ refers to the chemical potential of each element in the parentheses. Our calculations yield a negative ΔH_f of -1.24 (eV per atom), suggesting a good thermodynamic stability of MoSO Janus single layer.³¹ As a stable 2D Janus structure, the intrinsic strain induced by the large difference in atomic size of S and O atoms may favor rolling the MoSO flakes into a nanotube with unique electronic properties.^{43–45} Therefore, our results may stimulate future works treating about new MoSO nanotubes.

The electronic band structure of MoSO single layer has been calculated within the PBE and HSE06 formalism. Fig. 2a shows results depicted along the Γ -M-K- Γ high symmetry direction. Note that the indirect gap semiconductor nature is predicted by both employed functionals, since the valence band maximum takes place at Γ point and the conduction band minimum occurs at K point. Previous studies have indicated the K-K,⁴² and the direct-indirect gap transition may be induced with the formation of Janus structure as a result of the anisotropic

strains experienced by opposite O-side and S-side. At equilibrium, the energy gap of the pristine monolayer is 1.02 eV as obtained by PBE. Undoubtedly that with the introduction of 25% exact Hartree-Fock exchange potential, the hybrid functional HSE06 improves considerably the results of standard GGA potentials, giving more accurate energy gap of materials. In our case, the HSE06 yields a band gap value of 1.64 eV, which is 60.75% larger than that determined by PBE functional. Choosing the MoS₂ monolayer as a reference, it can be seen that this important parameter reduces according to the decrease in atomic number of VI-A group elements, similar to other Janus based on TMDs⁴⁶ and III-A chalcogenides.³³ To get deeper understanding on the band structure formation, the partial density of states (PDOS) is studied. Fig. 2b shows that the Mo-4d, S-3p, and O-2p are main contributors, exhibiting significant presence in both valence band and conduction band. A closer analysis indicates that the non-metal atoms have higher influence in the valence band, and the same behavior is observed for the transition metal in the conduction band. In addition, the charge density difference is investigated to examine the chemical bonds. Results illustrated in Fig. 2c indicate that the charge is accumulated at O- and S-sites, while the charge depletion is observed at the Mo-site, indicating a charge transfer from Mo atom to O and S atoms, suggesting an ionic chemical bond. According to our calculations, O and S atoms gain a charge quantity of 0.58 and 0.04e, respectively, in agreement with the considerably larger electronegativity of O atom.

Since one of the most frequent factors that influence the fundamental properties of 2D materials is the external strain, which may be generated by the hydrostatic pressure or chemical pressure. Therefore, to achieve an adequate design of these materials, a complete understanding on this dependence should not be forgotten. Herein, we investigate the strain effect on the electronic properties of the MoSO monolayer, which is defined by the strain lattice parameter a and equilibrium lattice parameter a_0 as follows: $\mu = \frac{a - a_0}{a_0} \times 100\%$. Results of the

band structure and energy gaps are given in Fig. 3. From the left panel, one can see that in the considered energy range from -6% to 6% , this Janus monolayer retains its indirect gap semiconductor nature considering that the VBM and CBM are located at Γ and K point at a given strain, respectively. The band gap plots in the right panel indicate that this parameter decreases considerably when switching the strain nature from compressive to tensile. Note that the reduction rate is considerably smaller in the strain range from -6% to -4% , from which a nearly linear decreasing trend is obtained. MoSO monolayer exhibits an increase of 72.52(48.90)% up to a compressive strain strength of -6% as predicted by PBE(HSE6) potential, while a reduction of the order of $-55.25(-40.66)\%$ when the lattice tension of 6% is applied.

B. Vacancy and doping at Mo site

Because of the atomic size difference and modification of electronic interactions, the formation of vacancy and doping

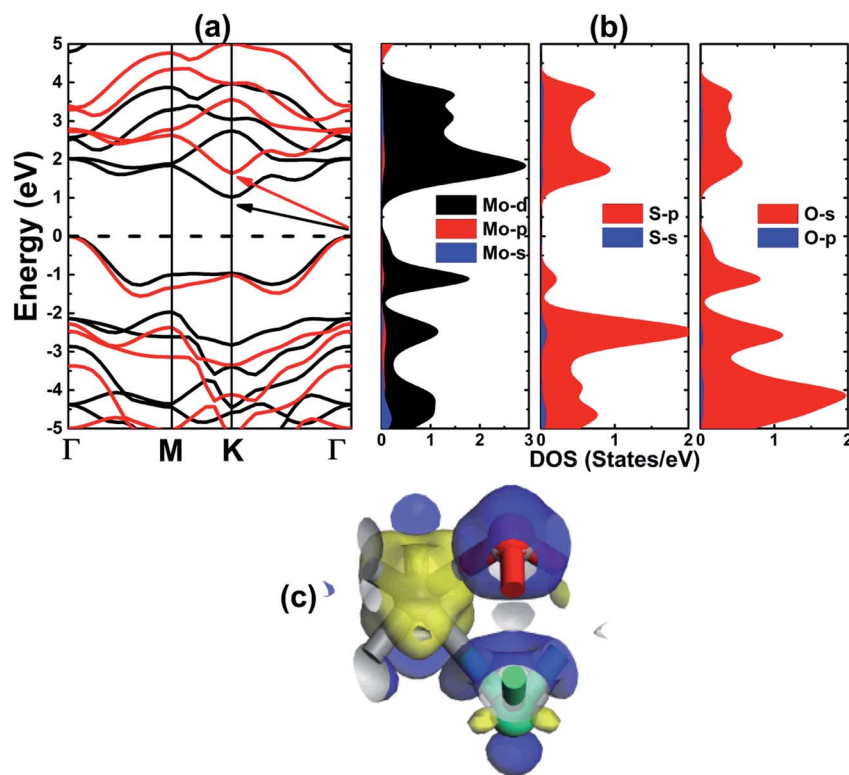

Fig. 2 (a) Electronic band structure (black line PBE; red line: HSE06), (b) partial density of states, and (c) charge density difference (blue surface: charge accumulation; yellow surface: charge depletion) of the MoSO monolayer.

Fig. 3 (a) Electronic band structure and (b) energy gap values of the MoSO monolayer at several strains.

induce local changes in the structure (see the relaxed atomic structures displayed in Fig. S1†), which are summarized in Table 1. Note that in the case of Mo_V system, the structural parameters exhibit quite small difference as compared with those of the pristine layer, suggesting that the Mo vacancy effect on the structure is negligible. In contrast, significant structural re-arrangements are noted for the cases of Al and Ga doping. Specifically, in comparison with the pristine monolayer both

$d_{\text{D-S}}$ and $d_{\text{D-O}}$ bonds lengths increase. A same behavior is noted for the buckling height $\Delta_{\text{D-S}}$, while $\Delta_{\text{D-O}}$ and interatomic angles show a decreasing variation. It is worth mentioning that the Al doping may induce stronger structural modification than Ga doping, where Al dopant is nearly found in the O-layer plane showing a buckle of only 0.07 (Å). These results suggest a stronger Al-O bond than Ga-O one.

Fig. 4 displays the spin-resolved band structures of the O-vacancy and doped MoSO Janus monolayer. It can be noted novel electronic features generated by the spin-polarization, mostly at vicinity of the Fermi level that is set as an energy reference. In the case of Mo_V system, the indirect KT - M band gaps of 0.28 and 0.48 eV are obtained in the spin-up and spin-down state, respectively. These are generated by the pair [VBM : CBM] at energies of $[-0.14 : 0.14]$ eV and $[-0.20 : 0.28]$ eV, respectively. The substitutional incorporation of Al and Ga at the Mo site gives place to the appearance of

Table 1 Bond length d (Å), buckling height Δ (Å), interatomic angle \angle (°), formation energy E_f (meV Å⁻²) and cohesive energy E_c (eV per atom) of the MoSO monolayer with defect at Mo-site ($D = \text{Mo}$ in Mo_V system; $D = \text{Al}$ in Mo_Al system; $D = \text{Ga}$ in Mo_Ga system)

Fig. 4 Spin-polarized band structure (black line: spin-up; red line: spin-down) (a) Mo_V, (b) Mo_{Al}, and (c) Mo_{Ga} systems.

a spin-up direct Γ - Γ gap of 0.51 and 0.60 eV, respectively. In the Mo_{Al} spin-down configuration, the VBM and CMB are found at Γ point (−0.38 eV) and K point (0.63 eV), respectively, originating an indirect gap of 1.01 eV. The indirect gap semiconductor behavior is also obtained in the Mo_{Ga} spin-down state with an energy gap of 1.07 eV generated by the separation of the VBM at −0.25 eV (along $K\Gamma$ direction) and CBM at 0.82 eV (at K point). Results indicate that the creation of Mo vacancy, as well as Al and Ga doping conduct to the formation of 2D magnetic semiconductor materials. It is well known that when the un-polarized electrons pass through a magnetic semiconductor film, the spin states will encounter different potential barriers which influence considerably the probability of tunneling of each of them.⁴⁷ Therefore, the systems studied herein may be prospectively used as a spin-filter to create the spin currents to be used in the spintronic devices. The band structures of Mo_V, Mo_{Al}, and Mo_{Ga} systems are formed mainly by the Mo-4d, S-3p, and P-2p states, similar to the pristine layer (see Fig. S4†). In addition, small contribution from the s and p orbitals of dopants is also noted in both valence band and conduction band. The population analysis indicates a significant charge transfer from Mo (a quantity between 0.61 and 0.78e) and dopants (1.62e of Al and 0.48e of Ga) to S and O atoms. Undoubtedly that most of these charges are transferred to

O atom considering its larger electronegativity as compared with that of S atom (see results listed in Table 2).

The break of spin symmetry close to the Fermi level may suggest significant magnetization in the MoSO Janus monolayer induced by Mo vacancy, and Al and Ga doping. According to our calculations, the magnetism is induced mainly by the Mo atoms (see Table 2). Specifically, in Mo_V system the first, second, and third Mo atoms closest to the vacancy exhibit magnetic moments of 0.14, −0.20, and −0.21 μ_B , respectively. While in the doped systems, larger values of [0.64 and 0.74], [−0.38 and −0.57], and [−0.52 and −0.64] μ_B are obtained. It is worth mentioning that the first Mo atoms from vacancy and doping site show an antiferromagnetic coupling with the remaining second and third ones provided that their magnetic moments exhibit opposite orientations. This feature is illustrated clearly in the spin density maps (Fig. 5). Such magnetization is originated mainly by the first Mo spin-up, and second and third Mo spin-down states, being in agreement with the numerical results. In all cases, the contribution of S, O, Al, and Ga atoms to the magnetic properties is quite small.

C. Vacancy and doping at S site

Now, the effect of single S vacancy, and F and Cl doping at S site on the structural, electronic, and magnetic properties of MoSO

monolayer is examined. The optimized atomic structures of the S_V, S_F, and S_{Cl} systems are illustrated in Fig. S2,† and parameters calculated around the vacancy and doping site are given in Table 3. It appears that the S vacancy induces negligible change of the interatomic distances ($d_{\text{Mo-S}}$ and $d_{\text{Mo-O}}$), and angle ($\angle \text{SMoO}$), and buckling height $\Delta_{\text{Mo-O}}$. The most notable modification is that of the layer thickness with an increase of 0.09 (Å) in the buckle $\Delta_{\text{Mo-S}}$. Results suggest that in terms of the structure, the O-side may not suffer of significant effect of a single S vacancy. Similar behavior is noted in the case of F and Cl doping, where only quite small differences of $d_{\text{Mo-O}}$ and $\Delta_{\text{Mo-O}}$ in comparison with their corresponding values in the pristine layer are perceived. However, in these two cases, the doping leads to an important local distortion in the S-side. Specifically, the F substitution causes a structural shrink indicated by the reduction of the chemical bond length $d_{\text{Mo-S}}$, buckling height $\Delta_{\text{Mo-S}}$, and angle $\angle \text{SMoO}$. On the contrary, a significant local tension is induced by Cl doping since these mentioned parameters increase after replacing one S atom by one Cl atom.

Fig. 6 shows the spin-polarized electronic band structure of the S_V, S_F, and S_{Cl} systems in panels a, b, and c, respectively. Note that the creation of single S vacancy in MoSO Janus monolayer leads to the formation of a non-magnetic 2D material since its spin channels exhibit a completely symmetric curves in both valence band and conduction band. Considering the Brillouin zone of the hexagonal defective supercell, S_V layer is a Γ - Γ direct gap semiconductor with an energy gap of 0.48 eV (generated by the VBM at 0.23 eV below the Fermi level and the CBM at 0.25 eV above the Fermi level). This result corresponds to a reduction of the order of 52.89% as compared with that of the pristine layer. In contrast, spin-polarized nature is noted around the Fermi energy in the cases of doping. With the similar valence configurations ($2s^22p^5$ of F and $3s^23p^5$ of Cl),

one can expect similar effect of F and Cl doping on the electronic structure of MoSO Janus single layer. This expectation is met in our case. To precise, the half-metallicity is achieved by the incorporation by substitution of these halogens at S site, which is generated by a metallic spin-up state and a semiconductor spin-down state. In the spin-up channel, the metallic nature is caused by electronic states overlapping the Fermi level. While the direct gap semiconductor behavior in the spin-down channel is a result of the separation between VBM and CBM, both at Γ point. In this later, the obtained spin-down band gap of the S_F and S_{Cl} layer is 1.04 eV (with VBM at -0.38 eV and CBM at 0.66 eV) and 1.06 eV (VBM at 0.36 eV and CBM at 0.70 eV), which are quite similar to that of the pristine MoSO layer. In recent years, spintronics has been considered as next generation electronics replacing the silicon based conventional electronics. In this regard, creating the spin current is a one of the main tasks. For such a goal, besides the magnetic semiconductors (as seen above), the half-metallic materials are widely employed.⁴⁸ Therefore, the F and Cl doping at S site may be an efficient method to functionalize the MoSO Janus monolayer for the use in spintronic devices to generate spin current. Further calculations of the PDOS indicate that in the considered energy range, the band structures of the studied nano-structures are formed mainly by the Mo-d, S-p, and O-p states (see Fig. S5†). It is also noted small contribution of the F-p and Cl-p orbitals in the S_S and S_{Cl} systems, respectively. The PDOS is totally symmetric in the layer with vacancy presence, in agreement with the band structure. Note that the spin-up metallic nature of the doped layers is induced mainly by the Mo-4d state since this exhibits quite high weight at the Fermi level. Analyzing the electronic population, we observe a charge transfer from Mo transition metal to the non-metal constituents including the F and Cl dopants (see details in Table 2). Clearly, greater amount is transferred to the O-side, while with a larger electronegativity the F and Cl atoms gain larger charge than S atoms in the S-side.

The electronic structure analysis suggests that the F and Cl doping at the S site, breaking mainly the spin symmetry of Mo-d orbital, have significantly magnetized the MoSO Janus monolayer. Consequently, the magnetic properties are produced mainly by the Mo transition metal (see Table 2). Our simulations yield magnetic moments of 0.77(0.73), -0.29(-0.26), and -0.07(-0.10) μ_B for the first, second, and third Mo atoms from the F(Cl) doping site, respectively. Note

Table 3 Bond length d (Å), buckling height Δ (Å), interatomic angle \angle (°), formation energy E_f (meV Å⁻²) and cohesive energy E_c (eV per atom) of the MoSO monolayer with defect at S-site (D = S in S_V system; D = F in S_F system; D = Cl in S_{Cl} system)

that the contribution of the third ones is quite small, whereas the opposite signs suggest an antiferromagnetic coupling of the first and second atoms in both cases. This result is illustrated *via* spin density in Fig. 7. The iso-surfaces indicate that the magnetism is induced mainly by the first Mo spin-up state and second Mo spin-down state, being consistent with the numerical results.

D. Vacancy and doping at O site

In this subsection, we investigate the structural, electronic, and magnetic properties of the MoSO Janus monolayer under effect of a single O vacancy, and F and Cl doping at the O site. The readers can find the optimized atomic structures of these systems in Fig. S3.† Structural parameters are given in Table 2. Similar to the S_V structure, creating an O vacancy induces insignificant structure modifications. Similar effect is obtained in the S-side when the layer is doped with F and Cl at O site provided that the bond length and buckling height related to the S atoms exhibit negligible difference in comparison with those in the pristine layer. On the contrary, a considerable atomic re-arrangement takes place at the O-side, causing a local tension since the parameters d_{Mo-F} – d_{Mo-Cl} , Δ_{Mo-F} – Δ_{Mo-Cl} , and $\angle SMOF$ – $\angle SMOCl$ are larger than their corresponding values related to O atom in the MoSO single layer. Clearly, a stronger effect is noted in the case of Cl doping than in the F doping due to its larger atomic size. However, it is worth mentioning that the local structural changes are results of the synergistic effect of atomic size and electronic interactions. Therefore, the Mo–O

chemical bond may be stronger than Mo–F one considering that O and F atoms have quite similar atomic size.

Fig. 8 displays the calculated electronic band structure of the O_V , O_F , and O_{Cl} systems. A single O vacancy forms a Γ – Γ direct gap semiconductor with an energy gap of 0.42 eV (VBM at an energy of 0.20 eV below Fermi level and CBM at an energy of 0.22 eV above Fermi level), indicating a gap reduction of the order of 58.78%. The band structure feature suggests that the decrease of energy gap is because of the flat branch appearance in the energy range from -0.77 to -0.20 eV. Unlikely, the F and Cl doping at O site causes significant spin polarization, for which the electronic states developed at vicinity of the Fermi level mainly regulate the electronic and magnetic properties. Specifically, with some electronic states crossing the Fermi level, the spin-up channel exhibits a metallic behavior, whereas the spin-down state is Γ – Γ direct gap semiconductor. The calculated spin-down band gaps are 1.29 eV (VBM at -1.13 eV and CBM at 0.16 eV) and 1.33 eV (VBM at -1.17 eV and CBM at 0.16 eV) for the O_F and O_{Cl} structures, respectively. Note that the half-metallic gap, which is defined as the smaller distance from VBM and CBM to the Fermi level, is smaller when F and Cl are doped at O site (0.16 eV) than at S site (0.36 and 0.38 eV). These results may suggest also the O_F and O_{Cl} systems as prospective sources of the spin-polarized electrons for spintronic applications. Similar to previous cases, the F-p and Cl-p states present small contribution to the band structure formation (see Fig. S6†). However, the host Mo-d, S-p, and O-p orbitals keep their dominant role with quite large contributions in both

Fig. 7 Spin density (blue surface: spin-up; yellow surface: spin-down) of (a) S_F and (b) S_{Cl} (iso-surface of value 0.05) systems.

Fig. 8 Spin-polarized band structure (black line: spin-up; red line: spin-down) of (a) O_V , (b) O_F , and (c) O_{Cl} systems.

valence band and conduction band. The population analysis indicates that there is a significant charge transfer from Mo atom to the non-metal atoms, the trend is as follows: O ($-0.58 \div -0.59e$) \rightarrow F ($-0.45e$) \rightarrow Cl ($-0.12e$) \rightarrow S ($-0.03 \div -0.05e$).

The illustration of the spin density given in Fig. 9 suggests that the magnetic properties of the doped systems are produced mainly by the Mo atoms. In the case of F doping, it can be noted an antiferromagnetic coupling since the magnetization of the first and second Mo atom from dopant site is because of a larger charge density in the spin-up channel and spin-down channel, respectively. On the contrary, the spin-up channel is the main contributor to the magnetism of the O_{Cl} system, indicating a parallel alignment, that is ferromagnetic coupling. The obtained magnetic moments are listed in Table 2. A value as large as of $0.42 (\mu_B)$ is obtained for the second Mo atom in the O_F structure, while two remaining Mo atoms exhibit quite smaller values. According to our calculations, Cl doping induces a weaker magnetization considering that the largest magnetic moment is $0.17 (\mu_B)$, which is 59.52% smaller than that in the O_F system. Also, making a reasonable comparison it can be concluded that the doping at S site may more efficient to magnetize the MoSO Janus monolayer, yielding magnetic systems with considerably larger magnetic moments than doping at the O site.

E. Formation and cohesive energy

Experimentally, the electron beam can create vacancies in the 2D TMDs, and the materials can be doped with a subsequent embedding impurity atoms in the vacancy sites.⁴⁹ Keeping this

two-step process in mind, we have calculated the formation energy E_f of defects using following formula:

$$E_f = \frac{E_t - E(\text{MoSO}) + \mu(X) - \mu(D)}{A} \quad (2)$$

where the total energy of defective systems is denoted by E_t ; $E(\text{MoSO})$ is total energy of the pristine MoSO single layer; μ refers to the chemical potential of X (Mo, S, and O) and D (Al, Ga, F, and Cl) atoms; and A is area of the supercell. Results are given in Tables 1, 3, and 4. The calculated E_f of Mo_V , S_V , and O_V systems is 74, 31, and 45.80 (meV \AA^{-2}), respectively. These results indicate that the formation of S single vacancy is energetically more favorable than Mo and O single vacancies, similar feature has been observed in MoS_2 single layer.⁵⁰ Doping the MoSO monolayer with Al (at Mo site) and F (at S site) impurities may be exothermic processes since their formation energy takes negative values of -4.40 and -10.60 (meV \AA^{-2}), respectively. Moreover, the incorporation of halogen atoms into S site may requires smaller energy than into O site.

Finally, to examine the structural stability of the considered defective and doped systems we calculate their cohesive energy E_c using following formula:

$$E_c = \frac{E_t - \sum_i n_i E(i)}{\sum_i n_i} \quad (3)$$

Herein, E_t denotes the system total energy; n_i is the number of atom i -th in the cell; and $E(i)$ refers to the energy of an isolated i atom. Results are listed in Tables 1, 3, and 4. It can be concluded that all systems are structurally stable since their

Fig. 9 Spin density (blue surface: spin-up; yellow surface: spin-down) of (a) O_F and (b) O_{Cl} (iso-surface of value 0.02) systems.

Table 4 Bond length d (\AA), buckling height Δ (\AA), interatomic angle \angle ($^\circ$), formation energy E_f (meV \AA^{-2}) and cohesive energy E_c (eV per atom) of the MoSO monolayer with defect at O-site (D = O in O_V system; D = F in O_F system; D = Cl in O_{Cl} system)

	$d_{\text{Mo-S}}$	$d_{\text{Mo-D}}$	$\Delta_{\text{Mo-S}}$	$\Delta_{\text{Mo-D}}$	$\angle \text{SMoD}$	E_f	E_c
O_V	2.40	2.10	1.66	1.19	78.10	45.80	-3.98
O_F	2.38	2.34	1.60	1.53	83.00	5.66	-4.01
O_{Cl}	2.39	2.57	1.60	1.86	88.27	24.29	-3.96

cohesive energies exhibit negative features. Considering the Mo site, the structure with a vacancy may be more stable than the those doped as suggested by its more negative E_c value. A similar trend is noted when the S site is considered for studies. In contrast, negligible differences in cohesive energies are obtained for the O_V , O_F , and O_{Cl} systems, implying similar structural stability of these systems.

IV. Conclusions

In conclusion, the structural, electronic, and magnetic properties of the pristine and defected MoSO Janus monolayer have been systematically investigated using first-principles calculations. The MoSO single layer exhibits good dynamical and thermal stability. This is an indirect gap semiconductor, whose band structure is originated mainly from the interactions of Mo-4d, S-3p, and O-2p states. Its energy gap exhibits a strong strain-dependence reducing values with lattice tension and increasing values with lattice compression. Feature-rich electronic and magnetic properties can be obtained by either creating vacancy or doping. Specifically, the Mo_V - Mo_{Al} - Mo_{Ga} and S_F - S_{Cl} - O_F - O_{Cl} structures are magnetic semiconductor and half-metallic 2D materials, respectively. Consequently, they exhibit significant magnetic properties, which are produced mainly by the spin-asymmetric Mo-4d orbital. These features make them promising 2D materials to create spin current for spintronic applications. While the non-magnetic semiconductor nature is obtained when creating a single S and O vacancy, the direct gap behavior and energy gap reduction suggest their prospect of optoelectronic applications. Our studies have introduced MoSO Janus monolayer to the family of Janus 2D materials, and pave a solid way to form novel multifunctional 2D materials for optoelectronic and spintronic applications. Therefore, results obtained herein may be used as a theoretical guidance for further experimental and theoretical investigations on Janus monolayers.
