Consistent inclusion of continuum solvation in energy decomposition analysis: theory and application to molecular CO₂ reduction catalysts

Yuezhi Mao, Matthias Loipersberger, Kareesa J. Kron, Jeffrey S. Derrick, Christopher J. Chang, Shaarma Mallikarjun Sharada and Martin Head-Gordon

To facilitate computational investigation of intermolecular interactions in the solution phase, we report the development of ALMO-EDA(solv), a scheme that allows the application of continuum solvent models within the framework of energy decomposition analysis (EDA) based on absolutely localized molecular orbitals (ALMOs). In this scheme, all the quantum mechanical states involved in the variational EDA procedure are computed with the presence of solvent environment so that solvation effects are incorporated in the evaluation of all its energy components. After validation on several model complexes, we employ ALMO-EDA(solv) to investigate substituent effects on two classes of complexes that are related to molecular CO₂ reduction catalysis. For [FeTPP(CO₂–κ²C)]²⁻ (TPP = tetraphenylporphyrin), we reveal that two ortho substituents which yield most favorable CO₂ binding, −N(CH₃)₃⁺ (TMA) and −OH, stabilize the complex via through-structure and through-space mechanisms, respectively. The coulombic interaction between the positively charged TMA group and activated CO₂ is found to be largely attenuated by the polar solvent. Furthermore, we also provide computational support for the design strategy of utilizing bulky, flexible ligands to stabilize activated CO₂ via long-range Coulomb interactions, which creates biomimetic solvent-inaccessible "pockets" in that electrostatics is unscreened. For the reactant and product complexes associated with the electron transfer from the p-terphenyl radical anion to CO₂, we demonstrate that the double terminal substitution of p-terphenyl by electron-withdrawing groups considerably strengthens the binding in the product state while moderately weakens that in the reactant state, which are both dominated by the substituent tuning of the electrostatics component. These applications illustrate that this new extension of ALMO-EDA provides a valuable means to unravel the nature of intermolecular interactions and quantify their impacts on chemical reactivity in solution.

1 Introduction

Intermolecular interactions play an essential role in modern chemical research. Most chemical processes take place in solution, making it desirable to develop computational chemistry tools to model and analyze intermolecular interactions with solvent effects taken into account. The inclusion of solvent brings new challenges to the existing methods as solvation is able to modulate intermolecular interactions in a variety of ways. For interactions involving ionic species, the solvent helps stabilize the charged moieties while screening the long-range electrostatic interactions as a dielectric medium. Even for a neutral solute species, its electronic structure and related properties, such as multipole moments, may be altered by polar solvents, which in turn affects its interaction with other solute molecules. Such effects can impose profound influences on relative stability of intermolecular complexes as well as thermodynamics and kinetics of chemical reactions in solution.¹ ² ³

Implicit solvent models, which typically treat the solvent environment as a dielectric continuum and ignore its molecular-level resolution, remain widely used in modern quantum chemistry calculations to incorporate solvation effects.¹ ² ³ ⁴ ⁵ These methods are also known as self-consistent...
reaction field (SCRF) models, since the implicit solvent perturbs the quantum mechanical (QM) Hamiltonian via an external field, and the field itself depends on the QM electron density. Many variants of SCRF models that differ significantly in their formulation and complexity have been developed, including methods based on apparent surface charges (ASC),\textsuperscript{6–11} generalized Born models,\textsuperscript{12–19} and models based on direct solution of inhomogeneous Poisson–Boltzmann equations.\textsuperscript{20–24} The popular conductor-like (C-PCM)\textsuperscript{11,12} and integral-equation–formalism (IEF-PCM)\textsuperscript{11,12} polarizable continuum models are outstanding examples among the ASC models.

Energy decomposition analysis (EDA)\textsuperscript{25–29} is a powerful tool that facilitates one's understanding of intermolecular interactions by quantifying the relative importance of various physically motivated components, such as permanent electrostatics, polarization, dispersion, etc. While there are many perturbative or variational EDA schemes available, these developments have been focusing on intermolecular interactions in vacuum. To extend the utility of EDA approaches to intermolecular interactions under solvent environment, it is natural to integrate existing EDA schemes with implicit solvent models, considering the wide usage of the latter for describing solute–solvent interactions with minimal computational cost. The simplest approach to achieve that is to include the solvent contribution to interaction energy as an \textit{a posteriori} correction to the gas-phase EDA result. This approach was adopted, for instance, in the EDA scheme implemented in the ONETEP\textsuperscript{30} linear-scaling density functional theory (DFT) program.\textsuperscript{31,32} While such an approach is applicable to most EDA schemes, it is not entirely satisfactory as it is unable to describe the solvation effect on each individual energy component.

In a pioneering effort to consistently incorporate solvent effect in an EDA procedure, Cammi et al.\textsuperscript{33} modified the Kitaura–Morokuma (KM)-EDA\textsuperscript{34,35} by adding the SCRF potential of the full dimer complex to the Fock matrix that was used to generate the energy components in this EDA scheme. Similar approaches were later proposed by Contador et al.\textsuperscript{36} to study hydrogen-bonded complexes in solution, where the KM-EDA was applied to decompose interaction energies evaluated within “dimeric” cavities, and also by Gora et al.\textsuperscript{37} where the intermolecular interaction (free) energy was separated into electrostatics, exchange-repulsion, delocalization, and reaction field (solvation) contributions. Fedorov and Kitaura extended their pair-interaction (PI)-EDA scheme\textsuperscript{38} to treat intermolecular interactions in solution by combining the fragment molecular orbital (FMO) method\textsuperscript{39} with PCM models,\textsuperscript{40} in which they characterized two types of solvent effects: (i) screening of electrostatics and (ii) desolvation upon the formation of complex.

The EDA-PCM scheme developed by Su et al.,\textsuperscript{41} which was based upon the localized molecular orbital (LMO)-EDA scheme,\textsuperscript{42} is more closely related to the present work. It accounts for the solvation environment in two stages: (i) the isolated fragment orbitals (LMOs) are optimized with continuum solvent, and are then used to construct the intermediate states that are required for the evaluation of the electrostatics, exchange, repulsion, and polarization terms; (ii) a “desolvation” term, which describes the change in solute–solvent interaction energies associated with the destruction of monomer SCRFs and the formation of the full complex SCRF, is introduced in addition to the original LMO-EDA scheme. In the more recent generalized Kohn–Sham (GKS)-EDA,\textsuperscript{43,44} this same approach is used to incorporate the solvent contribution to the interaction free energy. While this is a rather sophisticated approach that integrates implicit solvation with a modern DFT-based EDA, the solvent reaction field is constructed only for the initial (isolated fragment) and final (full complex) states. Since it is not re-optimized for the intermediates, the solvent effect on each individual term is still not explicitly characterized.

In this paper, we integrate SCRF implicit solvent models with energy decomposition analysis of DFT calculations based on absolutely localized molecular orbitals (ALMO-EDA), whose gas-phase version was previously developed by some of us.\textsuperscript{45–47} For brevity, we denote this new extension of the ALMO-EDA for studying non-covalent interactions in solution as “ALMO-EDA(solv)” throughout this paper. The second-generation ALMO-EDA method\textsuperscript{48,49} partitions the total interaction energy ($\Delta E_{\text{INT}}$) into contributions from permanent electrostatics (ELEC), Pauli repulsion (PAULI), dispersion (DISP), polarization (POL), and charge transfer (CT):

$$
\Delta E_{\text{INT}} = \Delta E_{\text{ELEC}} + \Delta E_{\text{PAULI}} + \Delta E_{\text{DISP}} + \Delta E_{\text{POL}} + \Delta E_{\text{CT}}
$$

where the first three terms constitute the frozen interaction energy ($\Delta E_{\text{FRI}}$). This decomposition relies on the definition of two intermediate states: (i) the frozen (FRZ) state, which is constructed as an antisymmetrized product of isolated fragment wavefunctions, and (ii) the polarized (POL) state, which is obtained from variationally relaxing the frozen wavefunction with respect to orbital rotations that are “absolutely localized” on each fragment.\textsuperscript{49,50} Differing from the scheme previously developed by Phipps et al.,\textsuperscript{51} our new approach incorporates continuum solvent effects at all stages of the EDA procedure, namely, the isolated fragment states and FRZ, POL, and fully relaxed supersystem states. We validate and rationalize the results given by ALMO-EDA(solv) on the Na$^+\cdot\cdot\cdot$Cl$^-$ model as well as the potential energy curves of two ion–water ($\text{H}_2\text{O}\cdot\cdot\cdot\text{Na}^+$ and $\text{H}_2\text{O}\cdot\cdot\cdot\text{Cl}^-$) complexes, in which the solvation environments are treated with C-PCM (with no empirical non-electrostatic terms)\textsuperscript{52} and the popular SMD model,\textsuperscript{53} respectively.

We then utilize the ALMO-EDA(solv) scheme to investigate the role of intermolecular interactions in two distinct examples of catalyzed $\text{CO}_2$ reduction reactions: one is assisted by the [Fe(nTTPP)]$^0$ catalyst (TPP = tetraphenylporphyrin) or its derivatives,\textsuperscript{54} which facilitates the 2e$^-2\text{H}^+$ reduction of $\text{CO}_2$ to CO with fast turnover rates and high product selectivity at a low overpotential\textsuperscript{55} by acting as an “electron mediator” between the electrode and $\text{CO}_2$ in solution and stabilizing intermediates such as adducts of activated $\text{CO}_2$; the other involves a single-electron transfer from a photoactivated and then reduced oligo(p-phenylenes) photocatalyst (OPP) to $\text{CO}_2$.\textsuperscript{56} The catalysts investigated in this work for these two $\text{CO}_2$ reduction processes are summarized in Fig. 1 and 2, respectively. Electronic structure calculations and EDA can help provide vital insights into catalytic pathways by identifying key intermediates and
characterizing substrate–catalyst interactions, allowing one to understand the origin of activity or selectivity as well as the cause of any intrinsic limitation of a catalyst. Many CO₂ reduction catalysts operate in aprotic polar solvents, aqueous solutions, or water/organic solvent mixtures. In such cases, it is essential to incorporate solvation effects in electronic structure calculations for one to obtain meaningful and reliable energetic results, especially for adducts of activated CO₂ (CO₂́) whose interactions with other species would be vastly different in the gas and solution phases.

2 Theory

The overall procedure of ALMO-EDA(solv) is illustrated in Fig. 3, which, like the gas-phase second-generation ALMO-EDA (eqn (1)), separates the total interaction into five terms:

\[
\Delta E_{\text{INT}}^{(s)} = \Delta E_{\text{ELEC}}^{(s)} + \Delta E_{\text{PAULI}}^{(s)} + \Delta E_{\text{DISP}}^{(s)} + \Delta E_{\text{POL}}^{(s)} + \Delta E_{\text{CT}}^{(s)} \tag{2}
\]

Here the superscript “(s)” indicates that the energetic terms are calculated with solvent taken into account. Unlike many other EDA schemes where the solvent contribution is treated as a correction to the EDA results in vacuum, our approach incorporates the solvation effect in all states (initial, intermediate, and final) involved in the EDA. The interaction energy to be decomposed is given by the difference between the energy of the solvated, fully relaxed complex (stage (iv) in Fig. 3) and the sum of energies of isolated fragments that are individually solvated (stage (i) in Fig. 3), which, as in the gas-phase ALMO-EDA, can be first partitioned into contributions from frozen interaction (FRZ), polarization (POL), and charge transfer (CT):

\[
\Delta E_{\text{INT}}^{(s)} = E_{\text{full}}^{(s)} - \sum A E_A^{(s)} \tag{3}
\]

\[
= \Delta E_{\text{FRZ}}^{(s)} + \Delta E_{\text{POL}}^{(s)} + \Delta E_{\text{CT}}^{(s)} \tag{4}
\]

The frozen interaction energy (\(\Delta E_{\text{FRZ}}^{(s)}\)) describes the energy change upon the formation of a solvated complex from several individually solvated, non-interacting fragments without relaxing their orbitals. It corresponds to the energy change from (i) to (ii) in Fig. 1:

\[
\Delta E_{\text{FRZ}}^{(s)} = E_{\text{FRZ}}^{(s)} - \sum A E_A^{(s)} \tag{5}
\]
To quantify the effect of the solvent on the interaction, we introduce a new term, $\Delta E_{\text{SOL}}$, to describe the gain or loss of solute–solvent interaction energy upon the formation of the frozen complex:

$$\Delta E_{\text{SOL}} = \left(E_{\text{FRZ}}^{(0)} - E_{\text{FRZ}}^{(s)}\right) - \sum_A \left(E_A^{(s)} - E_A^{(0)}\right)$$  

(6)

where the superscript “(0)” denotes internal electronic energies of the solute (i.e. excluding solute–solvent interaction, but orbitals optimized with solvent). Subtracting $\Delta E_{\text{SOL}}$ from $\Delta E_{\text{FRZ}}$ thus recovers $\Delta E_{\text{FRZ}}^{(s)}$, which can be further decomposed into permanent electrostatics (ELEC), Pauli repulsion (PAULI), and dispersion (DISP) contributions as in vacuum:  

$$\Delta E_{\text{FRZ}}^{(s)} = \Delta E_{\text{FRZ}}^{(c)} - \Delta E_{\text{SOL}}$$

$$= E_{\text{FRZ}}^{(0)} - \sum_A E_A^{(0)}$$

(7)

$$= \Delta E_{\text{ELEC}}^{(0)} + \Delta E_{\text{PAULI}}^{(0)} + \Delta E_{\text{DISP}}^{(0)}$$

The overall decomposition of the frozen interaction energy, including solvation, is thus given by

$$\Delta E_{\text{FRZ}}^{(0)} = \Delta E_{\text{SOL}} + \Delta E_{\text{ELEC}}^{(0)} + \Delta E_{\text{PAULI}}^{(0)} + \Delta E_{\text{DISP}}^{(0)}$$  

(8)

In this, the decomposition of the internal frozen interaction energy ($\Delta E_{\text{FRZ}}^{(c)}$) is based on the “quasiclassical” scheme exclusively,\(^{48,49}\) where the electrostatic component, $\Delta E_{\text{ELEC}}^{(0)}$, is defined as the Coulomb interaction between total charge distributions of isolated fragments.

For most generic implicit solvent models, the solute–solvent interaction comprises both electrostatic and non-electrostatic components. While the description of the electrostatic component plays a pivotal role in the formulation of a solvent model, the non-electrostatic solute–solvent interaction is typically described by empirical, highly parameterized functions (e.g. the cavity-dispersion-solvent structure (CDS) term in the SMD model\(^{51}\)) and sometimes even ignored. Upon the formation of a complex, the solute–solvent electrostatic interaction may be drastically changed due to the Coulomb interaction between induced charges on different fragment cavities as well as modifications to the shape of molecular cavities. The overall effect of the change in solute–solvent electrostatic interaction, as we observe in practice, is often screening the electrostatic interaction between each fragment’s “internal” charge distribution ($\Delta E_{\text{ELEC}}^{(0)}$). The change in the non-electrostatic component of the solute–solvent interaction energy is usually of lesser importance compared to the electrostatic component, and in most cases it supplies a destabilizing effect due to the reduction of total surface area of molecular cavities upon the formation of a complex. Bearing these considerations in mind, we separate $\Delta E_{\text{SOL}}$ into electrostatic ($\Delta E_{\text{ELEC}}^{\text{(SOL)}}$) and non-electrostatic ($\Delta E_{\text{non-elec}}^{\text{(SOL)}}$) components: the former is combined with $\Delta E_{\text{ELEC}}^{(0)}$, giving rise to a solvent-corrected electrostatic term that is denoted as $\Delta E_{\text{ELEC}}^{(s)}$, and the latter is combined with $\Delta E_{\text{PAULI}}^{(0)}$ because of their common short-ranged nature. The decomposition of the frozen term in ALMO-EDA(solv) (eqn [8]) can thus be rewritten as

$$\Delta E_{\text{FRZ}}^{(0)} = \left(\Delta E_{\text{ELEC}}^{(s)} + \Delta E_{\text{ELEC}}^{(0)}\right) + \left(\Delta E_{\text{PAULI}}^{(0)} + \Delta E_{\text{ELEC}}^{\text{(SOL)}}\right) + \Delta E_{\text{DISP}}^{(0)}$$

(9)

One should note that in eqn (9) we have assumed that $\Delta E_{\text{DISP}}^{(0)} \approx \Delta E_{\text{DISP}}^{(s)}$, that is, the dispersion interaction between fragments is unaffected by the presence of solvent except that the fragment wavefunctions are optimized with solvent. This assumption is plausible when the two interacting moieties are in close contact, especially when they reside in the same molecular cavity, but may become less justified when the two moieties are well-separated and reside in two non-overlapping cavities, since dispersion interaction, which can be viewed as interactions between fluctuating dipoles, may also be screened by the dielectric medium.\(^{64}\) This many-body dispersion effect\(^{65}\) seems non-trivial to include in a continuum solvent model, so we stick with this assumption for now and decompose the frozen interaction energy based on eqn (9) in the rest of this paper.

The polarization energy ($\Delta E_{\text{POL}}^{(s)}$) in ALMO-EDA(solv) is defined as the energy difference between the polarized intermediate state and the solvated frozen complex, which corresponds to the energy change from stage (ii) to (iii) in Fig. 3:

$$\Delta E_{\text{POL}}^{(s)} = E_{\text{POL}}^{(s)} - E_{\text{FRZ}}^{(0)}$$

(10)

It describes the energetic stabilization associated with the intramolecular relaxation of each fragment in the presence of other fragments as well as the solvent environment. In DFT-based ALMO-EDA, the POL state is obtained by variationally minimizing the supersystem energy subject to the constraint that the polarized molecular orbitals (MOs) of each fragment are expanded in fragment-specific basis functions (either atomic orbitals (AO) or frozen occupied MOs plus fragment electrical response functions\(^{50}\)), which is known as the “self-consistent field for molecular interaction” (SCF-MI) approach.\(^{49,50,56}\) In each iteration of the SCF-MI calculation, the solvent reaction field will be re-equilibrated in accord with the updated electron density of the complex, ensuring that the response of the solvent to the change in solute electronic structure is incorporated in a self-consistent manner.

Finally, we perform a standard, unconstrained SCF calculation within the solvent environment, and the energy lowering relative to the POL state (from (iii) to (iv) in Fig. 3) is defined as the charge-transfer (CT) energy:

$$\Delta E_{\text{CT}}^{(s)} = E_{\text{FULL}}^{(s)} - E_{\text{POL}}^{(s)}$$

(11)

Note that the charge transfer process might be associated with charge redistribution in the complex, which in turn induces responses in the reaction field. Such an effect is captured by the self-consistent minimization of $E_{\text{FULL}}^{(s)}$ in the presence of solvent.

In summary, the energy decomposition given by the ALMO-EDA(solv) scheme is formally identical to its gas-phase counterpart. The explicit change in solute–solvent interaction energy upon the formation of complex is reflected in $\Delta E_{\text{SOL}}$, which can
be further partitioned into electrostatic and non-electrostatic components that serve as corrections to the internal ELEC and PAULI terms, respectively. The POL and CT contributions to the interaction are calculated with all involved intermediate states properly solvated, and hence the solvent effect on these terms will also be taken into account.

3 Computational details

We implemented the ALMO-EDA(solv) scheme in a locally modified Q-Chem 5.2 software package, which serves as an extension of the original routines for the second-generation ALMO-EDA for DFT calculations. While this scheme, in principle, should be compatible with most of the available SCRF models, in this work we demonstrate it with two widely used approaches: the conductor-like PCM (C-PCM) and the SMD model. The non-electrostatic effects of the solvent were ignored in our calculations using C-PCM, whereas the solvation free energy ($\Delta G_S$) produced by SMD comprises both electrostatic and non-electrostatic contributions, which correspond to the "electronic-nuclear-polarization" (ENP) and the "cavity-dispersion-solvent structure" (CDS) terms, respectively:

$$\Delta G_S = \Delta G_{\text{ENP}} + \Delta G_{\text{CDS}}$$

In the Q-Chem implementation of the SMD model, IEF-PCM is employed to describe the solute–solvent electrostatic interaction.

Both C-PCM and IEF-PCM require solving for discretized point charges on the surface of a molecular cavity. In our calculations using C-PCM, the molecular cavities were constructed using the union of a series of atom-centered spheres whose radii are determined using each atom's van der Waals radius from the Universal Force Field scaled by a factor of 1.2. The boundary between solute and solvent constructed thereof is known as the solvent accessible surface (SAS). The calculations using SMD construct the molecular cavities in a similar manner but use its own set of atomic radii. To ensure the smoothness of potential energy surfaces (PESs) associated with molecular complexes, the switching/Gaussian method developed by Lange and Herbert was employed in both C-PCM and SMD calculations, in which the atomic spheres are discretized using Lebedev grids rather than more traditional tessellation schemes (e.g. the GEPOL algorithm). In this work, 302 Lebedev points were used for all atoms in our calculations using C-PCM or SMD.

Unless otherwise specified, the second-generation ALMO-EDA calculations are performed with the $\omega$B97X-V functional, which was shown to be one of the best-performing functionals for non-covalent interactions via extensive benchmarks and gave excellent results in our previous studies involving systems such as ion–water complexes. The DFT calculations employ a (99, 590) grid (99 radial shells with 590 Lebedev points on each) for the integration of the exchange–correlation (XC) functional and the SG-1 grid for the VV10 non-local correlation functional in $\omega$B97X-V. The decomposition of the frozen interaction energy in ALMO-EDA calculations follows the "quasiclassical" scheme exclusively in this work, as we have noted in Section 2. For the separation between POL and CT, the more sophisticated fragment electrical response function (FERF) method featuring a well-defined basis set limit was used for the small model systems (Sections 4.1 and 4.2), while the original ALMO scheme based on partition of the AO's was used for the applications in Sections 4.3 and 4.4 with more moderate basis sets (def2-TZVPP and def2-TZVPPD) given the substantial sizes of these systems.

4 Results

4.1 The sodium-chloride model complex

To validate the treatment of solvent effects in ALMO-EDA(solv), we first investigate a $\text{Na}^+\cdots\text{Cl}^-$ model complex where the two ions are separated by 20 Å and immersed in solvent with varying dielectric constant described by C-PCM. At the asymptotic limit, the strength of the electrostatic interaction between Na' and Cl' in a dielectric medium is $1/\varepsilon$ of that in vacuum according to Coulomb's law, where $\varepsilon$ is the (relative) dielectric constant of the medium. This relation is reproduced by ALMO-EDA as demonstrated in Table 1. The $\Delta E^{(s)}_{\text{ELEC}}$ term reflects the strength of the Coulomb interaction in vacuum, while $\Delta E^{(s)}_{\text{SOl}}$ is the correction from solute–solvent electrostatic interaction, which is an unfavorable term as its net effect is to damp the attractive Coulomb interaction between Na' and Cl'. The sum of these two terms obtained in EDA calculations gives the effective (screened) electrostatic interaction in solution, $\Delta E^{(0)}_{\text{ELEC}}$, whose relative strength against $\Delta E^{(0)}_{\text{ELEC}}$ shows excellent agreement with the dielectric constants ($\varepsilon$) specified as an initial parameter in these calculations. This agreement can also be reproduced with the widely used IEF-PCM approach (see Table S1 in the ES†), confirming that the treatment of solvent-screened permanent electrostatics in our EDA shows correct asymptotic behavior.

The distance dependence of the three electrostatics-related terms in Table 1 is shown in Fig. 4, where H2O($\varepsilon$ = 78.2) is described by C-PCM as employed as the implicit solvent. At long range, the attraction between Na' and Cl' is subjected to strong solvent screening, which renders the effective electrostatic interaction in solution minimal (e.g. at 5 Å $\Delta E^{(s)}_{\text{ELEC}}$ is only $-4.3 \text{ kJ mol}^{-1}$). Furthermore, the $\Delta E^{(0)}_{\text{ELEC}}/\Delta E^{(0)}_{\text{ELEC}}$ ratio stays constant, as expected.

Table 1: Energetic contributions (in kJ mol$^{-1}$) from internal QM electrostatics ($\Delta E^{(0)}_{\text{ELEC}}$) and solute–solvent electrostatic interaction ($\Delta E_{\text{SOl}}^{(s)}$) to the interaction between Na' and Cl' which are separated by 20 Å from each other. The calculations are performed using $\omega$B97X-V/def2-TZVP and C-PCM with varying dielectric constants. $\Delta E^{(0)}_{\text{ELEC}} = \Delta E_{\text{ELEC}}^{(0)} + \Delta E_{\text{SOl}}^{(s)}$ is the effective (screened) electrostatic interaction in solution.
close to the asymptotic limit (78.2) in this range, albeit with more pronounced deviation when moving closer. In contrast, at shorter distances (< 5 Å) this ratio decreases rapidly indicating less effective screening of the attractive electrostatics. At the minimum-energy distance (2.5 Å), \( \Delta E_{\text{ELEC}}^{(0)} \) gains appreciable magnitude (–140 kJ mol\(^{-1}\)) and the value of \( \Delta E_{\text{ELEC}}^{(0)}/\Delta E_{\text{ELEC}} \) lowers to 4.1. Further examining the distance dependence of \( \Delta E_{\text{SOL}} \) reveals an inflection point at 3.35 Å, i.e., the curve starts to flatten when moving to shorter distances.

The sharp contrast between the short- and long-range behavior of these terms can be rationalized schematically with Fig. 5. In the long-range limit (upper panel), the cavities for Na\(^+\) and Cl\(^-\) are well-separated and the surface charges are mainly induced by their respective nuclei and electrons, yielding strong solvent screening of the long-range electrostatics. With the decrease in inter-fragment distance, even before the cavities start to overlap, the surface charges on each cavity will be influenced by both solutes (Na\(^+\) and Cl\(^-\)) simultaneously, which then largely cancel each other in the interfragment region (see mid-panel of Fig. 5). This would result in weakened screening and potentially explains the modest increase in the deviation from the long-range limit for \( \Delta E_{\text{ELEC}}^{(0)}/\Delta E_{\text{ELEC}} \). Finally, when the two cavities start to overlap and merge with each other (for this system it occurs at 4.8 Å with our computational setup for PCM), as shown in the lower panel of Fig. 5, the dielectric solvent between the two fragments is “squeezed out” and the screening becomes even more incomplete. In addition, the inter-penetration of QM electron densities in the overlapping regime enhances the internal electrostatic attraction between Na\(^+\) and Cl\(^-\), which further contributes to the decrease in the value of \( \Delta E_{\text{ELEC}}^{(0)}/\Delta E_{\text{ELEC}} \) since this short-ranged effect is subject to almost no solvent screening. These effects, all together, result in only partial screening of the attractive internal electrostatics as well as the inflection point in the magnitude of \( \Delta E_{\text{SOL}} \) at short Na\(^+\)…Cl\(^-\) distances.

4.2 Potential energy curves for ion–water interactions
As a further validation of ALMO-EDA(solv), we employ it to investigate the distance dependence of ion–water interactions (H\(_2\)O…Na\(^+\) and H\(_2\)O…Cl\(^-\)) in three different solvents: toluene (\( \varepsilon = 2.37 \)), acetonitrile (\( \varepsilon = 37.5 \)), and water (\( \varepsilon = 78.3 \)). The gas-phase ALMO-EDA results for these systems are available in ref. 62. The long-range electrostatics in these systems can be depicted as charge–dipole interactions (\( R^{-2} \)), and in the short range polarization also contributes significantly to binding (especially in the H\(_2\)O…Na\(^+\) case). These strong interactions, however, will be diminished in solution due to solvent screening.

Fig. 6 shows the aB97X-V/def2-TZVPFP total interaction energy and its components for the H\(_2\)O…Na\(^+\) complex vs. \( r_{\text{O}..\text{Na}} \) in the range of 1.8–3.6 Å. Permanent electrostatics makes the largest contribution to binding at this full range despite solvent screening. Comparing the results for different solvents, one remarkable feature is that the internal electrostatic interaction, ELEC(0), becomes more favorable with the increase in solvent dielectric constant (from left to right in Fig. 6). This is because the dipole moment of an isolated H\(_2\)O molecule increases when placed in a more polar solvent environment. Nonetheless, since more polar solvent also screens more strongly, the total electrostatic interaction (ELEC) shows similar strength in both solvents around equilibrium (~2.2 Å). The strength of long-range electrostatics and the total interaction energy, on the
better reproduce experimental solvation free energies.

solvent electrostatic term attains a maximum when the O–Na+ distance is further shortened. This maximum in the solvent electrostatic contribution was also revealed by Su et al. with their LMO-EDA-PCM scheme for the water dimer.\textsuperscript{41} We attribute this behavior to the merging of fragment cavities upon the formation of complex, which leads to diminished screening of the internal electrostatic interaction (vide supra).

Another energy component that is strongly impacted by solvent effects is polarization (POL). According to ref. 62, the gas-phase polarization energy for H$_2$O···Na$^+$ at 2.2 Å is around −25 kJ mol$^{-1}$, while this value reduces to around −9 kJ mol$^{-1}$ in SMD water. Similar to long-range electrostatics, POL becomes less diminished when the solvent is less polar. The other three energy components, PAULI, DISP, and CT show much smaller variance with the change of solvent. They are apparently less affected by the solvent properties, at least within the present ALMO-EDA(solv) model.

Within the SMD model, the solvent contribution to binding can be further partitioned into electrostatic and non-electrostatic contributions. The distance dependence of these two terms as well as that of the overall $\Delta E_{SOL}$ is shown in Fig. S1 in the ESL\textsuperscript{†}. The non-electrostatic (CDS) term has minimal significance compared to the electrostatic contribution and vanishes in the long range when the cavities of two fragments are fully separated. It is noteworthy that the non-electronic contribution to binding does not have a definite sign: among the three solvents here, $\Delta E_{SOL}^{\text{non-el}}$ is exclusively positive for toluene while negative for acetonitrile and water. This is presumably a consequence of the CDS term in SMD aiming to account in aggregate for non-electrostatic solvation effects to better reproduce experimental solvation free energies.

The solvent electrostatic contribution (\(\Delta E_{SOL}^{\text{el}}\)), on the other hand, is repulsive over the full range (1.8–8.0 Å) for all three solvents. As in the Na$^+$···Cl$^-$ case (Fig. 4(a)), this contribution first increases rapidly with the shortening of intermolecular distance, which damps the increasingly attractive internal electrostatic interaction. $\Delta E_{SOL}^{\text{el}}$ is more repulsive in solvents with larger dielectric constants, indicating their stronger screening capability. Moving into the overlapping regime, the solvent electrostatic term flattens first and then reaches a maximum when the O···Na$^+$ distance is slightly below 3 Å, i.e., the magnitude of $\Delta E_{SOL}^{\text{el}}$ starts to decrease when the intermolecular distance is further shortened. This maximum in the solvent electrostatic contribution was also revealed by Su et al.

4.3 Substituent effects on the stability of [FeTPP(CO$_2$$^-$)] complexes: through-space vs. through-structure mechanisms

There is tremendous research interest in homogeneous electrochemical reduction of CO$_2$\textsuperscript{41–43} because CO$_2$ conversion to carbon-based fuels could underpin a future carbon-neutral economy. The initial step is activating CO$_2$, whose one-electron reduction potential is quite unfavorable (−1.90 V vs. NHE) by comparison with the reduction potential to convert CO$_2$ to more reduced products such as the 2e$^-$ reduction to CO (−0.53 V vs. NHE). The first function of a catalyst is thus to stabilize the activated CO$_2$ as it drives the first reduction, and thereby reduce the thermodynamic overpotential. Molecular catalysts are of great interest for this purpose, in addition to enhancing turnover rates, and suppressing competitive side reactions such as the hydrogen evolution reaction (HER). Among available transition metal based catalysts, iron complexes have received particular attention because of the earth abundance of Fe and their low toxicity. To date, several iron catalysts with different ligand frameworks have been
developed for the reduction of CO\textsubscript{2}.\textsuperscript{57,59,84–86} The most prominent family is [Fe(n)TPP]\textsuperscript{n} (TPP = tetraphenylporphyrin)\textsuperscript{87–88} and its derivatives.\textsuperscript{51,89–93} Mechanistic studies indicate that stabilizing the activated CO\textsubscript{2} adduct intermediate can substantially improve the performance of the catalyst.\textsuperscript{51,56,91} An “electronic scaling relationship” (so-called because it reflects electronic substituent effects) between overpotential and turnover frequency (TOF) was previously established by stepwise fluorination of the phenyl groups in the TPP ligand framework.\textsuperscript{90} The four derivatives FeTTPP, FeF\textsubscript{5}TTPP, FeF\textsubscript{10}TTPP and FeF\textsubscript{20}TTPP (full fluorination of zero, one, two, and four phenyl rings, respectively) show a linear correlation between a favorable decrease in overpotential and an unfavorable decrease in TOF. This effect stems from stronger inductive effects that accompany the addition of –F substituents, which was referred to as a “through-structure” electronic effect.\textsuperscript{90}

A subsequent experimental study\textsuperscript{51} further demonstrated that charged substituents can break electronic scaling relationships. Introducing a positively charged trimethylammonium (TMA, –NMe\textsubscript{3}+) group to either the ortho or para position of each phenyl group yields tetra-trimethylanilinium–porphyrin complexes (Fe-o-TMA or Fe-p-TMA). Unlike the fluorinated complexes, Fe-o-TMA exhibits high TOFs at low overpotentials. In contrast, introducing the negatively charged sulfonate (–SO\textsubscript{3}–) group to the para positions to yield Fe-p-SUL results in lower TOF at a higher overpotential relative to FeTTPP and Fe-o/p-TMA. Based on these results, the authors hypothesized that in these cases the strength of CO\textsubscript{2} binding is not only controlled by the through-structure inductive effect of the electron-withdrawing groups but more importantly modulated by the long-range (through-space) electrostatic interactions between these charged substituents and the negatively charged CO\textsubscript{2}– moiety. This suggested mechanism could explain why Fe-o-TMA catalyzes CO\textsubscript{2} reduction at such high TOFs.\textsuperscript{51} Further evidence for the importance of stabilizing the activated CO\textsubscript{2} adduct is provided by the ortho hydroxy substituted TPP complex, tetra-kis(2′,6′-dihydroxyphenyl)-porphyrin (CAT).\textsuperscript{89} This derivative is also a more active catalyst than unsubstituted FeTTPP, where the stabilization of activated CO\textsubscript{2} may also result from favorable (through-space) interactions between the hydroxyl groups and negatively charged CO\textsubscript{2}–.

Here we employed the ALMO-EDA(solv) approach to gain insights into the stabilization mechanisms of activated CO\textsubscript{2} in the [FeTPP(CO\textsubscript{2}–κC)]\textsuperscript{2–} adducts arising from the reaction of CO\textsubscript{2} with the doubly reduced FeTTPP ([FeTTPP]\textsuperscript{2–}, which is formally Fe(0)) complex (see Fig. 7 for a simplified reaction scheme). The solvent MeCN was described by C-PCM with the dielectric constant set to 35.88.\textsuperscript{88} The electronic ground state of the complex is a (broken-symmetry) triplet in an \(\eta^1\)-κC binding mode, whose spin density contours (Fig. 8) reveal a significant amount of excess spin in the ligand framework as well as on the CO\textsubscript{2} moiety indicating reduction of both the CO\textsubscript{2} and the noninnocent TPP ligand. These reduced moieties are both antiferromagnetically coupled to the metal center as previously discussed in ref. 58. Therefore, this complex can be best represented as [Fe(n)(TPP\textsuperscript{1–})(CO\textsubscript{2}–κC)]\textsuperscript{2–}. For brevity, in the following discussion we omit the “κC” notation that specifies the binding mode of CO\textsubscript{2} to the metal center.

We illustrate the effects of different substituents by comparing the EDA results of complexes with varying substitutions (–H, –NMe\textsubscript{3}+, –SO\textsubscript{3}–, –OH) on the phenyl rings. To reduce the computational expense, we truncated these systems by removing two of the four phenyl groups based on the fact that the CO\textsubscript{2} moiety is positioned in such a way that only two substituent groups can strongly interact with it (see Fig. 9). In total, we compare six different CO\textsubscript{2} adducts with varying net charges due to the distinction in substituents: (a) unsubstituted ([Fe(II)TPP(CO\textsubscript{2})]\textsuperscript{2–}), (b) para –NMe\textsubscript{3}+ substituted ([Fe-p-TMA(CO\textsubscript{2})]\textsuperscript{2–}), (c) ortho –NMe\textsubscript{3}+ substituted ([Fe-o-TMA(CO\textsubscript{2})]\textsuperscript{2–}), (d) para –SO\textsubscript{3}– substituted ([Fe-p-SUL(CO\textsubscript{2})]\textsuperscript{2–}), (e) ortho –OH substituted ([Fe-o-OH(CO\textsubscript{2})]\textsuperscript{2–}), and (f) perfluorinated ([FeF\textsubscript{10}TPP(CO\textsubscript{2})]\textsuperscript{2–}). The geometries of these complexes are shown in Fig. 9.

The results of the EDA calculations depend on the choice of reference states of both fragments, \(i.e.,\) the electronic states they

![Fig. 7 Simplified steps in the catalytic pathway of FeTTPP leading to the activated CO\textsubscript{2} intermediate.](Image)

![Fig. 8 Spin density of the doubly reduced CO\textsubscript{2} adduct [FeTTPP(CO\textsubscript{2}–κC)]\textsuperscript{2–} (green: excess α spin; gold: excess β spin).](Image)

![Fig. 9 Optimized geometries for the [FeTPP(CO\textsubscript{2}–κC)]\textsuperscript{2–} adduct with varying substitutions: (a) unsubstituted (–H); (b) para-trimethylammonio (–NMe\textsubscript{3}+); (c) ortho-trimethylammonio (–NMe\textsubscript{3}+); (d) para-sulfonate (–SO\textsubscript{3}–); (e) ortho-hydroxyl (–OH); (f) all-fluorinated (–F).](Image)
are in when they are infinitely separated. In this example two fragmentation schemes are plausible: (i) the “natural” fragmentation that corresponds to reactants in the catalytic cycle, where a neutral CO$_2$ ($S = 0$) molecule is bound to a doubly reduced iron complex ($S = 1$); (ii) fragmentation based on the charge population of the final product complex, giving a singly reduced metal complex ($S = 3/2$) and a singly reduced (activated) CO$_2$ radical anion (CO$_2$$^-$, $S = 1/2$). Our results show that the former fragmentation scheme is unsuitable here due to the drastic geometry distortion energy (>200 kJ mol$^{-1}$) that is associated with the bending of a neutral CO$_2$ molecule, which would lead to EDA results that are dominated by this geometry distortion term and are thus less insightful (see Table S2 in the ESI†). In contrast, the geometry distortion term associated with the CO$_2^-$ moiety in the latter fragmentation scheme is minimal (less than 1 kJ mol$^{-1}$). Therefore, we selected the second fragmentation scheme in the following discussion, which corresponds to the binding of CO$_2^-$ with singly reduced FeTPP and its substituted derivatives.

Our choice yields (up to) two charged fragments where the net charge on the FeTPP moiety depends on the substituents. A comparison across all these compounds without considering the solvent effect would lead to unreasonably large variations in total interaction energy due to the large variation in gas-phase electrostatic interaction (see Table S5†). Hence, we employ the new ALMO-EDA(solv) approach to better capture these interactions in solution. The EDA results for unsubstituted [FeTPP(CO$_2$)]$^{2-}$ are shown in Table S4 in the ESL†. This complex is subjected to strong Pauli repulsion (634 kJ mol$^{-1}$), which arises from the repulsion between the iron d-electrons and CO$_2^-$ whose excess spin density is mainly located on the carbon atom (see Fig. S4†). The strongly favorable electrostatic interaction (−363 kJ mol$^{-1}$) makes the largest contribution to binding, and is comprised of (i) a moderate gas-phase ELEC term ($\Delta E_{ELEC}^{gas} = −94$ kJ mol$^{-1}$) and (ii) a substantially favorable contribution from solute–solvent interaction ($\Delta E_{SOL} = −269$ kJ mol$^{-1}$). The former can be rationalized by the attractive short-range Coulomb interaction between the CO$_2^-$ moiety and the partially positive-charged iron center, and the latter reflects the solvent screening of the repulsive coulombic interaction between CO$_2^-$ and the reduced π system of the TPP ligand. Despite the appreciable electrostatic contribution, the net frozen interaction is still strongly repulsive (+205 kJ mol$^{-1}$), and thus both POL (−135 kJ mol$^{-1}$) and CT (−123 kJ mol$^{-1}$) are essential to the stabilization of CO$_2^-$. The electron density difference between the frozen and polarized states reveals that the occupation of iron’s d-orbitals changes due to interaction with CO$_2^-$. This is mainly to alleviate Pauli repulsion, $via$ depopulating the 3$d_z$ orbital (see Fig. 11(a)). The analysis of complementary occupied-virtual pairs (COVPs)$^5$ further demonstrates that the charge transfer in [FeTPP(CO$_2$)]$^{2-}$ is dominated by the donation from the odd-electron orbital of CO$_2^-$ into the vacant 3$d_z$ orbital of Fe, where CO$_2^-$ acts as a σ-donor as illustrated in Fig. 11(b).

To gauge the effect of the charged substituents (ortho- and para-TMA and para-sulfonate), we compare the total interaction energies and EDA components of these adducts against the

![Fig. 10](image-url) Differential ALMO-EDA(solv) results (in kJ mol$^{-1}$) relative to the unsubstituted [FeTPP(CO$_2$)]$^{2-}$ complex: (a) results for the charged substituent groups (–NMe$_2^+$, –SO$_3^-$, and the methylimidazolium-carrying group); (b) results for the substituent groups that retain the net charge of the unsubstituted complex (–OH, –F).

![Fig. 11](image-url) (a) Electron density difference between the FRZ and POL states (yellow: electron density increase, purple: electron density decrease); (b) the key COVPs illustrating the σ donation from the SOMO of CO$_2^-$ to Fe’s 3$d_z$ orbital (the donor and acceptor orbitals are plotted with solid and meshed isosurfaces, respectively).
TMA substitution relative to the unsubstituted adduct (by 67 kJ mol\(^{-1}\)) suggests a stronger inductive effect of the TMA group with respect to CO\(_2\). Indeed, the EDA results reveal that the TMA substitution yields a more favorable energy relative to the unsubstituted adduct. This reduction cannot be solely explained by the change in the Fe-C distance since its value is almost identical in [Fe-p-TMA-(CO\(_2\))]\(^0\) and [Fe-p-TMA-(CO\(_2\))]\(^p\). Surprisingly, the largest change among EDA components appears to be the reduction in Pauli repulsion (\(-183\) kJ mol\(^{-1}\)). This reduction cannot be solely explained by the change in the Fe-C distance since its value is almost identical in [Fe-p-SUL-(CO\(_2\))]\(^0\) and [Fe-p-TMA-(CO\(_2\))]\(^p\) (see Table S4†). We attribute it to the decrease in electron density at the iron center, which originates from the weakening of the coordination of the TPP ligand due to the strong electron-withdrawing inductive effect of the TMA group. The results are shown in Fig. 10(b). The o-OH substitution stabilizes the CO\(_2\) adduct by 64 kJ mol\(^{-1}\), and the EDA results reveal a significantly strengthened electrostatic interaction and moderately increased DISP, POL, and CT components relative to the unsubstituted TPP adduct. Collectively, these attractive terms outweigh the increase in Pauli repulsion. A pattern like this is typical of EDA results for hydrogen bonds,\(^{96,98,99}\) which in this case are formed between –OH groups at the ortho positions of phenyl and the oxygen atoms in CO\(_2\) (see Fig. 9(c)) thanks to the short distance between them (r(H⋯O) = 1.79 Å for H in o-OH and O in CO\(_2\)). When one moves the hydroxyl group to the para position (p-OH), no such hydrogen bonds can be formed and consequently there is no notable difference in any of the energy components relative to the unsubstituted adduct. This stark contrast between the results for the o-OH and p-OH substituted derivatives suggests that the –OH group at the ortho position stabilizes CO\(_2\) almost exclusively via a through-space mechanism (hydrogen bonding). We note that the stabilization of activated CO\(_2\) through hydrogen bonds can be further enhanced by precisely tuning the position of H-donor, which was achieved by Nichols et al. by introducing amide pendant at the ortho position of the meso phenyl groups.\(^{97}\) In contrast to [Fe-o-OH-(CO\(_2\))]\(^p\), the F10 derivative with only through-space electron-withdrawing inductive effect does not lead to enhanced stabilization of CO\(_2\) since the reduction in Pauli repulsion is far less pronounced than that in [Fe-p-TMA-(CO\(_2\))]\(^p\) or [Fe-o-TMA-(CO\(_2\))]\(^p\), which is then almost fully compensated by the diminished ELEC and CT contributions.

The EDA results for the TMA-substituted derivatives suggest that the strategy to stabilize activated CO\(_2\) through long-range electrostatic attraction may not be fully effective in solution due to solvent screening. However, making use of the steric effects of the substituents, one may be able to create a solvent-free “pocket” in which electrostatic interaction is almost unscreened. It was reported by Khadhraoui et al. that the introduction of four bulky, methylimidazolium-containing groups at the ortho positions of the phenyl groups in FeTPP elevates its electrocatalytic activity.\(^{89}\) Due to the substantial size of the substituent, we optimized the structure of the CO\(_2\) adduct of this FeTPP derivative with only one methylimidazolium-containing “arm” included (reducing the negative charge from \(-2\) to \(-1\)), which is denoted as [Fe-o-imid-(CO\(_2\))]\(^p\). The optimized structure of this adduct is depicted in Fig. 12(a). Differing from [Fe-o-TMA-(CO\(_2\))]\(^p\), the charged moiety (imidazolium ring) is far away from the central metal, excluding the possibility of any electron-withdrawing inductive effect from this positively charged substituent. A remarkable feature of the optimized structure is that this “long-arm” substituent folds over the
activated CO2 and thereby creating a small pocket that is inaccessible by solvent. The geometry also demonstrates that the activated CO2 is stabilized by both the hydrogen bonding from the amide group and the electrostatic attraction from the positively charged methylimidazolium moiety: the H...O distance in this hydrogen bond is 1.98 Å, and the distance between the mid-point of two N atoms in the imidazolium ring and the closest O atom in CO2 is 4.55 Å.

Our results show that [Fe-o-imid-(CO2)]− stabilizes CO2 more strongly by −49.2 kJ mol−1 relative to the unsubstituted FeTPP (see Table S4 in the ESI†), similar to the o-OH and o-TMA cases. However, it should be noted that here we only included one substituent group (“arm”) whereas the other derivatives are doubly substituted in our calculations. Therefore, once the two methylimidazolium-containing “arms” are both included, one can expect that this complex can stabilize activated CO2 more than the o-OH and o-TMA derivatives. The ALMO-EDA(solv) results (Table S4†) show that the dominant contributor to stabilization is electrostatic interaction (−85.9 kJ mol−1), which stems from both the N–H...O hydrogen bond and the positively charged methylimidazolium. The key difference from the p-TMA substituent is that this bulky ligand effectively “squeezes out” solvent from the space in between the activated CO2 and the positively charged moiety, rendering the attractive electrostatics nearly unscreened. Furthermore, as in the o-OH case, the strength of dispersion, polarization, and charge transfer is also enhanced by the introduction of this methylimidazolium-containing substituent, which, together with the gain in attractive electrostatics, contribute to this more stabilized CO2 adduct.

In order to further optimize this interaction motif, we removed the phenyl group in the methylimidazolium-containing “arm”, which moves the methylimidazolium moiety closer to the CO2 moiety. The optimized structure for this adduct (denoted as [Fe-o-imid2-(CO2)]p since the second substituent is added for a better comparison with the results of other derivatives) is shown in Fig. 12(b), in which the distance between the mid-point of two N atoms in the imidazolium ring and the closest O atom in CO2 reduces to 3.74 Å. The stabilization energy relative to the unsubstituted adduct is −143.5 kJ mol−1, which is significantly larger than that of the second most stabilized o-TMA and o-OH derivatives (see Fig. 10(a)). The relative stabilization arising from the electrostatic attraction is by far the strongest among the adducts that we investigated (−642.0 kJ mol−1), and we estimate that −140 kJ mol−1 out of that stems from the two hydrogen bonds (see the “NH-re” results in Table S4†) and the rest (about −500 kJ mol−1) from the imidazolium rings. These results indicate the importance of taking solvent effects into account if one wants to harness through-space Coulomb interaction in solution and pursue the promise of bulky, flexible substituents that can form a solvent-free “active” pocket mimicking that in enzymes to facilitate much stronger electrostatic interaction with CO2.

It is important to point out that we focused here on the concept of strengthening the binding of activated CO2 in adducts as that was presumed to accelerate catalysis. However, the substituents may also affect other intermediates in a catalytic cycle. This is illustrated by the ortho hydroxyl substituted TPP complex, CAT, where the hydroxyl group stabilizes the activated CO2 and also leads to a fast intramolecular protonation pathway.† Ultimately, detailed mechanistic studies are necessary to fully unravel the effect of each substituent on the catalytic activity.

4.4 Electron transfer from terphenyl− to CO2: Substituent effects on the intermolecular binding of reactant and product complexes

An alternative to transition metal based catalysts for CO2 reduction is organic (photo)redox catalysts, which can be more environment-friendly, economical, and are likewise highly tunable with substituents.† These catalysts access their electronic excited states through UV-Vis absorption and are subsequently quenched, yielding a reactive radical species that serves as the electron donor to CO2.† A prominent class of examples are oligo(p-phenylene) (OPPs), which, for instance, are able to catalyze hydrocarboxylation from CO2.51 The introduction of different substituents alters the absorption wavelength but also impacts the rate of electron transfer. Some of us recently investigated the substituent effects on the calculated rate of electron transfer (ET) reaction from an OPP radical anion to molecular CO2 using double terminal-substituted p-terphenyl as examples. We have shown that electron-donating groups (EDGs) facilitate this reaction in general by increasing the free energy driving force (ΔG in Marcus theory) since they elevate the LUMO level of OPP. Besides the reductive potential of OPP/OPP−, the difference in the association energies of the reactant (OPP−⋯CO2) and product (OPP⋯CO2−) complexes in solution, ΔEINT(R) − ΔEINT(P), also contributes to the free energy driving force (R and R denote optimized structures for the reactant and product states, respectively). Here we employ ALMO-EDA(solv) to investigate the substituent effects on the association energies of the reactant and product complexes in CH2Cl2 (ε = 8.93) described by the SMD model, which will allow us deeper insight into how these chemical modifications affect the reactivity of OPPs as photoredox catalysts.

The geometries of the reactant and product complexes are directly taken from our previous work,† which were optimized on their respective diabatic PESs constructed from constrained
DFT (CDFT)\textsuperscript{103,104} calculations at the B3LYP-D3(BJ)/6-311G(d,p)\textsuperscript{105-107} level of theory with C-PCM. As illustrative examples, in Fig. 13 we show the optimized structures of the reactant and product complexes between CO$_2$ (or CO$_2^-$) and p-terphenyl$^-$ (or neutral p-terphenyl) substituted with dimethylamino (\textsuperscript{\textit{NMe}}$_2$) and nitro (\textsuperscript{\textit{NO}}$_2$) groups. Compared to the reactant complexes where CO$_2$ is linear and mainly interacting with one of the terminal phenyl groups, in the product state the CO$_2$ moiety is bent and moves closer to the middle ring of p-terphenyl. By contrast with the adducts with FeTPP where CO$_2^-$ is ligated to Fe through the \textit{kC} mode (see Section 4.3), here in the product state the two oxygen atoms of CO$_2^-$ are in closer contact with the p-terphenyl moiety, an orientation that favours these dispersion-dominated anion-\pi interactions (\textit{vide infra}).

The substituent effect on the difference between interaction energies in the reactant and product states (\Delta\Delta\text{E}_\text{INT}) in CH$_2$Cl$_2$ solution is exhibited in the upper panel of Fig. 14 with three electron-donating (\textsuperscript{\textit{NMe}}$_2$, -OH, -CH$_3$) and three electron-withdrawing (\textsuperscript{\textit{Br}, -CF$_3$, -NO$_2$}) groups. The strength of the electronic effects of these substituent groups can be characterized using their Hammett parameters\textsuperscript{108} ($\sigma_p$): more negative (positive) $\sigma_p$ indicates stronger electron-donating (withdrawing) ability. It is shown that the difference in interaction energies decreases monotonically with increases in $\sigma_p$, \textit{i.e.}, strong electron-withdrawing groups (EWGs) such as -NO$_2$ facilitate the stabilization of the product complex relative to the reactant. Relative to the unsubstituted species, the differential product stabilization by the strongest EWG, -NO$_2$, is over 10 kJ mol$^{-1}$. ALMO-EDA(solv) reveals that this prominent substituent effect is dominated by electrostatics despite the presence of solvent (see Table S6 in ESI† for the full EDA results). As shown in the left panel of Fig. 14, \Delta\Delta\text{E}_{\text{ELEC}} reproduces the trend in \Delta\Delta\text{E}_\text{INT} with only one marginal exception (\textsuperscript{\textit{-CH$_3$}}).

To demonstrate the effect of solvent on the trend in \Delta\Delta\text{E}_\text{INT} versus $\sigma_p$, we also performed ALMO-EDA calculations for the same set of complexes in vacuum (see Table S7 in ESI† for the complete results). The results for the total interaction energy and the ELEC component are shown in the lower panel of Fig. 14. While the same trend in \Delta\Delta\text{E}_\text{INT} (monotonically decrease with increasing $\sigma_p$) is reproduced without solvent, the magnitude of \Delta\Delta\text{E}_\text{INT} with different substituent groups exhibits a much wider range, which, once again, mainly results from the larger variation in \Delta\Delta\text{E}_{\text{ELEC}} in vacuum. In contrast to the solution phase where the polarization component exhibits only minimal effects on \Delta\Delta\text{E}_\text{INT}, in the gas phase, POL stabilizes the product complex by $\sim$20 kJ mol$^{-1}$ relative to the reactant for these complexes. The contrast between the upper and lower panels of Fig. 14 demonstrates the attenuation of substituent effects on the differential interaction energies due to solvent screening.

In our previous study\textsuperscript{109} where the ALMO-EDA calculations were performed in vacuum at the B3LYP-D3(BJ)/6-311G(d,p) level of theory, we identified CT as another main contributor to the stabilization of the product complexes relative to the reactant ones and also to the trend in substituent effects. This contradicts the gas-phase ALMO-EDA results obtained here with ωB97X-V/def2-TZVPD, according to which CT only makes a minimal contribution to each complex’s \Delta\Delta\text{E}_\text{INT} (see the comparison between Tables S7 and S8 in the ESI†). We ascribe this discrepancy to the more substantial delocalization...
error\textsuperscript{109,110} associated with the B3LYP functional than that of oB97X-V, which, as shown in Table S10 in the ESI,\textsuperscript{†} has a more pronounced effect in the gas phase. We refer the reader to Section S3 in the ESI\textsuperscript{†} for a detailed discussion.

We then turn to the full ALMO-EDA(solv) results for the reactant and product complexes to gain further insights into the substituent effects on $\Delta E_{\text{INT}}$ revealed in Fig. 14. The reactant complexes (Fig. 15(a)) are mainly bound by electrostatic and dispersion interactions, which, taken together, overcome the Pauli repulsion between $p$-terphenyl$^-$ (or its substituted derivatives) and the neutral CO$_2$ moiety. Moderate substituent effects are exhibited among the reactant complexes, where the EDGs yield more attractive total interactions in general (e.g. the NMe$_2$-substituted complex is more favorable than NO$_2$-substituted by $\sim$3 kJ mol$^{-1}$). This trend, as revealed by the EDA results, mainly stems from the enhancement in electrostatic interaction with stronger electron-donating substituents. The same trend is also exhibited in the strength of POL and CT across different substituents, despite the relatively small magnitude of these two components. The product complexes, on the other hand, are not as strongly bound as in their respective reactant state, and they are mainly stabilized by dispersion interaction according to our EDA results (Fig. 15(b)).

The magnitude of the total interaction is strongly impacted by the substituent group on the $p$-terphenyl moiety: with EDGs (–NMe$_2$, –OH, and –CH$_3$), the intermolecular binding between terphenyl and CO$_2$ is of only minimal strength (less favorable than $\sim$1 kJ mol$^{-1}$), while with EWGs (–Br, –CF$_3$, and –NO$_2$) the interaction becomes increasingly more favorable with the increase in substituent’s electron-withdrawing ability ($\sigma_p$). Note that the resulting interaction energy for the NMe$_2$-substituted product complex is net repulsive ($\sim$1.96 kJ mol$^{-1}$), which most likely arises from the distinct levels of theory that were used in our previous CDFT geometry optimizations\textsuperscript{19} and the ALMO-EDA(solv) calculations in the present paper. Similar to the reactant complexes, the substituent effects on the total interaction strength in the product state is also dominated by the ELEC component, where the EWGs are shown to strengthen the binding by reducing the electrostatic repulsion between CO$_2$ and the $\pi$ electrons on the $p$-terphenyl moiety.

To summarize, the substituent effects on the intermolecular binding strength of the reactant and product $p$-terphenyl...-CO$_2$ radical anion complexes exhibit opposite trends, where EWGs diminish and enhance the interaction in the reactant and product states, respectively. While dispersion contributes significantly to binding in both states, the substituent effects are mainly controlled by the electrostatic component in both states despite the presence of solvent environment. These two opposite trends, combined together, lead to the trend shown in Fig. 14 where EWGs yield more strongly bound product complexes relative to the reactant ones. Interestingly, the trend in $\Delta E_{\text{INT}}$ with respect to varying $\sigma_p$ is opposite to that in the total free energy change ($\Delta G$) upon the electron transfer (ET), where EDGs yield more favorable driving forces.\textsuperscript{101} This implies that although EWGs assist in stabilizing the product complexes, they are unable to reverse the trend in the free energy driving force dominated by the gap between the monomer energies before and after ET. In Table S11 in the ESI,\textsuperscript{†} we show the comparison between $\Delta E_{\text{INT}}$ and the energy associated with the reactant-to-product electronic transitions at the monomer level (denoted as $\Delta E_{\text{PRED}}$) for this series of complexes.

### 5 Conclusions

In this work, we have developed the ALMO-EDA(solv) scheme to incorporate solvation effects described by dielectric continuum models into the second-generation ALMO-EDA based on DFT calculations.\textsuperscript{46} This method possesses the following main features:

1. The implicit solvent environment is included in the construction of all states across the EDA procedure. Hence all energy differences ($\Delta E_{\text{FRZ}}$, $\Delta E_{\text{POL}}$, and $\Delta E_{\text{CT}}$) are always computed between two consecutive states that are both properly solvated.

2. A new term, $\Delta E_{\text{SOL}}$, is introduced to describe the direct change in solute–solvant interaction energy upon the formation
of the frozen complex. In most generic cases, it comprises both electrostatic and non-electrostatic components, which can further be combined into the ELEC and PAULI components of the (internal) frozen interaction energy.

ALMO-EDA(solv) consistently incorporates continuum solvent effects, which permits study of solvation effects on each energy component in a systematic, physically motivated manner. To validate our EDA scheme, we first investigated the electrostatics-related terms using a solvated Na$^+$--Cl$^-$ model complex. Our EDA reproduces the correct bulk limit for long-range electrostatics in solvent. We also rationalized diminished screening in the short range. We next analyzed the distance dependence of the energy components produced by ALMO-EDA(solv) for the H$_2$O--Na$^+$ and H$_2$O--Cl$^-$ complexes and demonstrated how solvents with varying dielectric constants affect the net strength of permanent electrostatics and polarization in these systems. The results further confirmed that ALMO-EDA(solv) yields physically sensible results for the energy components of these simple interactions in the solution phase and correctly reflects the trend in the relative strength of solvent effect.

We then employed ALMO-EDA(solv) to investigate more complex chemical systems related to catalysis of CO$_2$ reduction reactions. We first considered CO$_2$ complexes with doubly reduced FeTPP (TPP = tetrathiaporphyrin) and its substituted derivatives.\textsuperscript{31,96} We found that the most strongly bound o-TMA-substituted complex is not mainly stabilized \textit{via} through-space electrostatic attraction as was presumed (since the solvation environment screens this interaction significantly). Instead, it mainly benefits from reduced Pauli repulsion compared to the unsubstituted [FeTPP(CO$_2$)\textit{κC}]$^+$ complex. This originates from the substantial electron-withdrawing inductive effect of the positively charged trimethylammonium groups that reduces electron density around the Fe center and give rise to a more Lewis acidic metal center. This stabilization is thus \textit{via} a through-structure mechanism. Another strongly bound complex with o-OH substitution, in contrast, is mainly stabilized \textit{via} hydrogen bonding between the o-OH groups and the negatively charged CO$_2$ moiety, which is exclusively a through-space effect. Our study thus provides new insights into how substituent effects influence the ability of FeTPP to stabilize activated CO$_2$. Inspired by the EDA results and the ligand reported in ref. 98, we designed a bulky, floppy substituent group that contains a positively charged methylimidazolium moiety. When introduced to the \textit{ortho} positions of the phenyl groups in FeTPP, they can create a solvent-inaccessible “pocket” in that stabilization of activated CO$_2$ \textit{via} long-range Coulomb interaction can be achieved due to the removal of solvent screening effects.

Second, we investigated complexes associated with the electron transfer reaction from p-terphenyl$^-$ (and its double terminal-substituted derivatives) to CO$_2$. We demonstrated that differences between the interaction energies in the reactant and product states ($\Delta E_{\text{INT}}$) are considerably modulated by the substituents, where electron-withdrawing groups were shown to stabilize the product complexes while moderately destabilizing the ones in the reactant state. Our EDA results further revealed that although dispersion plays an important role in the formation of both reactant and product complexes, the substituent tuning of $\Delta E_{\text{INT}}$ is almost entirely achieved through modulating the electrostatic component ($\Delta E_{\text{ELEC}}$) especially that in the product state. This example shows how ALMO-EDA(solv) assists in elucidating the nature of intermolecular interactions and mechanisms of chemical processes in the solution phase.

Finally, we shall note some of the limitations of the present ALMO-EDA(solv) scheme. First, as we have noted in Section 2, currently available DFT-based EDA schemes including our approach are most likely unable to fully describe the many-body solvent effect on dispersion interactions. Second, the current ALMO-EDA(solv) scheme is limited to the decomposition of single-point (\textit{vertical}) interaction energies, and it is certainly desirable to further extend its capability to enable analysis of molecular property shifts in solution based upon our previously developed \textit{adiabatic} ALMO-EDA scheme.\textsuperscript{133} This would require the development of nuclear gradients for the FRZ and POL intermediate states in the presence of implicit solvent. Besides these limitations from the perspective of EDA, one should also bear in mind that there are many other molecular approaches to describe solvent effects in modern theoretical chemistry that are more sophisticated than the relatively simple dielectric continuum model. It is an interesting challenge to make an EDA scheme compatible with those more advanced solvation models. These limitations, on the other hand, provide a wide range of future opportunities to further extend the treatment of solvation effects in ALMO-EDA calculations.
