Luminescent monomeric and dimeric Ru(II) acyclic carbene complexes as selective sensors for NH₃/amine vapor and humidity†

Jingqi Han,  Shun-Cheung Cheng,  Shek-Man Yiu, Man-Kit Tse and Chi-Chiu Ko *

A new class of luminescent bis(bipyridyl) Ru(II) pyridyl acyclic carbene complexes with environmentally-sensitive dimerization equilibrium have been developed. Owing to the involvement of the orbitals of the diaminocarbene ligand in the emissive excited state, the phosphorescence properties of these complexes are strongly affected by H-bonding interactions with various H-bonding donor/acceptor molecules. With the remarkable differences in the emission properties of the monomer, dimer, and H-bonded amine adducts together with the change of the dimerization equilibrium, these complexes can be used as luminescent gas sensors for humidity, ammonia, and amine vapors. With the responses to amines and humidity and the corresponding change in the luminescence properties, a proof-of-principle for binary optical data storage with a reversible concealment process has been described.

Introduction

Smart materials that exhibit a significant change in their absorption and emission colors in response to external stimulation have attracted increasing research interest because of their potential applications in the fields of luminescent probes and sensors,¹ light-emitting diodes,² cell imaging,³ information security,⁴ and so on.

Ammonia and volatile organic amine detections are essential because of their wide applications in food industries,⁵ environmental monitoring,⁶ and even disease diagnosis.⁷ As a result, there is a high demand for developing reliable sensors with high sensitivity and fast response to reduce food poisoning, ocular irritation, and respiratory infection. In this context, various optical amine sensors based on metal-organic frameworks and coordination polymers have been developed.⁸ On the other hand, moisture level or humidity is another important indicator for food quality assurance.⁹ Humidity

sensors have also found applications in different areas,¹⁰ such as skin-humidity level monitoring,^{10a} breath humidity detection,^{10b} moisture detection in organic solvents,^{10c} and sealed packaging humidity value visualization.^{10d}

To date, commercial semiconductor-based sensors for humidity and amines have been developed. However, their applications as sensors in food product quality monitoring, consumer products, or rapid screening tools are limited due to the need of a continuous energy supply, an electronic device for reading the signal, high cost, or poor gas selectivity. For practical applications, luminescent sensors for amine and humidity detection, particularly those with considerable changes suitable for naked-eye detection, are highly desired but have been hardly developed.^{8,10d,11} Compared with fluorescent sensors, phosphorescent sensors have better emission characteristics, including large Stokes shift and longer-lived lifetimes that provide methods to distinguish sensing emission signals from background fluorescence.¹² Moreover, phosphorescent transition metal complexes with environmental sensitive emission properties are ideal candidates for designing luminescent sensors.¹³

Based on the strongly dependent phosphorescent properties of the acyclic carbene complexes towards the conformational variations and the intermolecular interactions with hydrogen-bonding donor and acceptor molecules of the acyclic carbene ligands,¹⁴ herein, we report the design of a new class of bis(bipyridyl) Ru(II) complexes with pyridyl acyclic diaminocarbene ligands as amine and humidity chemosensor. It is hypothesized that the emission energy would be strongly affected by H-bonding interactions with various H-bonding donor and acceptor molecules due to the strong involvement of the orbitals of the diaminocarbene ligand. Interestingly, the N-

deprotonated diaminocarbene ligand would dimerize upon coordination to electron-deficient Ru(II) system by forming strong intermolecular H-bonding. As a result, these complexes exhibit dual phosphorescent properties. The H-bonded dimerization equilibrium and its impacts on the photophysical properties have been studied. Based on the shift of the dimerization equilibrium with various types of H-bonding donor and acceptor molecules and their different H-bonding interactions, the dimeric and monomeric forms of the complex can serve as luminescent humidity and amine sensors. With reference to its responses to amines and humidity and the corresponding luminescence responses, a proof-of-principle for binary optical data storage¹⁵ has been described.

Using the synthetic methodology for pyridyl diaminocarbene ligands,¹⁴ a series of bis(bipyridyl) Ru(II) complexes with pyridyl diaminocarbene ligands (1–3) has been synthesized by the coordination of substituted 2-aminopyridine ligands to the isocyano bis(bipyridyl) Ru(II) precursors¹⁶ (Scheme 1). The structures of all these complexes have been determined by X-ray crystallography. The crystal data and selected bonding parameters are summarized in Tables S1–S4 in ESI†. It is interesting to note that the complex units dimerize with two strong intermolecular H-bonds as evidenced by a short N⋯N distances¹⁷ in the range of 2.97–2.99 Å and N⋯H distances of *ca.* 2.10–2.11 Å in the crystal structures of **1** (Fig. 1a) and **2** (Fig. S1, ESI†). Unlike other structurally-related N-deprotonated carbene ligands in the iridium(III) cyclometalates,^{14b} the *N*-phenyl group of acyclic carbene ligands is *cis* to C–Ru in these H-bond dimers. For **3**, only a tiny amount of single crystals with quality suitable for X-ray crystallography in the recrystallization can be obtained. The difference of these single crystals from the bulk solid of **3** is verified by the different powder XRD patterns of the bulk solid compared to the simulated diffraction patterns from the single-crystal data of **3** (Fig. S2a, ESI†). This contrasts with the close agreement of the simulated patterns and the powder XRD patterns of the bulk solid of **1** (Fig. S2b, ESI†). The crystal structure of these single crystals of **3** is in the monomer form with the *N*-phenyl group *trans* to C–Ru (Fig. 1b). Although the bonding parameters of these complexes are within the typical bonding parameter ranges,¹⁸ a close scrutiny of acyclic carbene

Fig. 1 Perspective drawings of (a) H-bond dimer of **1** and (b) **3**.

ligands in these complexes reveals that Ru–C(carbene) of **3** is slightly shorter (2.01 Å for **3** vs. 2.03–2.04 Å for **1** and **2**) with a larger N–C–N angle (116.6° for **3** vs. 111.2–111.5° for **1** and **2**). Besides, the positions of N-deprotonation in the diaminocarbene ligands are different. In the structure of **3**, the nitrogen attached to the pyridine of the diaminocarbene is deprotonated, whereas the nitrogen attached to the chlorophenyl ring is deprotonated in the structures of **1** and **2**. This may be due to the difference between *trans* and *cis* conformation. Moreover, the presence of electron-withdrawing CF₃ substituent on the pyridine of **3** also renders its amine substituent more acidic.

Environment-dependent photophysical properties

The strong intermolecular H-bonding between the acyclic diaminocarbene leading to dimerization, as revealed from the X-ray crystallography, has also been observed in the solution. The absorption of **1** and **2**, in particular the lowest-energy absorption band, in dichloromethane solution does not follow the Beer–Lambert law (Fig. 2a). Fitting the lowest-energy absorption data, where monomer has minimal absorption, to the dimerization equilibrium model,¹⁹ a linear correlation in

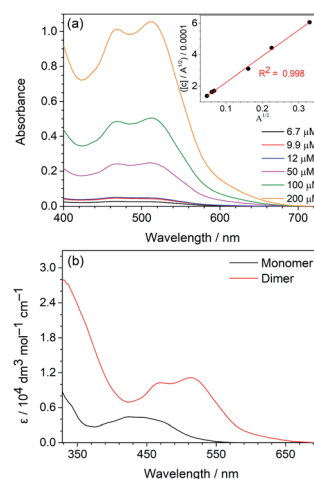

Fig. 2 (a) Overlaid UV-vis absorption spectra of different concentrations of **1** in dichloromethane solutions. Inset: A plot of $[C]/A^2$ vs. A^2 of **1** at 615 nm and the linear regression fit. (b) Calculated absorption spectra of the dimeric and monomeric forms of **1** in dichloromethane solution based on the dimerization equilibrium analysis.

Scheme 1 Synthetic route to **1**–**3**.

the plot of $[C]/A^{1/2}$ vs. $A^{1/2}$ (Fig. 2a: inset and Fig. S3a, ESI†) where $[C]$ is the concentration of the complex and A is the absorbance. From the linear regression of the plots, the dimerization equilibrium constants (4.28×10^5 for **1** and 5.44×10^4 for **2**), and thus the absorptivity of the H-bonded dimer and monomeric form (Table S5 in ESI, Fig. 2b, and Fig. S3b, ESI†) have been calculated. The dimerization equilibrium of **1** in dichloromethane solution is further supported by the decrease of intensity of the N–H stretch of the monomeric form at 3506 cm^{-1} relative to the N–H stretch of the dimeric form at 3437 cm^{-1} upon increasing the concentration (Fig. S4†). The extent of the shifting of the N–H stretching frequency from monomeric to dimeric form due to the strong N–H⋯N hydrogen bonding interactions is commonly observed in other systems.²⁰

On the contrary, the absorption features in the spectra of **3** do not change with the concentration (Fig. S5a, ESI†). The close resemblance of the lowest-energy absorption band of **3** to the dimeric form of **1** and **2** suggests that the major form of **3** in the dichloromethane solution is the dimer form. This is corroborated by the observation of the characteristic dimeric emission of **3** (see below). The much higher dimerization affinity of **3** than **1** and **2** is likely due to the presence of electron-withdrawing CF_3 substituent, which can strengthen the H-bonding interaction by enhancing the proton donating ability of the N–H group of the diaminocarbene ligand.

As similar to bis(bipyridyl) Ru(II) complexes, these complexes show intense ligand-centered $\pi\pi^*$ transitions in the UV region and moderately intense metal-to-ligand charge transfer (MLCT) transitions in the visible region. Compared to $[\text{Ru}(\text{bpy})_3]^{2+}$, the MLCT absorption bands/shoulders of these Ru(II) carbene complexes are broader and of much lower energy, which can be attributed to the mixing of two different MLCT transitions $[\text{d}\pi(\text{Ru}) \rightarrow \pi^*(\text{bpy})]$ and $[\text{d}\pi(\text{Ru}) \rightarrow \pi^*(\text{N}^+\text{C}_{\text{carbene}})]$. The lowest-energy MLCT transition in these complexes is ascribed to $\text{MLCT}[\text{d}\pi(\text{Ru}) \rightarrow \pi^*(\text{N}^+\text{C}_{\text{carbene}})]$. This is further supported by the high sensitivity and the drastic red-shift of this band upon dimerizing the acyclic carbene. The red-shifted MLCT absorption in these complexes (450–470 nm) compared to $[\text{d}\pi(\text{Ru}) \rightarrow \pi^*(\text{R-bpy})]$ transition in $[\text{Ru}(\text{R-bpy})_3]^{2+}$ (410–430 nm),²¹ is due to the lower-lying $\pi^*(\text{N}^+\text{C}_{\text{carbene}})$ orbital than that of the bipyridyl ligands (R-bpy).^{14e,18c}

As with absorption properties, the dimerization equilibrium of **1** and **2** in dichloromethane solution would result in strongly concentration-dependent emission properties (Fig. 3a), comprising two emission components characterized by two different emission lifetimes in the range of 81–88 ns and 193–264 ns. The longer-lived high-energy and the shorter-lived low-energy emission components are ascribed to the emission of the monomeric and dimeric form, respectively. The evolution of a lower-energy emission band, corresponding to the emission of the dimeric form, at higher concentrations is attributed to the increase of the ratio of the dimeric form. With distinguishable emission lifetimes, the two emission bands can be well-resolved using time-resolved emission spectroscopy (Table S5 in ESI, Fig. 3b and S3c in ESI†). Concerning the assignment of the lowest-energy absorption band and the red-shift of the emission

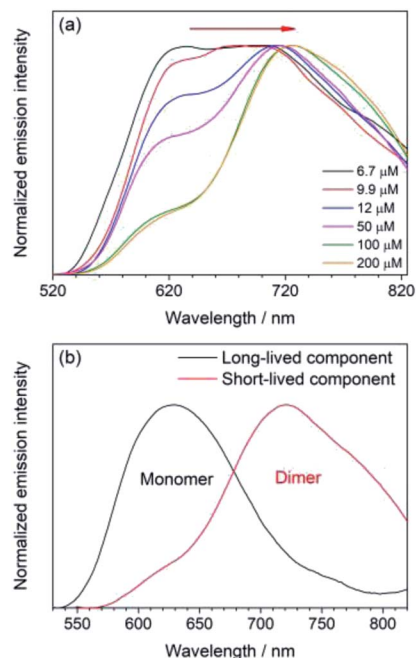

Fig. 3 (a) Overlaid normalized emission spectra of different concentrations of **1** in dichloromethane solutions. Excitation wavelength: 436 nm. (b) Time-resolved emission spectra of short-lived and long-lived components of **1** recorded at time windows of 0–5 ns and 1–200 μs , respectively, after the excitation laser pulse.

upon dimerization, these emissions are likely originated from the $^3\text{MLCT}[\text{d}\pi(\text{Ru}) \rightarrow \pi^*(\text{N}^+\text{C}_{\text{carbene}})]$ excited state. Based on the ratios of absorptivity, emission intensity, and absorbance, the luminescence quantum yields of the monomeric and dimeric forms (Table S5, ESI†) have been determined. For **3** in dichloromethane solution, the emission does not change with its concentration with a lifetime of 160 ns and emission energy similar but slightly higher than those of the dimeric form of **1** and **2** (Fig. S5b, ESI†). Therefore, it is also ascribed to the $\text{MLCT}[\text{d}\pi(\text{Ru}) \rightarrow \pi^*(\text{N}^+\text{C}_{\text{carbene}})]$ phosphorescence of the dimeric form.

As intermolecular hydrogen bonding is the major driving force for dimerization, the extent of dimer formation would be strongly affected by the environments, particularly H-bonding donor/acceptor molecules. Given the drastic differences in the emission properties of the monomer and dimer, the environment-dependent dimerization is examined by the solvatochromic behavior of **1**. The significant solvatochromism of **1**, readily distinguishable by the naked eyes, is shown in Fig. S6, ESI†. As dimerization is concentration-dependent, the absorption and emission spectra were recorded for a fixed concentration of 23 μM in different solvent media. On top of solvatochromic shifts commonly observed in other charge transfer transitions,^{13,22} the intensity ratio of the monomeric and dimeric MLCT absorption of **1** in the visible region varies with the nature of the solvent (Fig. S6c, ESI†). In non-polar dichloromethane, the absorption intensity of the dimeric form (lower-energy band) relative to the monomer is much higher than that in polar or H-bonding solvents. The complex

has the lowest absorption intensity of the dimeric MLCT transition in the strongest hydrogen-bonding organic solvent (methanol).

Consistent with the absorption properties, the intensity of the lower-energy emission band relative to the higher energy band also follow the order of dichloromethane > ethyl acetate > acetonitrile > ethanol \gg methanol (Fig. S6d, ESI†). Except for methanol, the emission decays of **1** in all the studied solvents follow clear biexponential kinetics for the monomeric and dimeric forms described in the dichloromethane solution. In methanol solution, the emission decay is almost single exponential with a lifetime similar to the monomeric form observed in ethanol, suggesting that the complex is mainly the monomeric form in methanol (Table S6, ESI†). The shift of dimerization equilibrium to the monomeric form is due to the solvation stabilization by the H-bonding interaction of the acyclic carbene with methanol.

The change in the monomer/dimer ratio is also clearly observed from the emission properties in different types of low-temperature solid matrices. In 77 K EtOH/MeOH glass, **1** and **2** only exhibit the phosphorescence with maxima at 584–587 nm (Fig. S7a, ESI†), ascribed to the emission of the monomeric form. This is consistent with the results in the solvatochromic study of **1**, in which only the emission from the monomeric form is observed in methanol. In contrast, **3** with the most stable dimeric form show a dual emission derived from the monomeric and dimeric forms peaking at 562 and 651 nm, respectively. Based on the relative emission intensities, the dimeric form of **3** is predominant in 77 K EtOH/MeOH glassy medium. In 77 K dichloromethane, the ratio of the monomeric and dimeric emission change considerably (Fig. S7b, ESI†). The higher-energy monomeric emission of **3** almost disappears compared with the dimeric lower-energy emission at 654 nm in 77 K dichloromethane. Similarly, the higher-energy monomeric emission of **1** becomes a minor component in the dual emission bands. For **2**, the monomeric emission is still the major component (Fig. S7b, ESI†). This is consistent with the trend of dimerization affinity $3 \gg 1 > 2$.

In acetonitrile solution, **1** (100 μ M) exhibits a dual phosphorescence with the dimeric emission as the major component. As with the solvatochromism induced by protic solvents, gradual addition of water to the acetonitrile solution of **1** (100 μ M) would lead to a blue-shift of the MLCT absorption bands and the growth of the high-energy emission band (Fig. 4). This is due to the shift of the dimerization equilibrium to the monomeric form as a result of the H-bonding interaction of the acyclic carbene with water.

Luminescent sensor for humidity monitoring

Inspired by the water-sensitive dimer-monomer transformation together with the resulting color and emission responses, the application of this complex as a luminescent humidity sensor has been explored. Neat film of mainly the dimeric form of **1** on quartz plate can be fabricated by spin-coating the dichloromethane solution of **1** (200 μ M). The initially formed neat film shows an emission band peaking at 714 nm, similar to solid-

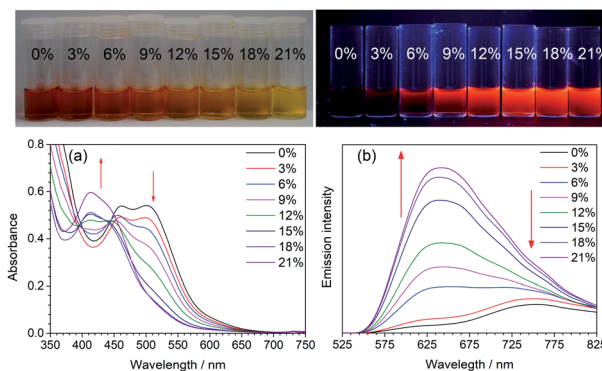

Fig. 4 Overlaid (a) UV-vis absorption and (b) emission spectra of **1** in MeCN–H₂O mixed solvent with different water fractions. Concentration: 100 μ M. Photos of the solution captured under daylight and UV illumination are shown in the upper panel.

state emission of the single crystal sample of **1** (Fig. S8, ESI†). This confirms that the dimeric form is the major component in the spin-coated film. When the film is stored in an atmosphere with relative humidity below 43%, the emission of the film remains unchanged. With a gradual increase of the humidity of the environment to 84%, the emission gradually shifts to the blue (λ_{em} 688 nm at 76% and λ_{em} 660 nm at 84%) with similar emission intensity (Fig. 5a). Further increase of the humidity to 94%, the emission shifts to 641 nm. Moreover, the emission intensity increases significantly by *ca.* 27 folds (Fig. 5b). This change is due to the conversion of the dimeric form to the monomeric form. By monitoring the emission maximum, the maximum humidity of storing environment can be determined.

Fig. 5 (a) Normalized emission spectra of spin-coated films of **1** in environments with relative humidity (RH) of 43%, 76%, 84% and 94%. Inset: photographs showing the emission of the films in the environments with RH of 43% and 94%. Excitation wavelength: 450 nm. (b) Emission spectra of the film in the environments with various RH. Inset: A plot of $I/I_0 - 1$ versus RH. I_0 = maximum emission intensity of the film in 43% RH.

This is particularly useful as an optical humidity sensor for packaged food, in which the water activity (relative humidity) of the storage environment is used as an indicator for food quality. For broken food packages, where food is exposed to high moisture levels that allow the growth of microorganisms, the sensing film becomes strongly emissive to indicate the food spoilage.

Luminescent sensor for amines

As discussed above, **1** would adopt a monomeric form in the presence of hydrogen-bonding donors. By loading a methanol solution of **1** on filter paper, the absorbed complex **1** on the filter paper (**1M_s**) is mainly the monomeric form. This is confirmed by its emission properties ($\lambda_{\text{max}} = 631$ nm, Fig. 6) resembling that of the monomeric form in the solution state. With reference to the strong intermolecular hydrogen bonding interactions between the NH–C–N[−] moieties of the diaminocarbene ligands in the dimeric form, it is anticipated that the NH–C–N[−] moiety of the monomeric unit could also form strong hydrogen-bonding interactions with the (NH) group of amines. Upon

exposure to ammonia and organic amines, the emission of **1** absorbed on filter paper (**1M_s**) changes significantly. The emission maximum of **1M_s** rapidly shifts to the red from 631 nm to 723 nm with intensity decreases linearly with the concentration of ammonia of the environment from 1754 (2.7-fold) and to 3.96×10^5 ppm (48-fold) (Fig. 6a).

The emission changes of **1M_s** towards different types of saturated organic amines, butylamine (BUA), cyclohexylamine (CYA), isopropylamine (IPA), diethylamine (DEA), diisopropylamine (DIPA), and triethylamine (TEA), have been studied (Fig. S9, ESI†). Upon exposure to amine vapor for four minutes, the emission intensity decreases with the extent showing strong dependence on the nature and bulkiness of the amines. On the other hand, the emission is also red-shifted with $\Delta\lambda_{\text{max}}$ following the same order as the change in the emission intensity: BUA (103 nm) > CYA (102 nm) > IPA (98 nm) > DEA (83 nm) \gg DIPA (19 nm) \approx TEA (17 nm) (Fig. 6b and S9, ESI†). This trend does not correlate with the vapor pressure nor the basicity of the amines. In general, the extent of the change follows the order of primary amine > secondary amine > tertiary amine and reverse order of bulkiness. For all the studied primary amines, it follows the order of BUA > CYA > IPA. Thus, the least bulky butylamine induces the most drastic change of the emission intensity and maximum amongst all the studied organic amines.

As shown in the plot of $[(I_{\lambda_{\text{max}}}[\text{Ru-A}]/I_{\lambda_{\text{max}}}[\text{Ru-A}])]/(I_{631}/I_{631})]$ (Fig. 6c), such changes are due to the decrease of emission band at 631 nm with a concomitant growth of new emission peaking at 713–734 nm. Because of the significant changes of the emission maximum induced by ammonia, primary and secondary amines, these changes are attributed to the formation of H-bonded carbene–amine adducts (Scheme 2). The sensitivity of the new emission band to the substituent on the amine further supports the adduct formation because the strength of the H-bonding is expected to be affected by the steric properties of the amine. The formation of H-bonded carbene–amine adduct is further verified by the isosbestic absorption in the UV-vis absorption spectral change in the titration of **1** (2 μM) with isopropylamine (IPA) (Fig. S10, ESI†). In the NMR study, the adduct is characterized by an upfield shift of NH proton of the diaminocarbene upon addition of isopropylamine (IPA) (Fig. S11, ESI†). In addition, the decrease of the diffusion coefficient in DOSY (Fig. S12, ESI†) after adding 75 mol equiv. of IPA is consistent with the decrease of molecular weight due to the shift of the dimerization equilibrium to the monomeric carbene–amine adduct. As these emission changes are due to the formation of the H-bonded carbene–amine adduct, the

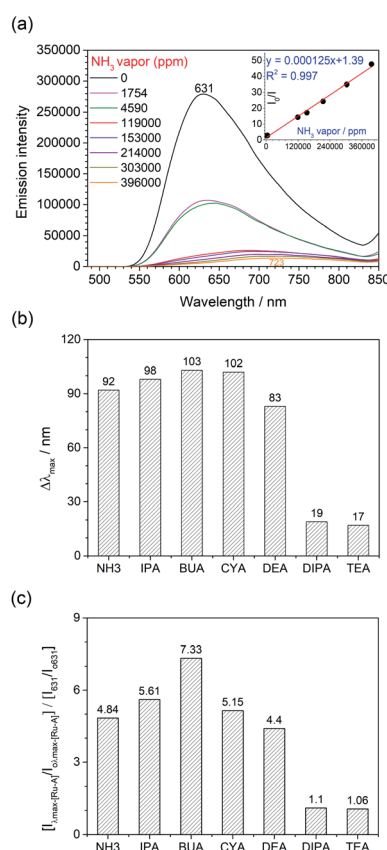

Fig. 6 (a) Emission spectra of the film upon exposure to different concentrations of NH₃ vapor for 4 min. Inset: quenching efficiency I_0/I of the film as a function of the vapor concentrations of NH₃. (b) A plot of emission maximum changes ($\Delta\lambda_{\text{max}}$) and (c) the changes of the emission intensities $[(I_{\lambda_{\text{max}}}[\text{Ru-A}]/I_{\lambda_{\text{max}}}[\text{Ru-A}])]/(I_{631}/I_{631})]$ where I_0 and I are the emission intensities before and after exposure to the tested vapor, of **1M_s** upon exposure to saturated ammonia and various organic amine vapors.

Scheme 2 Formation of H-bonded carbene–amine adducts from **1M_s**.

emission can be reverted when the amine vapor is removed (Fig. S13 and video, ESI†). Compared with other reported amine sensors,⁸ this amine sensor shows significantly improvement in its response time, stability, and reversibility, which can be reused many times and applied for real-time monitoring.

In the case of very bulky secondary amine (DIPA) and tertiary amine (TEA), the carbene-amine adduct cannot be formed. At a result, the emission of **1M**_s only shows minimal red-shift with much less decrease of the emission intensity after fuming with DIPA and TEA vapor (650 nm vs. 631 nm). As shown in Fig. 6c, the value of $[(I_{\lambda_{\max}[\text{Ru-A}]} / I_{0\lambda_{\max}[\text{Ru-A}]}) / (I_{631} / I_{0631})]$ is close to 1 for DIPA and TEA, suggesting the quenching of the initial emission band.

Concealable optical data storage

Based on the readily distinguishable luminescence responses towards H-bonding donor and acceptor, a proof-of-principle for binary optical data storage¹⁵ has been proposed. A 5×8 dot matrix of **1** loaded on a filter paper (Fig. 7), as five 8-digit ASCII codes, is fabricated by dropping dichloromethane solution of **1** (5 mM). Unlike deposition by methanol solution, which displays

strong orange phosphorescence of monomeric form, all the dots display weak dark red emission (Fig. 7). The emission of these dots could change from the dimeric form to orange phosphorescence of monomeric form by chemical encoding process with a drip of methanol from a glass capillary. The two different emission properties, weak dark red and bright orange emissions, can be used to store binary data of “0” and “1”, respectively. Since the methanol-induced conversion of the dimeric form to monomeric form involves the rearrangement of intermolecular packing, it is irreversible even after the removal of methanol.

As shown in Fig. 7, the initial deposit 5×8 dots translate into “000000”. The five ASCII codes for “CityU”, 01000011, 01101001, 01110100, 01111001, and 01010101, respectively, can be stored in the 5×8 dots by chemical encoding process with methanol. The data can be chemically concealed by fuming ammonia vapor for a few seconds, which converts all bright orange emissive dots into dark red emissive dots. This is due to the binding of the ammonia with the aminocarbene ligand of the emissive monomeric form (Scheme 2). After removing the NH₃ vapor, the unbounded monomeric form can be regenerated, and thus the original bright orange emission can be restored to show the hidden ASCII codes. Such concealment-restoration processes are reversible for many cycles. The stored information can be cleared by fuming methanol vapor for 10 min, after which all dots show bright orange emission.

Conclusions

In conclusion, a new series of Ru(II) carbene complexes having environmental sensitive dimerization through intermolecular H-bonding have been successfully designed, synthesized, and characterized. Based on dimerization equilibrium analysis and time-resolved spectroscopy, the equilibrium, absorption and emission properties of the monomeric and dimeric forms have been elucidated. Using different coating/deposition techniques and conditions, thin films/depositions of the monomeric and dimeric forms can be fabricated. Importantly, the highly sensitive luminescent properties of these films towards various H-bonding donors and acceptors can serve as optical sensors for humidity monitoring and amine sensing, both of which are important in food safety and can be visualized by the naked eye. Taking the advantage of the multi-stimuli responsive properties of **1**, a proof-of-principle for designing a binary optical data storage system with a reversible concealment process has been studied.

Data availability

Experimental data including characterization data, NMR, absorption and emission spectra upon addition of IPA, dimerization analysis are in the figures or ESI.† Crystal data have been deposited at CCDC.
