# Thermal annealing effects on hydrothermally synthesized unsupported MoS<sub>2</sub> for enhanced deoxygenation of propylguaiacol and kraft lignin†

You Wayne Cheah,<sup>a</sup> Muhammad Abdus Salam,<sup>a</sup> Joby Sebastian,<sup>a</sup> Sreetama Ghosh,<sup>a</sup> Olov Öhrman,<sup>b</sup> Derek Creaser <sup>a</sup> and Louise Olsson <sup>\*a</sup>

Catalytic hydrodeoxygenation (HDO) is an important hydrotreating process that is used to improve the quality of bio-oils to produce biomass-derived fuel components and chemicals. Molybdenum disulfide (MoS<sub>2</sub>) has been widely used as a catalyst in hydrodesulfurization (HDS) applications for several decades, which can be further improved for effective unsupported catalyst synthesis. Herein, we studied a universally applicable post-annealing treatment to a hydrothermally synthesized MoS<sub>2</sub> catalyst towards developing efficient unsupported catalysts for deoxygenation. The effect of the annealing treatment on the catalyst was studied and evaluated for HDO of 4-propylguaiacol (PG) at 300 °C with 50 bar H<sub>2</sub> pressure. The annealing of the as-synthesized catalyst under nitrogen flow at 400 °C for 2 h was found to enhance the HDO activity. This enhancement is largely induced by the changes in the microstructure of MoS<sub>2</sub> after the annealing in terms of slab length, stacking degree, defect-rich sites and the MoS<sub>2</sub> edge-to-corner site ratio. Besides, the effect of hydrothermal synthesis time and acid addition combined with the annealing treatment on the MoS<sub>2</sub> catalytic activity was also studied for the same model reaction. The annealed MoS<sub>2</sub> with a synthesis time of 12 h under an acidic environment was found to have improved crystallinity and exhibit the highest deoxygenation degree among all the studied catalysts. An acidic environment during the synthesis was found to be crucial in facilitating the growth of MoS<sub>2</sub> micelles, resulting in smaller particles that affected the HDO activity. The annealed unsupported MoS<sub>2</sub> with the best performance for PG hydrodeoxygenation was further evaluated for the hydrotreatment of kraft lignin and demonstrated a high deoxygenation ability. The results also indicate a catalyst with high activity for deoxygenation and hydrogenation reactions can suppress char formation and favor a high lignin bio-oil yield. This research uncovers the importance of a facile pretreatment on unsupported MoS<sub>2</sub> for achieving highly active HDO catalysts.

## 1. Introduction

The continuous increase in global emissions of greenhouse gases (GHG) from the burning of fossil fuels and the depleting fossil fuel reserves have prompted the search for alternative renewable fuels.<sup>1</sup> Lignin, a complex three-dimensional biopolymer that accounts for 15–30% of the dry weight of lignocellulosic biomass is often underutilized and burnt to produce excess utility heat for the paper processing industry.<sup>2</sup> It consists of methoxylated monolignol monomers (*e.g.* coniferyl, sinapyl, and *p*-coumaryl alcohol) that are largely linked together by different C–C and C–O bonds.<sup>3</sup> The breakdown of these

linkages is required to obtain low molecular weight compounds for further upgrading. Lignin-derived bio-oil, a potential advanced biofuel obtained from the fast pyrolysis or thermal liquefaction of lignin, can be seen as an attractive option for alternative fuels.<sup>4–6</sup> However, the bio-oil produced using these depolymerization techniques contains a large amount of oxygenates like phenolics, alcohol, and ketone compounds that require an upgrading process for further use. The high oxygen content leads to several undesirable characteristics like low pH value, high viscosity, and low heating value as a transportation fuel.<sup>7</sup> Hence, catalytic hydrodeoxygenation (HDO), a hydro-treating process can be adopted to remove excess oxygen in the form of water using hydrogen as a co-reactant and facilitated by the use of selective hydrotreating catalysts.<sup>8</sup>

The selection of an active and selective HDO catalyst is crucial in accelerating HDO reactions. The widely used sulfided transition metal catalysts (TMS) in the hydroprocessing unit for hydrodesulfurization (HDS) and hydrodenitrogenation (HDN) appear to be transferable and applicable to the HDO

technology. The sulfur content (1–2 wt%) in kraft lignin due to the pulping process can act as a poison to some catalyst systems like noble metal catalysts.<sup>9</sup> Hence, the use of sulfur tolerant catalysts like TMS can be beneficial and relevant when applied to the hydrotreatment of kraft lignin.

The traditional TMS catalysts are the typical molybdenum sulfide catalyst supported on  $\gamma$ -alumina promoted by nickel (Ni) or cobalt (Co).<sup>10</sup> Over the past few decades, the development of these supported Ni(Co)MoS hydrotreating catalysts has reached a mature stage with the possibility to enhance its performance by either replacing the alumina carrier with others such as carbon<sup>11–15</sup> or omitting the use of a support.<sup>16</sup> A good example of an unsupported catalyst system is the NEBULA technology that has been jointly established by ExxonMobil and Albemarle Catalysts.<sup>16,17</sup> This commercialized and patented technology has been able to show the superior activity of the unsupported catalysts as compared to the conventional hydroprocessing catalysts.<sup>17</sup> Another application of the unsupported hydroprocessing catalysts was the Eni Slurry Technology (EST) process.<sup>18</sup> The EST process uses highly dispersed MoS<sub>2</sub> nanoparticles formed by the oleo-soluble molybdenum precursor co-fed with heavy oil feedstocks under reaction conditions of 400–450 °C and 150 bar with a continuous hydrogen flow resulting in high hydrogenation activity.<sup>18</sup> Furthermore, the promising results were demonstrated in a recent study using unsupported Mo precursors for the co-processing of fast pyrolysis bio-oil (FPBO) with heavy fossil feedstocks in a slurry hydrocracking unit.<sup>19</sup> Besides, it is worth mentioning that kraft lignin has a high molecular weight of typically around 16.7 kDa.<sup>20</sup> The diffusion of huge lignin polymeric molecules through porous support materials to access the active sites of a supported catalyst poses a significant obstacle to the process. Besides, lignin reactive fragments formed by noncatalytic thermal reactions are thought to repolymerize and form char.<sup>21,22</sup> The transport limitations caused by supported catalysts can hinder the stabilization of these intermediates by hydrogenation reactions and result in greater char formation. Therefore, the use of an unsupported catalyst with high activity seems promising for kraft lignin hydrotreatment.

There are several ways to synthesize molybdenum-based sulfide unsupported catalysts that can be employed in HDO and hydrotreatment processes. For example, Varakin *et al.* prepared unsupported MoS<sub>2</sub> by the support leaching of MoS<sub>2</sub> supported on alumina or carbon-coated alumina which gave a high yield of C18 hydrocarbon in oleic acid HDO.<sup>23</sup> Yoosuk *et al.* synthesized amorphous unsupported MoS<sub>2</sub> and CoMoS catalysts hydrothermally using ammonium tetrathiomolybdate (ATTM) as the catalyst precursor under high hydrogen pressure (28 bar) and high reaction temperature (350 °C).<sup>24</sup> They concluded that the amorphous MoS<sub>2</sub> was selective in cleaving the hydroxyl group in phenol *via* a direct-deoxygenation (DDO) route.<sup>24</sup> Besides, Grilc *et al.* reported the preparation of urchin-like MoS<sub>2</sub> and inorganic-fullerene MoS<sub>2</sub> interconnected by carbon materials *via* the sulphidisation of precursors like MoI<sub>3</sub> and cyclopentadiene–MoCl<sub>4</sub>, respectively.<sup>25</sup> The results from their work demonstrated that both of these unsupported catalysts gave a high selectivity towards deoxygenation, and

possessed a three times higher rate in dehydroxylation as compare to bulk MoS<sub>2</sub>.<sup>25</sup> Recently, Zhang *et al.* reported the preparation of few-layer and defect rich MoS<sub>2</sub> and also Co-promoted MoS<sub>2</sub> nanosheets by a one-pot hydrothermal method.<sup>26</sup> These reduced stacking layers and defect-rich MoS<sub>2</sub> could accommodate Co atoms as a promoter and resulted in an active Co–Mo–S phase for *p*-cresol HDO under a low operation reaction temperature of 230 °C.<sup>26</sup>

Among all preparation methods, hydrothermal synthesis seems to be attractive from an industrial point of view for the preparation of unsupported MoS<sub>2</sub>, owing to the use of moderate temperature (150–250 °C) and the absence of hydrogen pressure while using ammonium molybdate as the Mo precursor.<sup>27–32</sup> A summary of the deoxygenation application of hydrothermally synthesized unsupported metal sulfides and the main highlight of these studies is provided in Table 1. In all of these studies, the synthesized catalysts were used in the HDO reaction without any pretreatment that can enhance the HDO activity. Herein, we have explored a hydrothermal synthesis method for unsupported MoS<sub>2</sub> catalysts inspired by several preparation methods reported elsewhere.<sup>27–29</sup> We then also further propose an additional annealing process to be applied to the as-synthesized unsupported MoS<sub>2</sub> that changes its structure and morphology that influences its HDO activity. To the best of our knowledge, this is the first work where the main effort has been emphasized on the pretreatment of a hydrothermally synthesized unsupported MoS<sub>2</sub> for deoxygenation enhancement. Synthesis parameters such as the effect of synthesis time and pH adjustment during the synthesis on the morphology of MoS<sub>2</sub> and relative HDO activity were also studied. The activity, selectivity, and effectiveness of the catalysts were first evaluated using an oxygenate model compound, 4-propylguaiaicol (PG) that can be obtained from depolymerized lignin fragments. The use of PG in the model reaction has also been shown in our previous work that it is useful to demonstrate the effectiveness of the catalysts for complex lignin hydrotreatment.<sup>33</sup> Hence the catalytic hydrotreatment of kraft lignin was studied using the unsupported MoS<sub>2</sub> showing the best performance for HDO of PG. The comparison between the commercially available bulk MoS<sub>2</sub> and MoS<sub>2</sub> synthesized in this work was made for the HDO of PG and kraft lignin. Besides, the synthesized and annealed unsupported MoS<sub>2</sub> catalysts were characterized in detail by N<sub>2</sub> physisorption, X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, high-resolution transmission electron microscope (HRTEM), and scanning electron microscopy (SEM) to discover relations between resulting properties of the materials and their catalytic performance. Our research is foreseen to contribute towards a better understanding of the role of a post-thermal annealing treatment on the unsupported MoS<sub>2</sub> for developing highly robust HDO catalysts.

## 2. Experimental

### 2.1 Catalyst synthesis

The unsupported MoS<sub>2</sub> catalysts were prepared starting from a simple hydrothermal method following various works from

Wang *et al.*<sup>27,29</sup> incorporating certain modifications in the synthesis steps. 0.35 g of ammonium heptamolybdate tetrahydrate (>99%) and 1.3 g of thiourea (>99%) were both dissolved in 55 ml of distilled water with gentle stirring. The pH of the solution was adjusted to 0.8 using hydrochloric acid (35 wt%). For one catalyst sample, this pH adjustment step was omitted to

**Table 1** Overview of literature survey related to the use of hydrothermal synthesized unsupported metal sulfides in deoxygenation application

| Unsupported catalysts                | Application                                | Highlights  | Ref. |
|--------------------------------------|--|---|------|
| CoMo sulfide and MoS <sub>2</sub>    | <i>p</i> -Cresol hydrodeoxygenation        | -Reduced stacking of MoS <sub>2</sub> layers and increased defect sites on basal planes formed more coordinatively unsaturated sites (CUS) to accommodate promoter atoms  | 26   |
| Co-doped nano sized MoS <sub>2</sub> | <i>p</i> -Cresol hydrodeoxygenation        | -Highly dispersed MoS <sub>2</sub> with abundance of defects and curvy slabs are important features to produce high density of CUS sites and for anchoring Co atoms<br>-Molar ratio of 0.3 for Co/(Co + Mo) gives almost complete <i>p</i> -cresol conversion and 98.9% toluene selectivity   | 30   |
| Ni–Mo sulfides                       | Palm oil hydrotreating                     | -Molar ratio of 0.2 for Ni/(Ni + Mo) shows good HDO performance and good recyclability<br>-The incorporation of Ni promoter increased the stacking and layers numbers which also contributed to the increase in the rim and edge sites that is the active site for the hydrogenation reaction   | 48   |
| Unsupported and supported CoMoS      | Waste cooking oil (WCO) hydrotreating      | -Unsupported metal sulfides give a higher degree of polymerization due to the lack of acidic sites (absence of catalyst support)<br>-Increased reaction temperature improved deoxygenation, and enhanced the cracking and polymerization degree for unsupported catalyst  | 31   |
| NiMo and CoMo sulfides               | Oleic acid and palmitic hydrodeoxygenation | -Ni promoter decreased the Ni–Mo–S bond strength leading to the formation of CUS on the edges of the MoS <sub>2</sub> slabs<br>-Hydrothermal synthesis of MoS <sub>2</sub> resulted in the bent and folded multi-layered structure of the catalyst  | 49   |
| CoMoS                                | <i>p</i> -Cresol hydrodeoxygenation        | -Optimal hydrothermal temperature is 200 °C<br>-The concentration of Co promoters affects the catalysts surface area, stacking numbers, and also MoS <sub>2</sub> slab length<br>-Increased Co amount hindered and inhibited the MoS <sub>2</sub> growth and caused aggregation of CoS <sub>2</sub> which reduced MoS <sub>2</sub> dispersion yielding longer slabs | 27   |
| Ni–Mo–W sulfides                     | <i>p</i> -Cresol hydrodeoxygenation        | -Molar ratio of 0.5 for W/Mo gives the highest HDO performance<br>-Optimum molar ratio for W/Mo resulted in the shortest average  | 32   |

Table 1 (Contd.)

| Unsupported catalysts                   | Application               | Highlights   | Ref. |
|---|---------------------------|--|------|
| MoS <sub>2</sub> and CoMoS <sub>2</sub> | Phenol hydrodeoxygenation | MoS <sub>2</sub> slab length and improved dispersion<br>-Amorphous and highly bent MoS <sub>2</sub> with multi-layered structure was more active than the crystalline sample<br>-Addition of Co changes the textural properties of the catalysts giving reduced specific surface area and shifted the pore-size distribution to smaller pore sizes | 24   |
| NiMo sulfides                           | Phenol hydrodeoxygenation | -HDO activity depends largely on the sulfide's morphology but not the catalysts surface area<br>-Low layer number in the MoS <sub>2</sub> stack and/or shorter slabs could give higher hydrogenation-dehydration (HYD) activity  | 50   |

evaluate its effect on the catalyst properties. The mixed solution was divided equally and transferred to a 70 ml Teflon liner. The filled Teflon liner was placed and sealed in a stainless-steel autoclave. The mixed solution was heated at 200 °C for either 12 h or 24 h. The synthesized catalyst was then filtered and washed with absolute ethanol several times. The filtered and washed catalyst was dried under vacuum at 50 °C overnight. These as-synthesized catalysts were tested without any pretreatment in the model reaction. The as-synthesized catalysts with synthesis times of 12 h and 24 h will be referred to as MoS<sub>2</sub>-12 and MoS<sub>2</sub>-24, respectively. The dried as-synthesized catalysts were further annealed at 400 °C for 2 h under nitrogen flow before their evaluation in the model reaction. These annealed catalysts with 12 h and 24 h synthesis time will be denoted as MoS<sub>2</sub>-12a and MoS<sub>2</sub>-24a. Bulk MoS<sub>2</sub> (Sigma-Aldrich) in powdered form with a particle size of ~6 μm (max. 40 μm) was used in the current work for comparison with our in-house synthesized MoS<sub>2</sub>. Alumina-supported MoS<sub>2</sub> (13.2 wt% Mo loading) catalyst was also prepared according to the procedure reported by our group earlier<sup>34</sup> for comparison in this work.

## 2.2 Characterization of unsupported MoS<sub>2</sub>

The specific surface area of the catalyst was measured by N<sub>2</sub> physisorption at -196 °C using a TriStar 3000 gas adsorption-desorption analyzer. The catalysts were degassed at 300 °C under nitrogen flow overnight before every measurement for drying purposes. The Brunauer-Emmett-Teller (BET) method was used to calculate the surface areas and the pore sizes were estimated by the Barrett-Joyner-Halenda (BJH) method. XRD measurement was performed using an X-ray powder diffractometer operated at 40 kV and 40 mA (Bruker AXSD8 Advance) with a CuKα monochromatic radiation (λ = 1.542 Å) source in the 2θ range of 10–80°. XPS measurements were carried out

using a PerkinElmer PHI 5000 VersaProbe III Scanning XPS Microprobe. The monochromatic Al-Kα X-ray source with a binding energy of 1486.6 eV was operated in the analysis chamber. The core-level spectra of Mo 3d, O 1s, S 2p, and C 1s were recorded with a step size of 0.1 eV. The raw data was then analyzed using a Shirley background using the software Casa XPS with the C 1s binding energy at 284.8 eV as a reference. The Raman spectra were recorded using a WITec alpha300 R confocal Raman microscope equipped with a thermoelectrically cooled (-60 °C) EMCCD detector. A 532 nm CW diode laser at 0.3 mW was used for excitation and the light was focused on the sample using a 100X/NA0.9 objective. The Raman scattering was collected using the same objective and was spectrally resolved using an 1800 grooves per nm grating. Calibration was performed on the position of the Raman spectra bands using the silicon peak at 519.3 nm. The morphologies and structure of the catalysts were obtained by HRTEM on an FEI Titan 80-300 TEM operated at 300 kV equipped with a high angle annular dark-field (HAADF) detector. SEM was performed on a JEOL 7800F Prime to acquire the morphology of the catalysts. The particle diameter of over two hundred MoS<sub>2</sub> particles from the SEM images was measured by ImageJ software and used to obtain average particle sizes.

Quantitative and statistical analyses were performed based on 15–20 representative TEM images taken from different regions of each catalyst. Approximately 500–550 MoS<sub>2</sub> slabs were measured and processed by ImageJ software to calculate the average MoS<sub>2</sub> slab length (ΔL) and stacking number (Δn) using the following equations:<sup>33</sup>

$$\text{Average MoS}_2 \text{ slab length } (\Delta L) = \frac{\sum_i^n x_i l_i}{\sum_i^n x_i} \quad (1)$$

$$\text{Average stacking number } (\Delta n) = \frac{\sum_i^n x_i N_i}{\sum_i^n x_i} \quad (2)$$

$i$ : total number of MoS<sub>2</sub> slabs,  $N_i$ : stacking number,  $l_i$ : MoS<sub>2</sub> slab length,  $x_i$ : number of MoS<sub>2</sub> slabs with  $N_i$  layers of length  $l_i$ .

Moreover, the MoS<sub>2</sub> dispersion ( $f_{\text{mo}}$ ) was calculated with the following equation reported in the literature:<sup>35</sup>

$$\text{MoS}_2 \text{ dispersion } (f_{\text{mo}}) = \frac{\text{Mo}_{\text{edge}}}{\text{Mo}_{\text{total}}} = \frac{\sum_i^m 6(n_i - 1)}{\sum_i^m (3n_i^2 - 3n_i + 1)} \quad (3)$$

Mo<sub>edge</sub>: number of Mo atoms that are located on the edges of the MoS<sub>2</sub> slabs, Mo<sub>total</sub>: total number of Mo atoms,  $n_i$ : number of Mo atoms along the edge of MoS<sub>2</sub> slabs with its length obtained by ( $L = 3.2(2n_i - 1) \text{ \AA}$ ),  $m$ : total number of MoS<sub>2</sub> slabs obtained from the TEM images of different catalysts.

The edge-to-corner ratio of MoS<sub>2</sub> slabs was calculated based on the following equation:<sup>36</sup>

$$\frac{f_{\text{edge}}}{f_{\text{corner}}} = \frac{5\Delta L}{3.2} - 1.5 \quad (4)$$

### 2.3 Catalytic test for HDO of 4-propylguaiaicol (PG)

The catalytic activity was measured using a 300 ml Parr batch reactor. In a typical catalytic test, 66 mg of as-synthesized or annealed unsupported catalyst, 1 g of 4-propylguaiaicol, 100 ml of dodecane as the solvent, and 0.5 ml of dimethyl disulfide (DMDS) were loaded into the reactor. The reactor was sealed and first purged three times with N<sub>2</sub> and then followed by H<sub>2</sub>. The reactor system was then pressurized to 20 bar of H<sub>2</sub> at room temperature and checked for any leaks. After the leak check, the system was depressurized to 0.1 bar gauge and further heated to a final temperature of 300 °C. It took 25 minutes to reach desired temperature. When the reaction temperature has reached, additional hydrogen was introduced and this point was regarded as the start of the reaction. Reaction conditions for all PG HDO experiments were kept constant at 50 bar H<sub>2</sub>, 300 °C, and 1000 rpm for 5 h. All reaction conditions were strictly kept constant during the evaluation of catalytic activities to ensure comparable kinetic results. Reaction liquid product samples were collected every hour during 5 h for further analysis. The withdrawal of the reaction sample caused a drop of *ca.* 1 bar in the reactor which was compensated by repressurizing to 50 bar with hydrogen. The reaction was stopped after 5 h by cooling the reactor with water cooling, followed by releasing the reactor pressure. After pressure release, the reactor was purged with N<sub>2</sub> before opening. The remaining reaction medium was centrifuged to collect all used catalysts. The used catalyst was washed with absolute ethanol several times and dried in an oven at 80 °C overnight.

The PG conversion ( $C_{\text{PG}}$ ), product yield ( $Y_{\text{product}}$ ), and selectivity ( $S_{\text{product}}$ ) at varying times were calculated based on the following expressions:

$$C_{\text{PG}}(\%) = \frac{C_0 - C_t}{C_0} \times 100 \quad (5)$$

$$Y_{\text{product}}(\%) = \frac{C_{\text{product},t}}{C_0} \times 100 \quad (6)$$

$$S_{\text{product}}(\%) = \frac{C_{\text{product},t}}{C_0 - C_t} \times 100 \quad (7)$$

$C_0$ : initial PG concentration loaded in the reactor,  $C_t$ : PG concentration at a given reaction time,  $C_{\text{product},t}$ : Product concentration at reaction time.

The units for the yields of reactants and products are expressed as molar percent (mol %). The molar balance for the reaction was assessed by calculating the material balance in the liquid phase. The molar balance was calculated by dividing the summation of the concentration of all identified products by the concentration of the initial PG concentration loaded in the reactor. The calculation is based on the observation that all products detected in the reaction samples retained the six-carbon ring structure of PG. The carbon balance for the liquid phase analysis was found to be ranged over 95–99% for all experiments.

### 2.4 Hydrotreatment of kraft lignin

The hydrotreatment reaction was carried out in the 300 ml Parr reactor system, the same as that used for the model reaction. Before starting the reaction, the reaction vessel was loaded with 0.75 g of catalysts, 2.25 g of kraft lignin (Sigma Aldrich), and 75 ml of hexadecane as a solvent. The composition of kraft lignin was analyzed by ICP and elemental analysis results are presented in Fig. S1 and Table S1.† The reactor was then sealed and purged with nitrogen three times to remove oxygen traces. The reactor was then pressurized to 40 bar H<sub>2</sub> at room temperature and monitored for leaks during 20 minutes. After a passed leak test, the reaction temperature was set to 340 °C and it took 40 minutes to reach the desired temperature. The stirring rate was set at 1000 rpm when the heating was started. Reaction time zero was recorded once the reaction temperature reached the desired temperature and the reaction was monitored for 5 h with continuous stirring of 1000 rpm. The reactor pressure immediately after reaching 340 °C was 73–76 bar depending on the type of catalyst used in the experiment. The pressure decreased by 1–3 bar to 70–73 bar during the course of the reaction (5 h). After the reaction was completed, all reaction products in liquid form and solid residues in the reaction vessel were collected in a glass bottle for product analysis. The solid residues retained in the reaction medium after the hydrotreatment were obtained by filtering the bio-liquid. The solid residues were washed first with acetone and then dried in an oven at 80 °C overnight. The unconverted lignin retained in the dried solid was dissolved by dimethyl sulfoxide (DMSO) washing. After dissolving the unconverted lignin with DMSO, the solid product was dried again in an oven at 80 °C overnight.

The initial solid residues obtained after filtration should contain spent catalyst, solid char, and unconverted lignin. The weight of the solid was recorded after each drying.

Kraft lignin conversion ( $C_{\text{kraft lignin}}$ ) was calculated based on the following equation:

$$C_{\text{kraft lignin}}(\%) = \frac{\text{initial kraft lignin feed (g)} - \text{unconverted lignin (g)}}{\text{initial kraft lignin feed (g)}} \times 100$$

The amount and yield of solid char were calculated by the following equations:

$$\text{Char amount (g)} = \text{total solid residues (g)} - 0.75 \text{ g of catalyst} - \text{unconverted lignin (g)}$$

$$\text{Char yield (\%)} = \frac{\text{char amount (g)}}{2.25 \text{ g of initial kraft lignin feed}} \times 100\%$$

Individual product selectivity in the bio-liquid were calculated by dividing the corresponding FID peak area of the product by the total FID peak area for all identifiable products in the bio-liquids.

## 2.5 Product analysis for model compound and kraft lignin hydrotreatment

The reaction products collected during the catalytic reaction for HDO of PG were analyzed by GC-MS (Agilent 7890-5977A, Agilent). The GC was equipped with an HP-5 column (30 m  $\times$  250  $\mu\text{m}$   $\times$  0.25  $\mu\text{m}$ ), and the injector temperature was kept at 325  $^{\circ}\text{C}$ . The initial oven temperature was 100  $^{\circ}\text{C}$  for 1 minute and then heated to 190  $^{\circ}\text{C}$  at a rate of 10  $^{\circ}\text{C min}^{-1}$ . The heating continued to 300  $^{\circ}\text{C}$  with a ramp of 30  $^{\circ}\text{C min}^{-1}$  and the final temperature was maintained for 80 s.

The bio-liquid products collected after the catalytic hydro-treatment of kraft lignin were analyzed by GC-MS (Agilent 7890-5977A, Agilent). The GC was equipped with an HP-5 column (30 m  $\times$  250  $\mu\text{m}$   $\times$  0.25  $\mu\text{m}$ ), and the injector temperature was kept at 325  $^{\circ}\text{C}$ . The initial oven temperature was 50  $^{\circ}\text{C}$  for 5 minutes and then heated to 300  $^{\circ}\text{C}$  at a rate of 10  $^{\circ}\text{C min}^{-1}$ . After which the final temperature was maintained constant for 5 minutes.

The bio-liquid products were also analyzed by two-dimensional GC  $\times$  GC-MS-FID on an Agilent 7890B gas chromatograph equipped with an oven, a flow splitter, a modulator, and a flame ionization detector. The injector temperature was 280  $^{\circ}\text{C}$  and the sample injection volume was 1  $\mu\text{L}$ . Helium gas was used as a carrier gas with a flow rate of 1  $\text{ml min}^{-1}$  with a split ratio of 30. The chromatographic separation involves two columns: a mid-polar phase column VF-1701 MS (30 m  $\times$  250  $\mu\text{m}$   $\times$  0.25  $\mu\text{m}$ ) and a non-polar phase column DB-5MS UI (1.2 m  $\times$  150  $\mu\text{m}$   $\times$  0.15  $\mu\text{m}$ ). Modulation time on the modulator is 8 s. The oven temperature was initially set at 40  $^{\circ}\text{C}$  for 1 min and then heated up to 280  $^{\circ}\text{C}$  at a rate of 2  $^{\circ}\text{C min}^{-1}$ . The flame ionization detector temperature was set at 250  $^{\circ}\text{C}$ . The analysis was performed using the GCImage software for multidimensional chromatography.

## 3. Results and discussion

### 3.1 Catalyst characterization

Table 2 lists the specific surface area, pore-volume, and pore size of the unsupported  $\text{MoS}_2$  catalysts in this study, and a bulk  $\text{MoS}_2$  sample. The specific surface area decreased in the order:  $\text{MoS}_2\text{-24a} > \text{MoS}_2\text{-12a} > \text{MoS}_2\text{-24} > \text{MoS}_2\text{-12} > \text{bulk MoS}_2$ . The results suggested that prolonging the synthesis time has a negligible effect on the specific surface area of the synthesized catalyst with  $\text{MoS}_2\text{-24}$  being 16.2  $\text{m}^2 \text{g}^{-1}$  while  $\text{MoS}_2\text{-12}$  was 15.4  $\text{m}^2 \text{g}^{-1}$ . However, the specific surface area of the annealed samples of  $\text{MoS}_2\text{-12a}$  and  $\text{MoS}_2\text{-24a}$  were 27.8  $\text{m}^2 \text{g}^{-1}$  and 37.1  $\text{m}^2 \text{g}^{-1}$ , respectively. The  $\text{N}_2$  adsorption-desorption isotherms for all studied catalysts are shown in Fig. S2.† The isotherms for the annealed  $\text{MoS}_2$  catalysts can be characterized as type IV isotherms following the IUPAC classification.<sup>37</sup> A prominent H3 type hysteresis loop can also be observed for both annealed  $\text{MoS}_2$  samples, featuring slit-shaped pores created by the build-up of  $\text{MoS}_2$  layers. While for the as-synthesized and bulk  $\text{MoS}_2$ , type II isotherms can be identified that are distinctive of material with a non-porous character. The observation can be explained by the agglomeration of particles forming larger lumped particles with reduced porosity as will be evident from the SEM images (discussed later in this section). The larger pore size exhibited by the  $\text{MoS}_2\text{-24}$  also indicates that prolonging the synthesis time resulted in a mixture of large and small particles forming larger cavities. While the results also showed that the annealing process significantly increased the specific surface area and porosity of the unsupported catalysts. It is important to highlight that this porosity was created by the shrinkage of particles during annealing and during the formation of  $\text{MoS}_2$  crystals (evident from XRD analysis, discussed later in this section), they were re-coordinated and agglomerated to generate cavities. It is also worth noting that  $\text{MoS}_2\text{-12a}$  has the highest pore volume and the smallest pore size among all unsupported catalysts.

The X-ray diffraction (XRD) patterns for all  $\text{MoS}_2$  unsupported catalysts are shown in (Fig. 1a) indicating the crystallinity and phase purity of the  $\text{MoS}_2$  catalysts. As can be observed from the XRD patterns, the as-synthesized samples showed a very low crystallinity with a small peak at  $2\theta = 14^{\circ}$  indicating the typical (0 0 2) plane of hexagonal  $\text{MoS}_2$ . The results confirmed that doubling the synthesis time from 12 h to 24 h did not improve the crystallinity of the samples. On the other hand, for both the annealed  $\text{MoS}_2$  samples, prominent peaks can be observed at  $2\theta = 14^{\circ}$ ,  $33^{\circ}$ ,  $39^{\circ}$ , and  $59^{\circ}$  attributed to the (002), (100), (103) and (110) planes of  $\text{MoS}_2$ .<sup>38</sup> The increase in the crystallinity of the as-synthesized  $\text{MoS}_2$  after a simple annealing treatment suggests that the annealing process at 400  $^{\circ}\text{C}$  for 2 h can promote the growth of  $\text{MoS}_2$  crystals. In comparison, the bulk  $\text{MoS}_2$  is highly crystalline as can be observed from the XRD pattern.

Additionally, Raman spectroscopy was performed to corroborate with XRD patterns and at the same time, to study the chemical state of the as-synthesized and annealed catalysts. The Raman spectrum of  $\text{MoS}_2\text{-24}$  and  $\text{MoS}_2\text{-24a}$  were obtained

**Table 2** Physical properties (surface area, pore-volume, and pore size) and HRTEM analysis of the synthesized unsupported catalysts and bulk MoS<sub>2</sub>

| Catalysts             | Surface area (m <sup>2</sup> g <sup>-1</sup> ) | Pore volume (cm <sup>3</sup> g <sup>-1</sup> ) | Pore size (Å) | Average MoS <sub>2</sub> slab length ( $\Delta L$ ) | Average stacking number ( $\Delta n$ ) | MoS <sub>2</sub> dispersion ( $f_{mo}$ ) | Edge-to-corner ratio of MoS <sub>2</sub> slabs |
|-----------------------|--|--|---------------|---|--|--|--|
| MoS <sub>2</sub> -12  | 15.4   | 0.34   | 108           | 5.07  | 4.01                                   | 0.150                                    | 6.42   |
| MoS <sub>2</sub> -12a | 27.8   | 0.60   | 83.8          | 8.41  | 2.72                                   | 0.103                                    | 11.6   |
| MoS <sub>2</sub> -24  | 16.2   | 0.13   | 317           | 6.58  | 3.26                                   | 0.130                                    | 8.78   |
| MoS <sub>2</sub> -24a | 37.1   | 0.11   | 105           | 8.71  | 3.85                                   | 0.105                                    | 12.1   |
| Bulk MoS <sub>2</sub> | 4.70   | 0.03   | 177           | —   | —                                      | —  | —  |

and the results are presented in (Fig. 1b). For MoS<sub>2</sub>-24a catalysts, four main Raman peaks located at 379 cm<sup>-1</sup> (E<sub>2g</sub><sup>1</sup>), 404 cm<sup>-1</sup> (A<sub>1g</sub>), 283 cm<sup>-1</sup> (E<sub>1g</sub>), and 454 cm<sup>-1</sup> (E<sub>1g</sub>) indicate that the usual 2H-MoS<sub>2</sub> phase can be observed.<sup>39</sup> Moreover, two low-intensity Raman peaks at 219 cm<sup>-1</sup> and 335 cm<sup>-1</sup> can be identified in the spectra for MoS<sub>2</sub>-24a proving the existence of the 1T phase of MoS<sub>2</sub>.<sup>39</sup> The results indicate that the annealing pre-treatment changes the structure of the as-synthesized catalysts and resulted in mixed 1T and 2H phases of MoS<sub>2</sub>. In contrast, for MoS<sub>2</sub>-24 catalysts, three peaks can be identified as shown in (Fig. 1b) with a relatively lower intensity showing the lower crystallinity of the as-synthesized catalyst.

X-ray photoelectron spectroscopy (XPS) was carried out to determine the chemical state and composition of the unsupported MoS<sub>2</sub> catalysts before and after the annealing treatment (Fig. 2). The Mo 3d spectrum in (Fig. 2a and c) were deconvoluted into three Mo 3d<sub>5/2</sub>-Mo 3d<sub>3/2</sub> doublets for the as-synthesized samples. Two characteristic peaks at 229.3 eV and

232.5 eV binding energies correspond to the presence of the Mo<sup>4+</sup> oxidation state, indicating the MoS<sub>2</sub> species.<sup>40</sup> For the Mo<sup>5+</sup> oxidation state, characteristic peaks at binding energies 230.0 eV and 233.0 eV can be identified, which demonstrate the presence of intermediate oxysulfide species (MoO<sub>x</sub>S<sub>y</sub>) in the as-synthesized catalysts.<sup>41</sup> An additional doublet at 233.4 eV and 235.8 eV associated with the Mo<sup>6+</sup> oxidation state which is associated with the MoO<sub>3</sub> species can be found.<sup>42</sup> Table 3 reports the Mo 3d composition of the Mo states obtained from the XPS data. It can be noticed that the sulfidation degree based on the Mo<sup>4+</sup> content increased for both annealed MoS<sub>2</sub> as compared to the as-synthesized unsupported catalysts with MoS<sub>2</sub>-24a having the highest degree and corresponding lowest degree of oxidation of Mo. The presence of oxysulfide species in the as-synthesized catalysts can be explained by one of the reactions that are expected to occur during the synthesis of MoS<sub>2</sub>, where the (NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub> reacts with H<sub>2</sub>S forming MoO<sub>x</sub>S<sub>y</sub>, ammonia, and water. However, the oxysulfide species

| Catalyst              | Mo 3d composition (area %) |                  |                  |
|-----------------------|----------------------------|------------------|------------------|
|                       | Mo <sup>4+</sup>           | Mo <sup>5+</sup> | Mo <sup>6+</sup> |
| MoS <sub>2</sub> -12  | 62.9                       | 22.2             | 14.9             |
| MoS <sub>2</sub> -12a | 88.6                       | —                | 11.4             |
| MoS <sub>2</sub> -24  | 82.9                       | 11.3             | 5.8              |
| MoS <sub>2</sub> -24a | 93.1                       | —                | 6.9              |

were not observed for both annealed catalysts. This result suggests that the MoO<sub>x</sub>S<sub>y</sub> phase may have been completely converted into MoS<sub>3</sub> and the annealing pretreatment can further facilitate the thermal decomposition of MoS<sub>3</sub> to MoS<sub>2</sub>.

The morphologies of the unsupported catalysts in this study (Fig. 3) were examined by scanning electron microscopy (SEM). Spherical particle agglomerates can be observed in the SEM images which are due to the laminar growth of the MoS<sub>2</sub> during hydrothermal synthesis. The average particle diameter was measured based on the SEM images using ImageJ software and the distribution of the particle size is shown in the insets of Fig. 3. As can be seen in Fig. 3e and f, the MoS<sub>2</sub>-24 catalyst, consists of a mixture of larger and smaller particles with an average particle diameter of 305 nm. A similar morphology can also be observed for MoS<sub>2</sub>-12 (Fig. 3a and b). While for the MoS<sub>2</sub>-24a catalyst, the SEM images revealed that the MoS<sub>2</sub> particles dispersed and distributed more uniformly with a smaller

average particle diameter of 190 nm. A more defined morphology can also be observed in the annealed catalysts. The result suggested that the annealing treatment resulted in a reduction of particle diameter and a narrower size distribution of particles. To evaluate the influence of the pH adjustment on the morphology of MoS<sub>2</sub>, a batch of unsupported MoS<sub>2</sub> was prepared following the same procedure, excluding the pH adjustment as described in the experimental section. The following batch was then examined by SEM and resulted in Fig. 4. A sharper and apparent flower-like morphology can be observed in the SEM image with a larger average particle diameter of 2 μm. Interestingly, this is almost the average particle size for the bulk MoS<sub>2</sub> sample (6 μm, max 40 μm). The results presented here are in line with the findings from Zhang *et al.*<sup>43</sup> The pH adjustment step in the catalyst synthesis was crucial to enhance the growth of MoS<sub>2</sub> micelles that eventually formed smaller crystallites in the MoS<sub>2</sub> catalysts. While the MoS<sub>2</sub> prepared without acid addition resulted in a larger particle size.

High-resolution transmission electron microscopy (HRTEM) was also performed to understand the effect of annealing on the structure of the unsupported catalyst, and the images are presented in Fig. 5. The usual thread-like fringes with an interplanar distance of 0.64 nm corresponding to the (0 0 2) basal planes of MoS<sub>2</sub> can be identified in all of the HRTEM images. One apparent difference that can be observed from the HRTEM images for the annealed catalysts was that the edges show a spiky feature that was not observed in the as-synthesized

Fig. 3 SEM images of (a and b) MoS<sub>2</sub>-12, (c and d) MoS<sub>2</sub>-12a, (e and f) MoS<sub>2</sub>-24, and (g and h) MoS<sub>2</sub>-24a.

catalysts. This difference in the character of the edges of the as-synthesized and annealed catalysts is indicated by the arrows in Fig. 5. The red arrows indicated more rounded edges as can be observed for the as-synthesized catalysts. The yellow arrows indicated the sharp edges for the annealed catalysts. The changes in the structure near the edges of the catalyst after the annealing process could be due to the further enhancement in the growth of the smaller MoS<sub>2</sub> crystallites from the as-synthesized catalysts. This further demonstrates the importance of the annealing treatment that changes the structure of the catalysts. Consequently, the spiky edges of the annealed

unsupported catalysts contribute to their higher specific surface area and exposure of more active sites for the HDO reaction. Owing to the interesting features of the as-synthesized and annealed catalysts, additional representative HRTEM micrographs (Fig. S3<sup>†</sup>) including 500–550 MoS<sub>2</sub> slabs were analyzed to study changes in the microstructure of the unsupported catalysts. The quantitative comparison of the average slab lengths, stacking layer number, MoS<sub>2</sub> dispersion, and the edge-to-corner of MoS<sub>2</sub> slabs are presented in Table 2. The distributions for the MoS<sub>2</sub> stacking numbers and slab length are shown in Fig. S4.<sup>†</sup> The average slab length for MoS<sub>2</sub> increases after the annealing

Fig. 4 SEM image for  $\text{MoS}_2$  prepared without pH adjustment.

treatment and the same trend was observed for both the 12 hours and 24 hours samples. The increase in average slab length also leads to a higher edge-to-corner ratio of  $\text{MoS}_2$  slabs for both annealed samples. Both as-synthesized catalysts ( $\text{MoS}_2$ -12 and  $\text{MoS}_2$ -24) show a 'defect-less' feature and a more curved

Scheme 1 Schematic illustration for the preparation of unsupported  $\text{MoS}_2$  with annealing treatment.

multi-layered structure as indicated by the red arrows in the HRTEM images (Fig. S3<sup>†</sup>). On the other hand, the  $\text{MoS}_2$  fringes in the annealed catalysts ( $\text{MoS}_2$ -12a and  $\text{MoS}_2$ -24a) are more randomly stacked and the sharp edges can be observed. These special features that can only be observed in the annealed catalysts confirm the greater presence of defect sites. The schematic illustration of the formation of unsupported  $\text{MoS}_2$  and changes in properties due to the annealing treatment is shown in Scheme 1.

Fig. 6 Reaction product selectivity and conversion at 4 h for HDO of PG over MoS<sub>2</sub>-12, MoS<sub>2</sub>-12a, MoS<sub>2</sub>-24, and MoS<sub>2</sub>-24a at 50 bar total H<sub>2</sub> pressure, 300 °C, and 1000 rpm.

### 3.2 Catalytic performance test using 4-propylguaiacol and kraft lignin

#### 3.2.1 Hydrodeoxygenation of 4-propylguaiacol (PG) over unsupported MoS<sub>2</sub> catalysts. The effects of catalyst synthesis

time and the annealing pretreatment on the PG conversion and product selectivity were studied for HDO of 4-propylguaiacol (PG) over unsupported MoS<sub>2</sub> at 50 bar total H<sub>2</sub> pressure, 300 °C and 1000 rpm. The reaction product selectivity and PG conversion after 4 h is illustrated in Fig. 6. Fig. 7 presents the time evolution of the conversion and product selectivity of the studied catalysts during a reaction period of 5 h. The deoxygenation route for PG occurred first *via* the removal of the methoxy group forming 4-propylphenol as the main initial intermediate. This observation indicates the initial preferential demethoxylation, followed by dehydroxylation since the methoxy bond connected to the phenyl ring is easier to break.<sup>44</sup> Then 4-propylphenol undergoes dehydroxylation producing 4-propylbenzene ('aromatics' in Fig. 6 and 7). The produced 4-propylbenzene was further hydrogenated forming 4-propylcyclohexene and 4-propylcyclohexane ('deoxygenated cycloalkanes' in Fig. 6 and 7). Reaction products that contain two oxygen atoms like 4-propylcatechol were also formed at the beginning of the reaction, but then their yield gradually decreased as the reaction proceeded. These products are referred to as '2O-compounds' in Fig. 6 and 7. A proposed reaction scheme for HDO of PG is shown in Scheme 2 based on the obtained results.

In Fig. 6, it can be seen that there was an improvement in the conversion of PG when the as-synthesized catalysts' synthesis

Fig. 7 Reaction product distribution for HDO of PG over (a) MoS<sub>2</sub>-12 (b) MoS<sub>2</sub>-12a (c) MoS<sub>2</sub>-24 and (d) MoS<sub>2</sub>-24a at 50 bar total H<sub>2</sub> pressure, 300 °C and 1000 rpm.

Scheme 2 Reaction scheme for HDO of PG over unsupported  $\text{MoS}_2$  at 50 bar total  $\text{H}_2$  pressure, 300 °C, and 1000 rpm.

time was increased from 12 h to 24 h. The PG conversion reached 90.1% using  $\text{MoS}_2$ -12, while almost complete conversion was achieved for  $\text{MoS}_2$ -24 after 4 h of reaction. There was also a difference in the selectivity for deoxygenated cycloalkanes like 4-propylcyclohexane and 4-propylcyclohexene where they were 27.5% and 43.4% for  $\text{MoS}_2$ -12 and  $\text{MoS}_2$ -24, respectively. On the other hand, the intermediate 4-propylphenol stayed in the range of between 47% and 48% selectivity after 4 h for both as-synthesized catalysts. In a previous study conducted by Wu *et al.*,<sup>45</sup> 34.7% selectivity for 4-propylphenol and 99.2% PG conversion were reported after 6 h of reaction at 300 °C showing a comparable result obtained with the as-synthesized catalyst in this study. The difference in results is likely due to the differences in the preparation methods, where they introduced silicomolybdic acid during the synthesis of their hydrophobic unsupported  $\text{MoS}_2$  catalyst.<sup>45</sup> There was also a three times difference in the selectivity for 4-propylcatechol (2O-compound) with 24.7% for  $\text{MoS}_2$ -12 and decreasing to 8.3% for  $\text{MoS}_2$ -24, taking 4 h as a reference reaction time.

Both as-synthesized catalysts further underwent an annealing treatment at 400 °C for 2 h under nitrogen flow and were tested for HDO of PG. It can be noted from Fig. 7b and d that there was a change in product selectivity with a clear increase in cycloalkanes selectivity to 76.6% and 60.5% after 5 h for  $\text{MoS}_2$ -12a and  $\text{MoS}_2$ -24a, respectively as compared to the catalysts without the annealing treatment (40% and 49.6% for  $\text{MoS}_2$ -12 and  $\text{MoS}_2$ -24, respectively). The selectivity for 4-propylphenol also showed a downward trend for both the annealed catalysts. For the  $\text{MoS}_2$ -12a catalyst, 4-propylphenol, the major intermediate, was fully deoxygenated after 5 h while the selectivity of 4-propylcatechol gradually decreased and disappeared after 3 h. Whereas, for the HDO of PG over  $\text{MoS}_2$ -24a, the same downward trend for 4-propylphenol selectivity was observed with a final 23.8% remaining at the end of the reaction. Moreover, the selectivity for 4-propylcatechol (2O-compound) was low at the beginning of the reaction already at 1 h for both annealed catalysts (11.3% and 19.0% for  $\text{MoS}_2$ -12a and  $\text{MoS}_2$ -24a, respectively) as compared to the as-synthesized catalysts (57.2% and 55.8% for  $\text{MoS}_2$ -12 and  $\text{MoS}_2$ -24, respectively).

Interestingly, for both annealed catalysts, an aromatic compound (4-propylbenzene) could be identified after 2 h of reaction and its selectivity gradually increased reaching 23.4% and 19.8% for  $\text{MoS}_2$ -12a and  $\text{MoS}_2$ -24a, respectively after 5 h. The observed results showed that a 2 h annealing step improved the PG conversion and gave 19–24% selectivity for aromatic compounds with the same reaction parameters. The yield of fully deoxygenated products observed after 5 h decreased in the order of:  $\text{MoS}_2$ -12a (100%) >  $\text{MoS}_2$ -24a (80.4%) >  $\text{MoS}_2$ -24 (49.6%) >  $\text{MoS}_2$ -12 (40.0%). The absence of propylbenzene in the case of as-synthesized catalysts ( $\text{MoS}_2$ -12 and  $\text{MoS}_2$ -24) is mainly attributed to the higher amount of corner sites as indicated by the edge-to-corner sites ratio (Table 2) which is beneficial for hydrogenation reaction.<sup>46</sup> It was noteworthy that, one of the intermediates, 4-propylcyclohexanol was not detected in the reaction product. This suggests that 4-propylphenol was rapidly hydrogenated and deoxygenated to 4-propylcyclohexene and propylcyclohexane. The present data shows that the HDO activity and reaction routes are dependent largely on the  $\text{MoS}_2$  morphology and a more favourable morphology is induced by a post thermal treatment of the as-synthesized catalysts as proposed in this work.

Additionally, for the as-synthesized catalysts, a longer synthesis time was preferred to achieve a better PG deoxygenation. While for the annealed catalysts, a shorter synthesis time was advantageous for PG deoxygenation. This could be reasoned by that the 12 h synthesis time is adequate to nucleate enough  $\text{MoS}_2$  crystallites and the annealing treatment can facilitate the  $\text{MoS}_2$  crystal growth with further rearrangement. Also, it is worth pointing out that  $\text{MoS}_2$ -12a achieved a full PG deoxygenation after 5 h even though the  $\text{MoS}_2$ -24a had a higher surface area while  $\text{MoS}_2$ -12a possessed the highest pore volume and the smallest pore size.

The difference in the catalytic performance of the annealed and as-synthesized unsupported  $\text{MoS}_2$  catalysts depends largely on the  $\text{MoS}_2$  morphology. For instance, the greater presence of defect sites as can be seen in the annealed catalysts in all the HRTEM images. These defect sites have been found to be important for creating more active sites, and further improving the HDO selectivity.<sup>26</sup> It should also be noted that these defect

sites contributed to the formation of additional edge active sites. It is noteworthy from the statistical analysis of the MoS<sub>2</sub> slabs (Table 2) for all catalysts that the annealing treatment increased the slab length of both MoS<sub>2</sub>-12 and MoS<sub>2</sub>-24. The longer MoS<sub>2</sub> slab length exhibited by the annealed catalysts correlates to the higher edge-to-corner ratio of the MoS<sub>2</sub> slabs. This also explained the higher HDO selectivity for both annealed catalysts which was attributed to the higher ratio of edge-to-corner of MoS<sub>2</sub> slabs. Thus, the annealing treatment proposed in this study was found to be able to create defect sites and further exposed MoS<sub>2</sub> edge sulfur vacancies for HDO activity enhancement.

To evaluate the performance of the unsupported MoS<sub>2</sub> prepared without the pH adjustment, both as-synthesized and annealed unsupported MoS<sub>2</sub> catalysts were employed for HDO of PG. The reaction product time evolution for both catalysts was measured, as shown in Fig. 8. A steady increase in PG conversion can be observed and a final PG conversion of 86.6% was obtained after 5 h for the as-synthesized MoS<sub>2</sub> prepared without acid addition. The selectivity for 4-propylphenol increased to 42.5% after 2 h and stabilized, reaching 40.8% at 5 h. A downward trend was observed for the selectivity for oxygenated intermediates (2O-compounds) giving a final selectivity of 19.5% (Fig. 8a). While for deoxygenated cycloalkanes product selectivity, a gradual increase in selectivity was observed achieving a final selectivity of 40%. The fresh as-synthesized MoS<sub>2</sub> (without acid) then underwent a similar annealing treatment as described previously and was applied for HDO of PG. Surprisingly, the annealing treatment, in this case, had a negative effect on the PG conversion, showing a final PG conversion of 74.2% after 5 h (Fig. 8b). Comparatively, there was a slight increase in the cycloalkanes selectivity, affording a final selectivity of 46.6% (Fig. 8b). While the selectivity for intermediate oxygenated compounds shows a decreasing trend with reaction time giving 36.6% selectivity for 4-propylphenol and 15.8% selectivity for 4-propylcatechol (2O-compounds) at the end of the reaction. From the clear difference in the product distribution for HDO of PG between the unsupported MoS<sub>2</sub> prepared in the presence and absence of acid addition, it can be

concluded that creating an acidic environment while synthesizing unsupported MoS<sub>2</sub> is crucial to produce MoS<sub>2</sub> with smaller particle size. As for the MoS<sub>2</sub> particle size, the resulting surface has a direct effect on the HDO selectivity. This result is in line with the conclusion outlined by Zhang *et al.*,<sup>43</sup> which shows that higher HDS and hydrogenation activities can be achieved using MoS<sub>2</sub> prepared in low pH values. The smaller MoS<sub>2</sub> particles synthesized under an acidic environment possessed more active sites, leading to a higher HDO selectivity. It was also worth mentioning that the annealing treatment proposed in this study has a positive enhancement on the HDO activity while using MoS<sub>2</sub> prepared with pH adjustment. While for MoS<sub>2</sub> prepared without pH adjustment, it has an opposite effect, especially on the PG conversion and apparently in this case does not facilitate the growth of MoS<sub>2</sub> crystals.

Moreover, the effect of different pretreatment atmospheres on the PG product evolution and catalytic activity was investigated. The usual annealed MoS<sub>2</sub> catalysts in this study were all pretreated under continuous nitrogen flow. We performed an additional experiment where MoS<sub>2</sub>-24 was annealed under air at 400 °C for 2 h and the PG conversion and products selectivity at 5 h are presented in Fig. S5.† PG was completely transformed after 5 h. Interestingly, a steady increase in the selectivity for 4-propylphenol can be observed, giving a final selectivity of 66.2%. High selectivity of 50% towards 4-propylcatechol (2O-compound) can be seen after 2 h which decreased abruptly to a final selectivity of 7%. The changes in the activity of the catalyst towards HDO could mainly be caused by changes in the nature and number of HDO active sites. These results also demonstrate the detrimental effect of an oxidative environment on the catalyst properties during annealing, which should result in producing more molybdenum oxysulfide species that are less favourable for HDO activity.<sup>47</sup>

To obtain a comparison in the HDO activity between the unsupported MoS<sub>2</sub> prepared in this work and commercially available bulk MoS<sub>2</sub>, we performed the HDO of PG under the same reaction conditions over the bulk MoS<sub>2</sub>, as shown in Fig. S6a.† Comparing the bulk MoS<sub>2</sub> and MoS<sub>2</sub>-12a, the conversion of PG on bulk MoS<sub>2</sub> reached only 81.3% after 5 h,

Fig. 8 Reaction product distribution for HDO of PG over (a) MoS<sub>2</sub> prepared without acid adjustment and (b) annealed MoS<sub>2</sub> without acid adjustment at 50 bar total H<sub>2</sub> pressure, 300 °C and 1000 rpm.

whereas for MoS<sub>2</sub>-12a, PG was fully converted after 4 h. Selectivity for 4-propylphenol increased after 2 h and reached 44.8% after 5 h for bulk MoS<sub>2</sub>. Selectivity for oxygenates like 4-propylcatechol (2O compound) was decreasing after 2 h and 26.9% remained at the end of the reaction. The poorer performance of the bulk MoS<sub>2</sub> could be reasoned by its 6 times lower specific surface area as compared to MoS<sub>2</sub>-12a and its average particle size of 6 μm, which results in very limited active site accessibility. The current results show that the unsupported MoS<sub>2</sub> prepared in this work gives a superior PG conversion and higher deoxygenation activity as compared to the commercial bulk MoS<sub>2</sub>.

The product distribution of unsupported MoS<sub>2</sub>-12a and MoS<sub>2</sub> supported on Al<sub>2</sub>O<sub>3</sub> (13.2 wt% Mo loading) catalyst was also compared. The experiments were performed with 500 mg and 66 mg of supported and unsupported catalysts, respectively. These different total masses of catalysts enabled a comparison of the catalysts based on an equal mass of the active component of Mo. The product evolution for the supported catalyst is shown in Fig. S6b.† The supported MoS<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> was prepared using a wetness impregnation method as described previously.<sup>33</sup> The use of a high surface area support during the synthesis of hydrotreatment catalysts ensures a high dispersion of the active phase that could provide more active sites for the HDO reaction to occur. A complete PG conversion was achieved after 2 h for the supported MoS<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst as compared to the 4 h needed for the unsupported MoS<sub>2</sub>-12a. The selectivity for deoxygenated cycloalkanes also increased steadily from 38.8% to 70.2% during 5 h of reaction for the supported MoS<sub>2</sub>. However, a two-fold higher aromatic selectivity (23.3%) could be obtained for MoS<sub>2</sub>-12a at the end of the reaction. It was worth highlighting that the use of a high surface area alumina for supporting MoS<sub>2</sub> resulted in a faster PG conversion achieving full conversion in just 2 h. However, it should be noticed that PG was fully deoxygenated after 5 h in the case of the MoS<sub>2</sub>-12a catalyst while 17.5% of 4-propylphenol selectivity can still be observed for the supported MoS<sub>2</sub> catalyst. These results show that a higher surface area is beneficial in improving the transformation of PG to various compounds but not the HDO activity. This is consistent with the conclusion made by Wang *et al.*,<sup>27</sup> stating that a higher specific surface area may not be the major factor in giving high HDO activity. Also, the active site density per mass active phase (MoS<sub>2</sub>) with the supported catalyst may be higher since it gives a higher PG conversion, however, the nature of these sites is undoubtedly different since the unsupported catalyst gave a higher degree of deoxygenation.

**3.2.2 Hydrotreatment of kraft lignin over an unsupported MoS<sub>2</sub> and bulk MoS<sub>2</sub>.** To extend the scope of the application of the annealed unsupported MoS<sub>2</sub> to a more complex and realistic bio-feedstock, kraft lignin was selected, which contains an array of oxygenates (hydroxyl, methoxy and various oxygenate linkages). Both MoS<sub>2</sub>-12a and bulk MoS<sub>2</sub> were employed in the hydrotreatment of kraft lignin at 340 °C and 40 bar initial H<sub>2</sub> pressure. The focus was on the analysis of the upgraded lignin oil fraction and quantifying its main groups of product compounds. A complete kraft lignin conversion could be

Fig. 9 GCMS analysis for the comparison of product selectivities and char yield between bulk MoS<sub>2</sub> and MoS<sub>2</sub>-12a for hydrotreatment of kraft lignin. Reaction conditions: 3 : 1 lignin to catalyst mass ratio, 340 °C, 40 bar initial H<sub>2</sub> pressure, 5 h, and 1000 rpm.

observed after 5 h of hydrotreatment for both catalysts, forming bio-oils and char. A 43% char yield was obtained for commercial bulk MoS<sub>2</sub> while it dropped to 27% for MoS<sub>2</sub>-12a. Fig. 9 presents a comparison between the selectivity of cycloalkanes, aromatics, and phenolic compounds obtained for both unsupported catalysts. The results indicate a notable difference between the chemical compositions of the upgraded lignin oil fractions. Due to the complexity of the lignin feed, a wide range of monomer and dimer products were expected from the lignin depolymerization due to hydrotreatment. Table S2† listed all the compounds in the lignin oil fraction that were identified and detected by the GC-MS according to their retention times with their individual selectivities (in terms of relative FID peak area %). The GC spectra for both catalysts are shown in Fig. S7.† The noticeable difference between both catalysts was that the major compounds in the lignin oil fraction for MoS<sub>2</sub>-12a were both cycloalkanes (*e.g.* methylcyclopentane, cyclohexane, methylcyclohexane, ethylcyclopentane, ethylcyclohexane, and propylcyclohexane) and aromatic compounds (*e.g.* toluene, 1,3-dimethylbenzene, and propylbenzene). However, for the bulk MoS<sub>2</sub> catalysts, oxygenates like guaiacol, creosol, 4-ethyl-2-methoxyphenol and propylguaiacol were the major compounds that remained in the lignin product mixture. All of the identified compounds in the GC spectrum were grouped and classified into cycloalkanes, aromatics, and phenolic compound groups as presented in Fig. 9. The reaction products were also subjected to 2D GC × GC analysis and the results as shown in Fig. 10 giving a qualitative illustration of the different product distributions. It is clearly visible from Fig. 10 that there is a difference in product distribution between bulk MoS<sub>2</sub> and MoS<sub>2</sub>-12a. The major products that can be observed in the GC × GC chromatogram for bulk MoS<sub>2</sub> (Fig. 10a) represented mainly phenolics components like guaiacol-derived components and alkylphenols. On the other hand, the highlighted blobs in the GC × GC chromatogram for MoS<sub>2</sub>-12a (Fig. 10b) are associated with deoxygenated compounds like naphthenes and aromatics with traces of polyaromatics. The blob intensities for oxygenates

Fig. 10 Chromatograms (2D GC  $\times$  GC-MS-FID) of the reaction liquid products obtained in the hydrotreatment of kraft lignin over (a) Bulk  $\text{MoS}_2$  and (b)  $\text{MoS}_2$ -12a.

are clearly reduced as can be seen in the chromatograms for  $\text{MoS}_2$ -12a (Fig. 10b). A total selectivity of 90.5% for phenolics and only 8.3% of cycloalkanes were observed using the bulk  $\text{MoS}_2$ . In contrast, 78.6% of cycloalkanes and 20.1% of aromatic selectivity were achieved in the case of  $\text{MoS}_2$ -12a.

The higher deoxygenation achieved in kraft lignin hydro-treatment for the annealed unsupported  $\text{MoS}_2$ -12a as compared to the bulk  $\text{MoS}_2$  is consistent with the results for the model reaction, HDO of PG. Also, the formation of carbonaceous solid products (char) from the re-polymerization or condensation of lignin fragments is less in the case of the synthesized unsupported  $\text{MoS}_2$ . This indicates that a catalyst with high activity and accessibility of sites for deoxygenation and hydrogenation reactions is important to prevent these char formation reactions.

## 4. Conclusions

In summary, a facile hydrothermal synthesis method has been successfully employed to prepare unsupported  $\text{MoS}_2$  catalysts and the work also revealed the significance of a post-thermal annealing treatment to the as-synthesized catalysts for enhancing HDO performance. Increasing the synthesis time from 12 h to 24 h has an overall positive effect on the PG conversion and deoxygenated cycloalkanes selectivity. For instance, a complete PG conversion was achieved using  $\text{MoS}_2$ -24, while 90.1% PG conversion was obtained for  $\text{MoS}_2$ -12 after 4 h. There was also a 1.6-fold higher deoxygenated cycloalkanes selectivity for  $\text{MoS}_2$ -24 as compared to  $\text{MoS}_2$ -12 after 4 h of

reaction. An annealing treatment of the as-synthesized catalysts performed at 400 °C for 2 h under nitrogen atmosphere was found to have a remarkable effect on the HDO activity. The present results in this work indicated that the annealing treatment was found to be effective in the creation of a greater abundance of defect sites that further enhance HDO activity. An increase in deoxygenated cycloalkane selectivity was observed for both annealed samples, with 76.6% for  $\text{MoS}_2$ -12a and 60.5% for  $\text{MoS}_2$ -24a after 5 h. Moreover, an aromatic compound like 4-propylbenzene could be detected for both annealed samples after 2 h which was not the case for the as-synthesized catalysts. The  $\text{MoS}_2$  morphology change caused by the annealing for both as synthesized catalysts also contributed to differences in HDO activity and reaction routes. The fully deoxygenated product yields after 5 h was ranked in the following order:  $\text{MoS}_2$ -12a (100%) >  $\text{MoS}_2$ -24a (80.4%) >  $\text{MoS}_2$ -24 (49.6%) >  $\text{MoS}_2$ -12 (40.0%). It was found that the longer synthesis time was advantageous to achieve a higher PG deoxygenation for as-synthesized catalysts, however for the annealed samples, a shorter synthesis time was better. It can be hypothesized that 12 h synthesis time is sufficient to nucleate enough  $\text{MoS}_2$  crystals that undergo crystallite growth and rearrangement during the annealing treatment for a high yield of optimal crystal size and morphology for HDO activity. Also, the acidic environment during the synthesis was important to promote the growth of  $\text{MoS}_2$  crystals which has a direct effect on the HDO activity. The effect of annealing on the samples prepared without pH adjustment was studied and it was shown to have an adverse effect on the PG conversion and therefore did not facilitate the further growth of the  $\text{MoS}_2$  crystallites.

There was an increase in crystallinity of  $\text{MoS}_2$  after the annealing treatment based on XRD analysis. These changes were consistent with observations of particle size and  $\text{MoS}_2$  structure according to SEM and TEM analysis. The  $\text{MoS}_2$  particles had a more uniform and reduced average particle size after the annealing treatment. The absence of the molybdenum oxysulfide species in the annealed catalysts was consistent with higher  $\text{MoS}_2$  yield and improved activity for HDO of PG. The clear difference in product distribution and selectivity for  $\text{MoS}_2$  annealed under nitrogen and air atmosphere suggested that an inert environment during annealing was vital to avoid oxidation during the annealing process. We further compared the HDO activity between the unsupported  $\text{MoS}_2$  with alumina-supported  $\text{MoS}_2$ , using the same Mo content in both experiments, and concluded the differences in the nature of the active sites of the catalysts may explain their different final degrees of deoxygenation.

Additionally, the application of the annealed  $\text{MoS}_2$  was further demonstrated in the hydrotreatment of kraft lignin. The higher deoxygenation activity of the annealed unsupported  $\text{MoS}_2$  was found to be vital for achieving a lower char yield from the lignin. The high selectivity for deoxygenated products in the liquid products revealed the feasibility of utilizing unsupported catalytic materials for the upgrading of renewable bio-feedstocks.
