Spatial reactant distribution in CO₂ electrolysis: balancing CO₂ utilization and faradaic efficiency†

Siddhartha Subramanian,  Joost Middelkoop and Thomas Burdyny *

The production of value added C1 and C2 compounds within CO₂ electrolyzers has reached sufficient catalytic performance that system and process performance – such as CO₂ utilization – have come more into consideration. Efforts to assess the limitations of CO₂ conversion and crossover within electrochemical systems have been performed, providing valuable information to position CO₂ electrolyzers within a larger process. Currently missing, however, is a clear elucidation of the inevitable trade-offs that exist between CO₂ utilization and electrolyzer performance, specifically how the faradaic efficiency of a system varies with CO₂ availability. Such information is needed to properly assess the viability of the technology. In this work, we provide a combined experimental and 3D modelling assessment of the trade-offs between CO₂ utilization and selectivity at 200 mA cm⁻² within a membrane-electrode assembly CO₂ electrolyzer. Using varying inlet flow rates we demonstrate that the variation in spatial concentration of CO₂ leads to spatial variations in faradaic efficiency that cannot be captured using common 'black box' measurement procedures. Specifically, losses of faradaic efficiency are observed to occur even at incomplete CO₂ consumption (80%). Modelling of the gas channel and diffusion layers indicated that at least a portion of the H₂ generated is considered as avoidable by proper flow field design and modification. The combined work allows for a spatially resolved interpretation of product selectivity occurring inside the reactor, providing the foundation for design rules in balancing CO₂ utilization and device performance in both lab and scaled applications.

Introduction

One of the emerging technologies to mitigate fossil fuel-based carbon emissions is the electrochemical conversion of CO₂ to fuels and value-added products. In electrochemical CO₂ reduction, an electric potential is applied in the presence of an appropriate catalyst to convert CO₂ and H₂O to syngas (CO + H₂), ethylene (C₂H₄), ethanol (C₂H₅OH) and formate (HCOOH) among other products.^{1–4} To meaningfully mitigate CO₂ emissions and be cost-competitive with alternative production routes, CO₂ electrolyzers will need to be proven as scalable to global production rates on the order of 100's of Mtons per year.^{5–7} While water electrolyzers are developmentally able to reach such scales, CO₂ electrolyzers are at a much earlier stage of development. Thus, while producing an anthropogenic carbon cycle composed of converting atmospheric CO₂ to fuels using solar and other renewable energy sources is appealing, additional research and development is needed to improve the performance metrics and scale of the technology for it to become a viable option.^{8–10}

To perform research into CO₂ electrolyzers at increased production rates, a greater fraction of research has taken place under elevated current densities (>100 mA cm⁻²), using either high pressure systems or gas diffusion electrodes to enhance the availability of CO₂ at the catalyst surface. Gas diffusion electrodes (GDE) in particular have been found to be promising due to their ease of operation at atmospheric conditions which lowers the barrier for research to adopt their use.^{11–13} When paired with novel catalyst architectures and cell designs, CO₂ electrolysis on GDEs has then achieved current densities on the order of 1 A cm⁻² for promising products such as both CO¹⁴ and ethylene¹⁵ with reasonable faradaic efficiencies and cell voltages. Additionally, some researchers have begun discussing the importance of CO₂ utilization (as known as single-pass conversion efficiency) within such systems. Separate works have assessed the maximum conversion for a given configuration,¹⁶ the crossover of the CO₂ to the anode as carbonate,¹⁷ and the observed drop in faradaic efficiency at higher CO₂ utilizations.¹⁸ Such research has made it clear that trade-offs will ultimately exist between the traditional performance metrics of the CO₂ electrolyzer itself (current density, faradaic efficiency, overpotential), and the efficiency and cost of the entire CO₂ conversion process consisting of upstream and downstream processes.¹⁹

The balance between CO₂ utilization and faradaic efficiency is particularly interesting as these metrics are directly impacted by the gas flow rate, the applied current density, temperature and the electrolyte alkalinity, all of which affect the CO₂ that is available for conversion. For example, Jeng *et al.*¹⁶ highlighted the trade-off between partial current density for CO and the fraction of CO₂ converted to products for a 25 cm² membrane-electrode assembly (MEA) CO₂ electrolyzer under various operating conditions, noting a consistent maximum CO₂ utilization of 43% for the given reaction. While such observations provide valuable information around CO₂ utilization in such systems, the trade-off in faradaic efficiency with CO₂ utilization under varying CO₂ concentrations has received less attention and is less well-described. Specifically, while the CO₂RR faradaic efficiency of a system under excess flow conditions can be determined using either a high gas flow rate or a very small geometric surface area (*e.g.* <1 cm²), the selectivity of the system under decreasing CO₂ partial pressures is less clear with only a few studies available.²⁰ Importantly, as the surface area of standard test cells increases, *the concentration of CO₂ will also vary spatially throughout the reactor*, leading to spatial differences in reactivity and faradaic efficiency that will need to be understood to scale-up and optimize the technology.

While the influence of spatial reactant distribution on performance has not been well-investigated in the CO₂ electrolysis community, there is a wealth of research in the fuel cell community assessing the influence of reactant concentrations, flow patterning and under-rib convection on efficiency, utilization and mass transport on the overall performance of the device.^{21–24} Using previous electrochemical fields as a guidepost, it is apparent that understanding the spatial variation of selectivity within a CO₂ electrolyzer device will also be an essential step towards scaling-up such devices as well as choosing configurations which maximize CO₂ utilization without unnecessary penalties in selectivity. For CO₂ electrolysis, these efforts are complicated by competing and homogeneous reactions which poses additional challenges as compared to well-studied parallel electrochemical fields. There is also less data presently available evaluating the performance differences between different flow fields for the gaseous CO₂ channel as most research is performed using smaller geometric catalyst areas and a fully open cavity.

Here, we sought to provide a framework for how reactant flow rate and spatial CO₂ distribution impacts product selectivity at higher CO₂ utilizations using a well-utilized electrochemical testing platform. Firstly, we performed CO₂ electrolysis using a silver (Ag) gas diffusion electrode in a 5 cm² MEA at various reactant flow rates to determine the macroscopic influence on product selectivity. From these experiments a 'black box' evaluation of faradaic efficiencies (FE) at various CO₂ utilizations is defined. We then built a 3D mass transport model of the cathode side of the MEA to estimate the spatial CO₂ distribution inside the reactor and catalyst layer under each of the varying flow conditions to convert the 'black box' results of the CO₂ distribution throughout the 5 cm² cell into a more spatially resolved interpretation of reactant concentration at the catalyst's surface (Fig. 1). Finally, we show

that by using a combined experimental and modelling approach, the influence of reactant flow rate and spatial CO₂ distribution can in turn be used to predict a spatial product selectivity across the device. Once defined, such a combined experimental and modelling system can then be used to predict the impacts of varying flow fields, cell areas and current densities, providing the groundwork for designing and prototyping CO₂ electrolyzers which balance CO₂ utilization with product selectivity.

Results and discussion

Product quantification within gaseous-fed CO₂ electrolyzers is presently performed by measuring the composition of the outlet gas phase using a gas chromatography (GC), and measuring the composition of the liquid electrolyte phases using nuclear magnetic resonance spectroscopy (NMR) or high performance liquid chromatography (HPLC). Such measurements provide a point-in-time 'black box' interpretation of the FE at a given flow rate, current density and configuration that can be monitored through periodic measurements (Fig. 1a). At elevated inlet flow rates where CO₂ utilizations are low, the outlet gas stream remains >90% CO₂ and it is subsequently assumed that ample CO₂ can reach the entire catalytic surface area. In other words, no specific area of the catalyst surface exhibits mass transport limitations and the faradaic efficiency is assumed to be equal across the entire catalyst area (*e.g.* FE ≠ *f*(*x,y*)). Such an assumption is particularly valid for smaller catalyst areas, high CO₂ flow rates and open cavity gas channels which are assumed as well-mixed and maintained at similar temperature and pressures.

As industrial and lab geometric cell areas increase, CO₂ must be distributed to the GDL and catalyst area through flow fields, which are also critically acting as a current collector to ensure homogenous electrode potentials. Within these CO₂ flow channels, the reactant and product compositions will then change along the length of each flow channel²⁵ as the catalyst consumes CO₂ and produces products such as CO and H₂. In cases where CO₂ utilizations are increased, spatial variations in performance and selectivity will occur when areas of the catalyst no longer have access to sufficient CO₂, and produce unwanted H₂ instead (see Fig. 1b for representation).^{26–28} To begin assessing this trade-off we first collected a data set under varying flow rate conditions for CO₂ conversion to carbon-monoxide (CO) on a silver (Ag) catalyst in a membrane-electrode assembly with a serpentine flow field of 5 cm² geometric area (Fig. S2†).

For the data set we performed electrolysis at a constant current density of 200 mA cm⁻² for 3600 seconds at inlet CO₂ flow rates between 10 and 50 sccm. The gas products and unreacted CO₂ were quantified using a mass-flow metre (MFM) and GC installed at the exit of the reactor (Fig. 1a). As shown in Fig. 2a, we found that at excess flow rates between 20 and 50 sccm the faradaic efficiency of CO₂ reduction products (CO and formate) was maintained between 93–97%, indicating that sufficient reactant is available throughout the system. At lower flow rates (<20 sccm), however the FE of hydrogen begins

increasing steadily with increasing CO_2 utilization, reaching an H_2 selectivity of 38.9% at 10 sccm and a measured CO_2 utilization of $\sim 50\%$ (Fig. 2b). Over the entire examined region, CO_2

utilization decreases with an increase in the inlet flow rate from 50.8% at 10 sccm to 16.8% at 50 sccm as shown in Fig. 2b. The highlighted grey region in Fig. 2a and b represents the likely

operating region of a commercial CO₂ electrolyzer as it best balances selectivity and utilization. Understanding and quantifying the performance trade-off is necessary to manufacture performance curves for CO₂ electrolyzers, similar to other applications where trade-offs exist (e.g. centrifugal pumps). Such data is essential for positioning CO₂ electrolyzers within integrated process and cost models that assess a broad operational parameter space. Additionally, better design of the reactant flow fields and gas-diffusion layers may improve performance further.

To better quantify the trade-off in utilization and selectivity, the available CO₂ for reduction in the system must be known. To track this a carbon balance of the system is performed at various flow rates (Fig. 2c). In this analysis the inlet and outlet flow rates of CO₂, CO and formate are all measured directly, with the exception of CO₂ crossing the membrane as carbonate ions which was assumed to complete the carbon balance. Observing the trends in carbon flow rates, two interesting points arise. First, even under low flow rates of 10 sccm, some CO₂ is observed in the outlet of the reactor (~5%/v) even though the reaction appears CO₂-limited. This indicates a measure of transport limitations between the serpentine gas channel and the catalyst's surface as a result of transport through the gas-diffusion media and into the catalyst layer. And second, the consumption of CO₂ by OH⁻ ions is non-linear and varies with the availability of CO₂ throughout the reactor. Both of these observations can be qualitatively interpreted from the presented data, but lack a quantitative interpretation in their present form as a result of the 'black box' measurement approach. Thus, a numerical transport model built upon the experimental results can be used to provide further understanding.

Modelling CO₂ spatial distribution

To gain deeper understanding of the reactant distribution inside the reactor, a 3D model of the mass transport and fluid flow in the cathode compartment of the MEA cell was created using COMSOL Multiphysics (Fig. 3a). The ultimate goal of the model is to provide a simple estimate of the concentration of CO₂ at the surface of the catalyst layer for various operating conditions, which can then be used to predict a spatial and average faradaic efficiency ($FE = f(x,y)$ and FE_{average}). The predicted average FE of the system in particular provides a comparison to the experimental data, while the spatial assessment is useful to advance performance further and for the design of scaled systems beyond 5 cm².

Included within the model are the CO₂ serpentine gas channel and a gas-diffusion layer composed of a carbon fibre backing and a microporous layer (Fig. S6†). The gas-diffusion electrode is then modelled as a porous media similar to other works.²⁹ In the model an inlet flux of CO₂ is provided to the system in the gas channel, while a fixed current density is imposed at the surface of the gas-diffusion electrode to model the electrochemical reactions and consumption of CO₂ by the electrolyte. The physical parameters and properties used in the model are shown in Table S6.†

Due to the complexity of constructing a fully-representative macroscopic and nanoscopic transport model, we have chosen to set our system boundaries at the interface of the microporous layer and the catalyst layer. The model then does not directly take into account the interaction between the catalyst layer and the membrane, 3D transport effects within the nanopores of the catalyst layer, or the homogenous CO₂/HCO₃⁻/CO₃²⁻ reactions occurring within the liquid water and Sustainion membrane. To account for this we have constructed three modelling scenarios using experimental mass flows as inputs to construct different empirical models that highlight the effect of different scenarios on CO₂ distribution. The most representative system is then used to continue the discussion on CO₂ utilization and faradaic efficiency.

The three examined cases are as follows: in Case A, we ignore the fraction of CO₂ reacting with hydroxide ions. In Case B, the amount of CO₂ lost to hydroxide ions is subtracted at the inlet resulting in a reduced inlet flow rate. In Case C, the fraction of CO₂ lost to hydroxide ions is assumed to occur homogeneously throughout the catalyst surface. These three cases are visually depicted in Fig. 3b along with their resulting simulated CO₂ concentrations at the catalyst layer interface at 10 sccm and 200 mA cm⁻². Fig. 3c shows the analysed data set from Fig. 3b represented as a cumulative distribution function for the percentage of the catalyst area with a minimum concentration of CO₂.

Case A: Modelling the cathode without accounting for CO₂ reacting with OH⁻ ions. In this approach, CO₂ losses due to its reaction with OH⁻ ions forming bicarbonate and carbonate ions are ignored. The results obtained for an inlet flow rate of 10 sccm at 200 mA cm⁻² are shown in Fig. 3c, where the two-dimensional data set has been converted into a cumulative distribution functions as a percentage of the geometric area of the catalyst layer. Thus the percentage of catalyst area with ample and deficient CO₂ can be visualized (Fig. S8†). From Fig. 3b it can be seen that the CO₂ concentration decreases from the inlet to the outlet of the gas channels and at the catalyst surface. As shown in Fig. 3b, the cumulative distribution plot for CO₂ at the catalyst surface shows that only 2.1% of the catalyst area is deficit of CO₂ for an inlet flow rate of 10 sccm. Hence, Case A shows almost no CO₂ limitation indicating that this reactant feed is sufficient to sustain the current density that is applied (200 mA cm⁻²). However, as could be expected, Case A clashes with the experimental observation of a low CO selectivity (35.9%) and a relatively high H₂ selectivity (38.9%) at 10 sccm. This discrepancy between the modelling and the experimental results shows that CO₂ losses (due to its reaction with OH⁻) cannot be ignored in modelling the spatial CO₂ distribution.

Case B: Modified inlet flow rate approach. In Case B the inlet boundary condition of CO₂ flux has been reduced to account for the amount of CO₂ lost to OH⁻ ions over the entire reactor. Here, the amount of CO₂ lost to OH⁻ ions was experimentally measured and subtracted from the inlet flow rate to obtain a modified inlet flow rate (Table S2†). In contrast to Case A, using the modified inlet flow rate approach a significant portion of catalyst surface (59%) is deficit of CO₂ at 10 sccm (Fig. 3b).

Fig. 3 (a) 3D model of the flow channel and gas diffusion electrode. (b) Modelling cases examined to mimic the experimental observations. Shown here are the simulation results of CO₂ concentration at the catalyst surface for an inlet flow rate of 10 sccm and 200 mA cm⁻², (c) a cumulative distribution plot for the three cases showing the [CO₂] distribution at the catalyst surface, (d) portion of catalyst surface having access to CO₂ ([CO₂] > 0) for all the inlet flow rates studied experimentally.

Although this agrees with the experimental observation of an increased H₂ production (38.9%) at low flow rates, the change in catalyst area with access to CO₂ is too abrupt under varied flow rates (Fig. 3d), which does not pair well with the gradual change in selectivity seen in the experiments (Fig. 2a). The flaw in a modified inlet flow rate approach is that the CO₂ losses to OH⁻ ions are not distributed throughout the catalyst surface, meaning that the CO₂ available in the front half of the serpentine channel is unfairly limited. Case B is then too much of a simplification to predict the spatial CO₂ distribution and device selectivity accurately.

Of note, using a modified inlet flow rate would also slightly impact the fluid velocity and pressure drop between the inlet and outlet, altering the actual physical phenomena occurring inside the reactor. Such an approach would then have significant effects when large flow rates are used where a significant pressure drop might exist between the inlet and outlet of the reactor. Critically, Case B over penalizes the CO₂ concentration throughout the majority of the reactor as CO₂ lost to OH⁻ ions near the exit of the reactor has been removed prior to the reactor inlet.

Case C: Modified current density approach (modified CO₂ flux to the catalyst). With the aim of predicting the 2D spatial CO₂ concentration in the reactor while maintaining a simplified modelling approach, Case C aimed to spatially account for CO₂ loss to OH⁻ as well. To institute this within the model without implementing pore scale phenomena and homogeneous reactions, we instead imposed a penalty current density (j_{loss}) that

accounts for the additional consumption of CO₂. The magnitude of the imposed penalty current density was calculated using the experimentally-measured loss of CO₂ at each independent flow rate (eqn (1) and Fig. 2c), resulting in an empirical representation of the experiment. This modified current density was then added to the actual applied current density term to provide the spatial rate of CO₂ consumption (eqn (2)). Fig. S3† shows the modified current densities which have been imposed in the model as a result of Case C, with all current density above 200 mA cm⁻² being deployed as a non-faradaic consumption of CO₂.

$$j_{\text{loss}} = \frac{n^e \times n_{\text{CO}_2 \text{ to OH}^-} \times F}{A} \quad (1)$$

$$R_{\text{CO}_2} = \frac{(j_{\text{applied}} + j_{\text{loss}})}{n^e F} \quad (2)$$

Here, R_{CO_2} is the reaction rate of CO₂, j_{loss} is the modified current density calculated based on the amount of CO₂ lost to OH⁻ ions (from experimental data), n^e is the number of electrons (2 for CO₂ RR), $n_{\text{CO}_2 \text{ to OH}^-}$ is the moles of CO₂ lost to OH⁻, F – Faraday's constant and A is the area of the catalyst surface (6.25 cm²).

Once imposed, Case C provides the spatial distribution of CO₂ observed in Fig. 3b for an inlet flow rate of 10 sccm. Translating this to the cumulative distribution function in Fig. 3c, the net catalyst area with no access to CO₂ is approximately 37%. Further, Fig. 3d shows the percentage of catalyst

area with access to reagent results for all of the simulated cases and flow rates. Notably at flow rates within the utilization area of interest (10–20 sccm), Case C falls in between Cases A and B. The effect of parasitic CO₂ loss is still not eliminated above 20 sccm, however, which can be attributed to poor CO₂ access on the fringes of the gas-diffusion layer. In this case, this is due to the area of the GDE (6.25 cm²) expanding beyond the edge of the serpentine flow channel (5 cm²). Due to accounting for spatial effects, Case C is chosen as the most representative model for the remainder of the work.

Predicted spatial and average faradaic efficiency

The previous section provided a set of models to predict the spatial concentration of CO₂ within an experimentally-tested membrane-electrode assembly reactor. As the primary focus is to better understand the trade-offs between selectivity and utilization in these systems, these predicted concentrations of CO₂ must be translated to a predicted spatial and average faradaic efficiency. To accomplish this we imposed the following selectivity criteria in eqn (3) and (4) based upon the predicted CO₂ concentration, and the experimentally-measured faradaic efficiency under an excess CO₂ flow rate of 50 sccm (97% CO₂RR/3% HER). The data has been normalized to 100% (96.8% CO₂RR/3.2% HER) for the purposes of the model.

$$FE_{\text{CO}_2\text{RR}}(x, y) = \begin{cases} 96.8\%, & [\text{CO}_2] > 0 \\ 0\%, & [\text{CO}_2] = 0 \end{cases} \quad (3)$$

$$FE_{\text{H}_2}(x, y) = \begin{cases} 3.2\%, & [\text{CO}_2] > 0 \\ 100\%, & [\text{CO}_2] = 0 \end{cases} \quad (4)$$

Using this criteria, the spatial faradaic efficiency across the catalyst layer of the GDE is visually shown in Fig. 4a for three different flow rates. Observing the low flow rate case of 10 sccm, the loss of selectivity towards CO₂RR is shown to be primarily due to insufficient CO₂ along the length of the reactor towards the outlet. In the 20 sccm case, however, it is only the edges near the outlet of the reactor that are expected to primarily produce H₂ instead of CO₂RR products. The plots in Fig. 4a for spatial selectivity are predicated on the assumption that there is not a transition region of selectivity between the shown blue and red regions. In an actual system the switch in selectivity from primarily CO₂RR to H₂ along the reactor of CO₂-deficient system would be more gradual, but high selectivities are known to be possible even at lower partial pressures.³⁰ A secondary check of the approach is to translate the spatially-predicted faradaic efficiency into a device-averaged FE like that reported experimentally.

Fig. 4 (a) CO₂ concentration map at the catalyst surface determined from the numerical simulations showing the spatial CO₂ distribution at various inlet flow rates, (b) a cumulative distribution plot of CO₂ concentration at the catalyst surface for different inlet CO₂ flow rates studied using a modified current density approach and (c) comparison of predicted faradaic efficiency of CO₂RR with experimentally determined faradaic efficiency (FE_{CO} + FE_{HCOO}⁻).

The device-averaged FE can be calculated by using the distribution function in Fig. 4b for a variety of different flow rates, and combining this with the criteria presented in eqn (1) and (2). The resulting predicted FE of CO₂RR and H₂ for all the inlet flow rates studied are then shown in Fig. 4c, with the experimentally-measured values overlaid. It can be seen clearly that the predicted FE is in close agreement with the experimental FE of CO₂RR, showing the promise for using predicted CO₂ distribution within the reactor to predict spatial and average device selectivity. The consistent over prediction can be attributed to the experimental FE's being less than 100%, most likely due to the inability to capture all produced formate in MEA cell. Importantly both the trend in selectivity within the higher CO₂ utilization region (10 to 20 sccm), as well as in the lower utilization range (20–50 sccm), follow the experimental data set well. Such a model forms the foundation for comparing GDE's with different permeability, flow fields with different geometries, and the trade-offs with selectivity and utilization under different current densities.

The model can also be used to draw new observations from the experimental data set. For example, the incremental change in CO₂RR from 20–50 sccm is shown to be due to a CO₂ deficiency on the outer edges of the domain where the larger gas-diffusion layer (6.25 cm²) loses access to CO₂ from the 5 cm² serpentine channel area (see 20 sccm plot in Fig. 4a). Such an

area then only produced H₂, which slightly lowers the “black box” measured FE *via* gas chromatography. We are then able to predict the location on the catalyst surface where CO₂ limitation occurs, which can help in understanding and designing flow channel designs at the cathode.

Finally, we emphasize here that at an applied current density of 200 mA cm⁻², there is an increase in the amount of CO₂ reacting with OH⁻ ions with an increase in the reactant flow rate, which is identified in the increase in the j_{loss} value (Table S2†). This is quite reasonable since the local OH⁻ ions generated at 200 mA cm⁻² is a constant (1.3×10^{-5} mol s⁻¹) and an increase in the local CO₂ concentration due to increased inlet flow rate shifts the reaction to the right producing more HCO₃⁻ and CO₃²⁻ ions. Moreover, this reduction in local [OH⁻] with increasing inlet flow rates would also reduce the local pH altering the reaction environment around the catalyst surface. A further increase in inlet flow rate (60–100 sccm) would result in the consumption of all the OH⁻ ions generated at the catalyst producing more HCO₃⁻ and CO₃²⁻ ions with a subsequent alteration of the local reaction environment. Operating at such high reactant flow rates would however reduce the CO₂ utilization to less than 10% and also increase the pressure drop between the inlet and outlet (serpentine channel) resulting in an increased pumping power.³¹ Hence, optimizing the reactant flow rate to overcome CO₂ mass transport losses as well as

Fig. 5 (a) Ratio of partial current densities of CO₂ RR (CO + HCOO⁻) and H₂. Partial current densities of CO and formate with (b) varying inlet CO₂ flow rates and (c) catalyst area with CO₂ access.

ensuring a high CO₂ utilization and a low pressure drop is a challenge. Therefore, we restricted our focus of this study to flow rates of up to 50 sccm.

Formate production from Ag GDE

While much of the work here focused on the availability of CO₂ and the subsequent CO₂RR selectivity as a result of this, the experimental data set noted interesting and opposing trends in CO and formate selectivity under a variety of flow rate conditions (Fig. 2a). In particular while overall CO₂RR *versus* HER trended downward as flow rates decreased as could be expected (Fig. 5a), the selectivity of CO to formate also followed a similar linear trend, both within the CO₂-limited and non-limited flow rate regions (Fig. 5b). Here, we briefly contextualize these results and offer possible explanations given previous literature reports and our spatial model constructed here. It is worth noting that to measure formate we performed HPLC measurements of the anolyte samples post electrolysis for our Ag GDE system, meaning that only formed formate which crossed the anion exchange membrane could be measured, likely explaining some missing FE in our data set. We will provide speculation in spite of this.

The trend in CO to formate within the two flow rate regions have two possible explanations from literature: (i) the reaction pathway to formate exists through surface-adsorbed protons and competition with HER, (ii) formate selectivity supplants some CO selectivity under higher alkalinity conditions. The first point has been reported previously by Bohra *et al.*³² using DFT calculations which showed that *OCHO towards formate forms through a bound *H, whereas CO formation proceeds first through direct CO₂ absorption. Thus, formate formation requires the Volmer step from HER formation in order to be formed. It would then be expected to see a lower CO/formate ratio when *H is more common, which would be the case in decreased and depleted CO₂ conditions like those observed from 10 to 20 sccm. Regarding (ii), previous studies on GDE flow cells have shown increased formate/CO ratios under extremely alkaline conditions (11 M KOH in Seifitokaldani *et al.*³³) and decreased formate/CO ratios under higher CO₂ pressures (Gabardo *et al.*³⁴). Both reports indicate that the pH of the reaction environment will influence the ratio of CO to formate produced. Within our system, this hypothesis could help to explain the decreasing trend in formate production as the inlet flow rate ranges from 20–50 sccm. At higher flow rates excess CO₂ is available to negate the formed OH⁻ from the fixed current density reaction (see $V_{\text{CO}_2 \text{ to OH}^-}$ blocks in Fig. 2c). It is then likely that the reaction environment surrounding the catalyst layer leans to lower alkalinities at 50 sccm *versus* that of 20 sccm, even though ample CO₂ is available in both cases. The experimental decrease in j_{HCOO^-} is also seen when the model and experiments are combined (Fig. 5c), where formate current density drops when the full catalyst area has access to CO₂.

Operating feed rate for larger cells at high current densities

Within this study a serpentine flow channel was utilized to provide CO₂ to a 6.25 cm² catalyst area. The experimental and

modelling results can be extended to reactor areas of various sizes and current densities, presuming the dominating phenomena are not altered by doing so. Here we first provide a calculation for the required flow rate of CO₂ to balance utilization while maintaining higher CO₂ reduction selectivity. We then comment on the important phenomena to consider in scale-up regarding CO₂ feed rate.

To formulate the operating CO₂ feed which best balances CO₂ utilization and device selectivity for a given electrode area and current density, we utilized our 20 sccm flow rate as a base case. From Fig. 4a, the 20 sccm case best balances CO₂ utilization (40%) and CO selectivity. Normalizing this flow rate with the geometric surface area of the GDE (6.25 cm²) and partial current density of CO (125 mA cm⁻²), we predict that the operating reactant feed for industrial operation should be 0.0256 cm³ min⁻¹ mA⁻¹. We compared this value with a study from Endrődi *et al.*¹⁴ where a similar study using Ag GDE in a zero gap CO₂ electrolyzer at 1 A cm⁻² was performed. In their study, a large geometric surface area of 100 cm² was employed and a feed rate of 12.5 cm³ min⁻¹ cm⁻² was used to obtain the same CO₂ utilization of 40%. Normalizing this feed rate to their CO partial current density (630 mA cm⁻²), the operating feed comes to 0.0198 cm³ min⁻¹ mA⁻¹ which agrees closely with our predicted value.

From the modelling studies performed we can comment that a number of factors would change the flow rate of CO₂ required at the reactor inlet. Specifically, while the inlet flow rate can be well controlled, diffusion of CO₂ from a gas channel into the liquid immersed catalyst layer is less tuneable and will be impacted by such things as specific device configuration, the catalyst thickness and deposition type, pressure drop within the system, temperature, *etc.* As reactors scale to larger and larger sizes these factors may alter the ideal CO₂ feed rate. For example, for large reactors larger pressure drops in the gas-phase will occur if singular serpentine channels are used as the gas may prefer to shortcut under the gas channel and through the gas-diffusion layer. This would then result in a higher degree of under-rib convection changing localized CO₂ concentrations from the 6.25 cm² reactor. Thus, when moving from smaller to larger reactors, proper engineering design is needed to ensure that local phenomena are maintained near their ideal conditions, even as the reactor scales up.

Conclusion

The balance between CO₂ utilization and selectivity with electrochemical systems will be ever more important as CO₂ electrolyzers are scaled to larger areas and considered within larger chemical processes due to implications they have on reliability, separation processes and system costs. The trade-offs in these metrics are currently measured and reported for an entire reactor, while being driven by spatial variation in concentrations across an entire electrochemical reactor. At present, the experimental ability for direct localized measurement of CO₂ electrolysis products has not been demonstrated however. The work presented here aims to predict this trade-off by pairing bulk product measurement with a transport model to provide

a measure of spatial resolution to our electrochemical cell. We believe that our approach can provide a starting point for a more extensive modelling study to enhance the understanding of the local reaction environment around the catalyst surface in a membrane electrode assembly configuration, employing anion exchange membranes. Importantly, we hope this work inspires experts from adjacent fuel cell community to provide their wealth of experience to accelerate the CO₂ reduction field forward.

Author contributions

S. S. completed all of the experiments and modelling work. J. M. setup the experimental apparatus and assisted with experimental issues. T. B. and S. S. conceived the project. All authors contributed to writing and editing of the manuscript.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

Thomas Burdyny and Siddhartha Subramanian would like to acknowledge the co-financing provided by Shell and a PPP-allowance from Top Consortia for Knowledge and Innovation (TKI's) of the Ministry of Economic Affairs and Climate in the context of the TU Delft e-Refinery Institute. TB would also like to acknowledge the NWO for an individual Veni grant. The authors would also like to acknowledge Mark Sassenburg for HPLC analysis and Sanjana Chandrasekar, Erdem Irtem and all members of Burdyny Energy lab for helpful discussions.
