A heparin-specific binding peptide was conjugated to a cowpea chlorotic mottle virus (CCMV) capsid protein, which was subsequently allowed to encapsulate heparin and form capsid-like protein cages. The encapsulation is specific and the capsid-heparin assemblies display negligible hemolytic activity, indicating proper blood compatibility and promising possibilities for heparin antidote applications.

Heparin (Fig. 1a) is a highly anionic polysaccharide belonging to the family of glycosaminoglycans and is widely used as an anticoagulant in surgical practices and thrombotic events.¹ The anticoagulant activity is based on its ability to bind and subsequently activate antithrombin-III, which leads to the inactivation of vital coagulation cascade substances such as thrombin and factor Xa.² For safe clinical operation, heparin requires an antidote, which can counteract the anticoagulant effect and suppress potential side effects, if needed.³ Protamine sulfate is a small arginine-rich cationic protein that binds heparin *via* electrostatic interactions, and is commonly used for this purpose.^{2,4} This interaction is electrostatic in nature, but nonspecific, and protamine sulfate can cause multiple adverse effects.⁵ This has initiated diverse attempts to develop safer heparin antidotes, such as cationic polymers and small molecules, which all largely rely on the electrostatic binding with heparin.^{6–12}

Salla Välimäki,^{‡a} Qing Liu,^{‡a} Lise Schoonen,^{id b} Daan F. M. Vervoort,^c Nonappa,^{id d} Veikko Linko,^{id ad} Roeland J. M. Nolte,^{id b} Jan C. M. van Hest,^{id bc} and Mauri A. Kostiaainen^{id *ad}

Although efficient binding can be achieved, cationic platforms often lack specificity to heparin and usually exhibit high cytotoxicity. Furthermore, the complexes formed with heparin are often large and ill-defined aggregates. Therefore, more sophisticated alternatives that would transform heparin into small and well-defined particles, which are biologically inert, are needed.^{9,12}

Virus-like particles (VLPs) are protein assemblies derived from wild-type viruses. They lack the viral genome but have similar well-defined capsid structures as native virus particles, and have therefore been explored for biomedical and nanotechnological applications.^{13–17} Indeed, their most appealing features are the accurate sizes and shapes, which are combined with a relatively high stability and versatile modification potential.¹⁸ The removal of the viral genome also generates a highly confined cavity, which can be harnessed to compartmentalize other nanoscale substances.^{19–21} Cowpea chlorotic mottle virus (CCMV) capsid is one of the most studied VLPs as they can be produced in high yields²² and undergo pH and ionic strength-dependent swelling and assembly,^{23,24} which have therefore been intensively utilized in cargo-loading.²⁵

In more detail, CCMV is a plant-infecting icosahedral virus consisting of 180 capsid proteins (CPs) in its native $T = 3$ form, leading to a capsid with an outer diameter of 28 nm and an inner cavity diameter of 18 nm (Fig. 1b).²⁶ Its $T = 1$ and pseudo $T = 2$ forms consist of 60 and 120 capsid proteins and have diameters of roughly 18 and 22 nm, respectively.²⁷ Each CP is formed from 190 amino acids with its N-terminus located on the interior of the capsid. CCMV can be modified in multiple different ways, for example, by functionalizing carboxylic acids or amines on the exterior of the capsid.^{28,29} In addition, the CCMV interior may be altered to enable enhanced cargo loading and encapsulation through electrostatic interactions.^{30,31} To obtain a highly defined modification of the capsid interior, an appealing approach is to engineer the N-termini, which provides site- and number-specificity. For this purpose, an enzymatic method involving a reaction catalyzed by the enzyme Sortase A (SrtA) has been developed.³² This benign methodology was first utilized to label the CCMV capsids with a fluorescent tag, but

due to the generic nature of the strategy, a wide range of cargos loaded in VLPs can be envisioned.^{33,34}

So far, only the exteriors of virions have been employed to display polycationic motifs (poly-Arg) for heparin-binding.^{35–38} However, multiple mutations may yield unstable virions and lead to nonspecific electrostatic interactions with heparin. In this work, we report on the conjugation of a heparin-binding peptide (HBP), *i.e.* a heparin-specific sequence derived from the fibroblast growth factor having a dissociation constant of ~ 134 pM with heparin, to the interior of the CCMV capsid.³⁹ The binding and packing of heparin into the protein cage was studied with dynamic light scattering (DLS), transmission electron microscopy (TEM), and fast protein liquid chromatography (FPLC). Assemblies were not observed in the presence of two other glycosaminoglycan analogues, demonstrating high selectivity towards heparin. Moreover, no hemolytic activity was detected, implying proper biocompatibility.

The particular HBP was selected based on its high selectivity and affinity to heparin, thus minimizing off-target binding even in complex biological environments.^{12,39} Conjugation of HBP to the CP N-terminus was realized with the SrtA-based method, as illustrated in Fig. 1c. SrtA catalyzes the cleavage of the HBP C-terminal sorting signal (LPETG) after threonine and the subsequent ligation with an N-terminal glycine in the CP. The detailed coupling procedure and characterization of the intermediate conjugates can be found in the ESI† (Fig. S1–S6, ESI†). The final product was characterized by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry. Based on the SDS-PAGE and MALDI-TOF analysis, approximately 25% of the CPs were successfully conjugated with HBP (Fig. 1d and Fig. S7, ESI†), which corresponds on average to 45 modified CPs per one $T = 3$ CCMV capsid. Initially, TEM imaging was employed to investigate the morphology of the

assemblies formed by HBP modified CPs alone. Negatively stained spherical VLPs were observed under the TEM microscope, having a diameter of ~ 28 nm, which corresponds well with the expected dimension of the $T = 3$ icosahedral capsids (Fig. 1e and Fig. S9a, ESI†). The presence of dark regions in the capsid cores indicates that the capsids are empty as the stain is able to enter the voids.⁴⁰ Empty CCMV capsids were then disassembled by dialysis against Tris-HCl buffer (50 mM, pH = 7.4). Disassembly was confirmed by TEM and DLS measurements, which showed a size shift from 28 nm to 8–9 nm (Fig. 1f and Fig. S9b, ESI†). The obtained CP solution was then mixed with heparin in different quantities yielding heparin-loaded capsids (Fig. 1g).

As observed in Fig. 2a–c and Fig. S12, ESI† the heparin-loaded capsid assemblies formed with three different heparin to protein mass ratios ($\rho = 0.02, 0.22,$ and 0.44) all had a roughly spherical morphology and a smaller diameter than the empty $T = 3$ capsid (28 nm). For instance, TEM images indicated an average size of 18.6 nm at $\rho = 0.02$ (Fig. 2d). Similar diameters were observed with the $\rho = 0.22$ (18.6 nm) and 0.44 (20.2 nm) samples (Fig. 2d), matching well with the dimension of $T = 1$ capsids. The preferential formation of $T = 1$ capsids has been observed previously, *i.e.* when highly negatively charged synthetic polymers^{40–43} and nucleic acids were encapsulated in CCMV VLPs.^{44,45} The particle size has been shown to depend on the molecular weight of the encapsulated compound, and commonly higher molecular weight compounds promote the formation of larger capsids.^{40,45} Unlike empty capsids, the heparin-loaded assemblies did not show dark cores (Fig. 2e), demonstrating that the capsid voids were filled and successfully loaded with heparin molecules. Cryo-TEM images of the heparin-loaded capsids further verified the spherical morphology and ~ 18 nm size of the complexes and confirmed that the observed structures are not a result of a drying effect.

Fig. 2 TEM images of heparin-loaded capsids at (a) $\rho = 0.02$, (b) $\rho = 0.22$, (c) $\rho = 0.44$. (d) Analysis of the dimensions of the complexes ($\rho = 0.02$ – 0.44) and capsids before disassembly ($\rho = 0$), as derived from the TEM images. Solid curves show Gaussian fits. (e) Averaged ($n = 40$) particle images (size $50 \text{ nm} \times 50 \text{ nm}$), as taken from panels a–c (left) and their 3D intensity profiles (right). (f) Cryo-TEM image of heparin-loaded capsids at $\rho = 0.16$. (g) FPLC chromatogram (280 nm) of free CPs and heparin-loaded capsids ($\rho = 0.02$ – 0.44). Free CPs elute at 19.6 mL and 17.1 mL, and $T = 1$ heparin-loaded capsids elute at 13.9 mL. Inset graph shows the fluorescence emission spectrum (excitation at 485 nm) of the heparin-loaded capsids ($\rho = 0.22$, green line) and pure heparin-FITC (black dashed line) collected at the 13.9 mL.

The effect of the amount of heparin on capsid formation was quantified with fluorescein (FITC) moieties according to a previously published method.⁴⁶ Successful heparin-FITC conjugation was confirmed with FPLC and nuclear magnetic resonance (NMR) spectroscopy (Fig. S8, ESI[†]). Fig. 2g shows that the free CPs were eluting at 19.6 mL and 17.1 mL. Comparison of the peak areas revealed that 71% of protein was eluting at the higher elution volume (19.6 mL, Fig. S11, ESI[†]), which corresponds to the protein dimers. These values are well in line with previously published work conducted under similar conditions where the CP dimers were eluting at 18.5 mL.⁴² In the present studies, another peak at 17.1 mL, corresponding to slightly larger capsomers, was also observed.⁴⁷ The assembled capsids were expected to elute at lower volumes, and for the $\rho = 0.02$ sample, a minor broad peak appeared around 13.9 mL (Fig. 2g), which corresponds to $T = 1$ capsids.⁴² When heparin concentration was increased to $\rho = 0.22$, the peak fraction at 13.9 mL increased from 6% to 37%, showing the formation of more $T = 1$ capsids. However, further addition of heparin ($\rho = 0.44$) did not significantly increase the fraction of $T = 1$ capsids. Instead it enhanced the amount of the intermediate particles as observed by the larger peak area between 17.1 mL and 13.9 mL. Additionally, unbound heparin (peak at 22.4 mL) started to appear (Fig. S12d, ESI[†]), indicating that the excess of heparin did not induce further formation of capsids. This finding is supported by previous studies, which have shown that capsid formation depends on the amount of the encapsulated compound and that high cargo ratios limit capsid formation.^{41,42} Fractions corresponding to the $T = 1$ capsids (13 mL) were collected and investigated with the help

of fluorescence spectroscopy measurements. A clear emission spectrum from the fluorescein-conjugated heparin was observed for all the heparin-loaded samples, while that for pure heparin-FITC was neglectable, demonstrating that the encapsulations had been successful (Fig. 2g inset and Fig. S13, ESI[†]).

The selectivity of the heparin encapsulation was evaluated qualitatively with DLS. Studies aimed at encapsulating other negatively charged target molecules were conducted with two glycosaminoglycan analogues, *i.e.* hyaluronic acid and chondroitin sulfate as well as bovine serum albumin. No size change was observed when these compounds were added to CCMV CPs ($\rho = 0.02$ – 0.22), indicating that capsids or other higher-order structures are not formed (Fig. 3a). However, adding heparin in similar mass ratio clearly induced $T = 1$ capsid formation, which is visible as a peak between the CP dimers and $T = 3$ capsid (Fig. 3b and Fig. S14, ESI[†]). Adding heparin to the preassembled $T = 3$ capsid did not result in any changes in the size distribution indicating that heparin is not bound to the exterior of the capsid. Such observation is expected since the empty capsid remains assembled only at pH 5 in the presence of high electrolyte concentration (500 mM NaCl and 10 mM MgCl_2), which efficiently screens electrostatic interactions.

Furthermore, we found negligible hemolytic activity of the CPs up to 0.5 mg mL^{-1} concentration on red blood cells (RBCs) (Fig. 3c), which is in sharp contrast to the effect of commonly employed protamine sulfate, thus providing a promising strategy in heparin neutralization.

In conclusion, we have shown that CCMV capsid proteins modified with a heparin-binding peptide exhibit specific heparin

Fig. 3 Selectivity of the capsid assembly induced by (a) hyaluronic acid, chondroitin sulfate, bovine serum albumin and (b) heparin, as measured by DLS. (c) Hemolytic activity of the unmodified and HBP-conjugated CPs. Protamine sulfate (PS) was tested for comparison. Solutions of 1× phosphate-buffered saline (PBS) and 1% Triton X-100 were used as the negative and positive controls, respectively. Measurements were performed using triplicate samples, and the averaged results with standard deviation are presented.

binding at physiological pH's. Co-assembly with heparin yielded $T = 1$ capsids with diameters ranging between 18–20 nm according to the DLS measurements and TEM characterization. FPLC results further confirmed the capsid formation and revealed a heparin concentration-limiting effect on capsid formation. The binding of heparin was proved to be specific as no capsid formation was induced with two other glycosaminoglycan analogs. Moreover, hemolysis assays demonstrated a better biocompatibility than the commercial heparin antidote protamine sulfate. These results indicate that VLPs are promising materials for heparin binding, especially when the binding is further optimized for physiological conditions and after thorough hematologic studies have been conducted.
