Rapid, energy-efficient and pseudomorphic microwave-induced-metal-plasma (MIMP) synthesis of Mg₂Si and Mg₂Ge†

Zhen Fan,^a Hsi-Nien Ho,^b Robert Szczęśny,^c
 Wei-Ren Liu ^b and Duncan H. Gregory ^{*a}

Polycrystalline magnesium silicide, Mg₂Si and magnesium germanide, Mg₂Ge were synthesised from the elemental powders *via* the microwave-induced-metal-plasma (MIMP) approach at 200 W within 1 min *in vacuo* for the first time. The formation of reactive Mg plasma facilitated by the high-frequency electromagnetic field (2.45 GHz) is at the origin of the ultrafast reaction kinetics in these preparations. Powder X-ray diffraction (PXRD), Scanning Electron Microscopy (SEM) combined with Energy Dispersive X-ray Spectroscopy (EDX) and X-ray Photoelectron Spectroscopy (XPS) attest to the high purity of the products. Both SEM and Transmission Electron Microscopy (with Selected Area Electron Diffraction) (TEM/SAED) demonstrate the pseudomorphic nature of the metal plasma reactions such that use of nanoporous Ge starting material leads to the production of nanoporous germanide, Mg₂Ge. Covalent Mg–Si and Mg–Ge bonds with partial ionic character are suggested by XPS, while the refined crystal structures are consistent with Mg–Mg interactions within the cubane-like clusters in Mg₂X antiferroite unit cells. The MIMP method unlocks not only the sustainable synthesis of Mg₂X materials but also the wider production of intermetallics and *Zintl* phases of prescribed morphology.

Introduction

The societal benefits of a low-carbon future demand the means of harvesting, producing, converting and storing renewable energy efficiently. Energy demand and utilisation must also be efficiently managed. The sustainable green synthesis and fabrication of functional solid-state materials and devices is an integral part of this process; energy consumption and environmental impact must be minimised as a priority.^{1–3} For several decades now, the physics of microwaves (MWs) has inspired the creativity of synthetic chemists.^{4,5} Correspondingly, MW synthesis routes have produced a myriad of inorganic solid materials with various structures and morphologies. Simultaneously, the major benefits of time/energy savings; rapid heating rates; fast

throughput; precise, selective heating, and reduction of waste heat/hazardous chemicals have been delivered.^{2–11} Nevertheless, MW synthesis still faces many challenges before its implementation as a primary route to advanced materials manufacturing could be considered.^{2–7,10}

The Mg₂X (X = Si, Ge, Sn) family crystallises with the face-centered cubic, antiferroite structure (space group *Fm* $\bar{3}$ *m*) in which Mg atoms occupy the 8c (1/4, 1/4, 1/4) interstitial sites within a CCP lattice of X atoms (4a sites; Fig. 1b).^{5,12} These *Zintl* phase compounds are intrinsically n-type semiconductors with narrow indirect band gaps (*e.g.* *ca.* 0.73, 0.72 and 0.31 eV experimentally for Mg₂Si, Mg₂Ge and Mg₂Sn, respectively).^{13,14} Since the 1960s, members of the Mg₂X family (often forming solid-solutions) have continuously emerged as promising energy materials given excellent mid-temperature (*ca.* 500–800 K) thermoelectric (TE) performance combined with simple structures and flexible compositions of abundant, non-toxic environmentally-friendly elements.^{5,12} Common traits of large Seebeck coefficients, high electrical conductivity and unusually low lattice thermal conductivities permit the dimensionless figure of merit (*zT*) values to exceed unity comfortably for n-type Mg₂X materials.^{15–18} More recently, Mg₂X compounds have been proposed as candidate anode materials for rechargeable Mg-ion batteries,^{19–21} and these Mg₂X materials (especially Mg₂Si) have also demonstrated promise as the basis for the large-scale fabrication of nanoporous X anodes for Li- and Na-ion

secondary batteries.^{5,22–26} Beside applications in energy conversion and storage, narrow-gap Mg_2X compounds are considered as good candidates for infrared optoelectronic devices,²⁷ whereas the mechanical and anti-corrosive properties of Mg_2Si prove it an effective additive in metallurgy and for biodegradable implants.^{28–30} Presently, the high-profile medical value of non-toxic Mg_2Si nanoparticles as an outstanding deoxygenation agent for cancer starvation therapy has been discovered recently.³¹

Among several well-established synthesis routes to Mg_2X materials, conventional high-temperature solid-state methods and reactive ball-milling synthesis typically require long durations, whereas newer spark plasma sintering (SPS) and self-propagating high-temperature synthesis methods still require high temperatures and special equipment

requirements.^{5,12,15–17,20} Careful and/or multiple-step treatments are often needed. These synthesis approaches have to compromise the different physical and chemical properties of reactants and products, such as the solubility of Mg cations in solid-state X phases, boiling/melting points, volatility of Mg, mechanical hardness or ductility, and the ready tendency of Mg (and its products) to oxidise in air.^{5,12,15–17,32,33} Accordingly, the compositions of final products can be challenging to control, often involving impurities and potential safety issues (e.g. air exposure may cause the self-ignition of ball-milled products).^{5,17,20,32} A few early attempts to synthesise Mg_2Si -based TE materials in the solid state using MWs demanded very high input powers (a few kW) for tens of minutes under inert conditions.^{5,34,35} It was the pioneering work of Savary *et al.* in 2010 that first led to the successful production of Mg_2Si nanopowders, placing an encouraging milestone for the MW synthesis of Mg_2X compounds (although control of purity could not then be mastered).³⁶ In this case, pucks of Mg and Si powders were ball-milled for 2 h prior to heating using an incident MW power of only 175 W for 2 min under N_2 .³⁶ Savary *et al.* applicator possessed the capability to deliver two modes of MW excitation separately to the sample; both magnetic and electric field components. Their experimental observations indicated that semiconducting Si coupled with the magnetic field whereas Mg coupled to neither mode and that it was the rapid heating of Si that principally drove the reaction towards Mg_2Si .^{5,36} A similar instrument and methodology were then applied to prepare both n- and p-doped Mg_2Si .³⁷ This was perhaps unexpected given that both theory and experiment demonstrate that fine metal powders can couple with MWs (at 2.45 GHz) to reach high temperatures rapidly.^{2–5,10}

We previously conceived a new microwave-induced-metal-plasma (MIMP) approach towards the synthesis of phase-pure Mg_2Sn within 1 min, employing an incident power of 200 W *in vacuo*.^{3,5} In (sub)micron form, Mg and Sn powders coupled effectively with the MW field to form reactant metal plasmas (composed of ionised cations and electrons) *in situ*, such that the reaction kinetics were significantly promoted in the presence of the 2.45 GHz electromagnetic field.^{3,5} This new approach, where synthesis occurs *via* the reaction of species in the plasma phase, contrasts markedly with high-temperature solid-state reactions. The diffusion of atoms/ions in *the solid state* is relatively slow even at elevated temperatures and at the increased heating rates achievable by MW heating. Herein, we extend the MIMP method to the reaction of Mg with the metalloids Si and Ge in the rapid, energy-efficient synthesis of crystalline Mg_2Si and Mg_2Ge . Notably, the MIMP reaction between Mg and nanoporous Ge preserved the nanostructure of the latter in the Mg_2Ge product, affirming that Mg plasma is the key reactive species in the Mg_2X syntheses. In these respects, the MIMP method contrasts distinctively with MW syntheses in the solid state,^{36,37} showing great promise for Mg-based phases and for other alloys and compounds more broadly.

Experimental

Materials synthesis

The syntheses of Mg₂Si and Mg₂Ge followed similar procedures to that of Mg₂Sn in our previous study.^{3,5} All manipulations and preparations were performed inside an N₂-filled LABstar glovebox (mBraun; H₂O, O₂ < 0.5 ppm). Typically, either 70 mg (2.88 mmol) of Mg (99.8%, 325 mesh, Alfa Aesar) was combined with 35 mg (1.25 mmol) of Si (99.5%, 325 mesh, Sigma Aldrich) or 35 mg (1.44 mmol) of Mg (99.8%, 325 mesh, Alfa Aesar) with 45 mg (0.62 mmol) of nanoporous Ge (synthesised from Mg₂Ge by de-alloying using literature methods³⁸) and mixed thoroughly before the transfer of the respective powders into an alumina crucible (which can be considered MW-transparent). One control experiment using 35 mg of Mg and 45 mg of commercial bulk Ge powders (Trace metal basis, 99.999%, Acros Organics) was also performed (full details in ESI†). In each case, an excess of Mg powder (15 at%) was employed (equating to a 2.3:1 molar ratio) to compensate for the evaporation of Mg.^{3,5} The crucible was placed within a quartz tube, which was subsequently closed and connected to a vacuum line outside the glovebox.

A modified single-mode cavity MW reactor (CEM Discovery, 2.45 GHz) with the input power adjustable from 0–300 W was employed.^{3,5} An incident MW power of 200 W was applied to the powder mixture under a static vacuum of $P < 10^{-6}$ mbar.⁵ The irradiation time was typically 60 s for both Mg₂Si and Mg₂Ge. In order to analyse the composition during the reaction, one Mg₂Ge experiment was performed for 30 s. Following the irradiation, the quartz tube was allowed to cool naturally to room temperature. All samples were ground and stored in the glovebox for further characterisation.

Materials characterisation

Powder X-ray diffraction (PXRD) was performed using a PANalytical X'pert Pro MPD diffractometer in Bragg–Brentano geometry (Cu-Kα₁, $\lambda = 1.5406$ Å; accelerating voltage of 40 kV; emission current of 40 mA). For phase identification purposes, PXRD patterns were collected at room temperature over a 2θ range of 15–85° with a step size of 0.0334° and 30 s per step. For structure determination/quantitative analysis by Rietveld refinement, PXRD datasets were collected over extended ranges of 15–110° and 15–100° (2θ) for Mg₂Si and Mg₂Ge respectively, with a step size of 0.01667° and 100 s per step. Previously published Mg₂Si, Mg₂Ge, Si, Ge, MgO and Mg structures were used for phase identification purposes and as initial models for Rietveld refinements.^{39–44} Rietveld refinements were performed by using GSAS *via* the EXPGUI interface.⁴⁵ As-refined crystal structures were plotted using the VESTA package.⁴⁶

Scanning Electron Microscopy (SEM) and Energy Dispersive X-ray Spectroscopy (EDX) were performed using a Philips/FEI XL30 ESEM instrument (beam voltage 20 kV, maximum magnification 20 k) equipped with an INCA X-Act

detector (Oxford Instruments Analytical, UK). The samples were coated with Pt plasma under vacuum to optimise the quality of SEM images. Transmission Electron Microscopy (TEM) and selected area electron diffraction (SAED) were performed using an FEI Tecnai G2 F20 X-Twin; 200 kV, FEG microscope. High-resolution Si2p, Ge3d, and Mg1s X-ray Photoelectron Spectroscopy (XPS) spectra were measured using a monochromatic Al-Kα Photoelectron Spectrometer (Thermo Scientific) under vacuum, both before and after etching with an Ar-ion beam (at 2.0 keV for 30 s).

Results and discussion

MIMP synthesis and characterisation of Mg₂Si

MW syntheses of Mg₂Si and Mg₂Ge were conducted from elemental mixtures with an initial Mg/Si or Mg/Ge ratio of 2.3:1, under a static vacuum of $P < 10^{-6}$ mbar with an incident power of 200 W, typically for a duration of 60 s. Plasma formed almost immediately (within *ca.* 2 s of MW irradiation), evolving initially from a pale purple colour to persistent green for both samples. These closely resembled the plasmas observed in the MIMP synthesis of Mg₂Sn,⁵ suggesting the dominance of Mg plasma formation across the MIMP syntheses of the wider Mg₂X family (X = Sn, Si, Ge).^{3,5} Fine dark blue powders were obtained from the reaction in each case, with no visible evidence of sintering or agglomeration to larger solid pieces.

Fig. 1a shows the profile plot obtained from the Rietveld refinement performed against laboratory PXRD data for the Mg₂Si product synthesised from 60 s of irradiation. The silicide formed with the cubic antiferroite structure (space group *Fm* $\bar{3}$ *m*) with a lattice parameter of $a = 6.3525(1)$ Å (Fig. 1b; Table 1), in good agreement with previous reports in the literature.³⁹ The refinement indicated that the sample was Mg-deficient with a site-occupancy-factor (SOF) of 0.976(4) for the Mg site (Table 2). Mg sub-stoichiometry and vacancies on the Mg site are not uncommon features in Mg₂-Si synthesised at high temperature (and/or reduced pressure) and occur even in the presence of excess magnesium due to a combination of evaporation and oxidation (to MgO).^{17,47,48}

Interestingly, such Mg vacancies rarely lead to intrinsic p-doping due to the trapping of states within the band gap. Nevertheless, the PXRD results showed that the MIMP method yields crystalline Mg₂Si of high purity (98.9(6) wt%), with the almost negligible amount of MgO (1.1(6) wt%) likely originating from the surface oxidation of Mg₂Si during handling and the reaction of Mg plasma with trace amounts of oxygen in the closed quartz tube (Table 1).^{5,17,31}

The SEM images show highly crystalline fine powders with a relatively uniform size distribution ranging from sub-microns to ~1 μm across (Fig. 1c and d). In addition to this majority of particles, small clusters of much smaller (nanoscale) particles can be observed, which were potentially formed by the rapid reaction of Mg plasma with pulverised or existing Si nanoparticles and with the small amount of residual oxygen in the tube. Additional pulverisation of Mg₂Si itself is also perhaps not surprising given the action of the plasma on the particles in the MW field. The observation of the nanoparticles herein is consistent with findings from our previous MIMP study on Mg₂Sn.⁵ The EDX spectrum corresponding to the section of sample imaged in Fig. 1d led to an Mg/Si atomic ratio of 2.0 ± 0.1, in excellent agreement with the theoretical composition of Mg₂Si (Fig. S1a, ESI†). The presence of a small concentration of O at the sample surface might be attributed largely to the brief air exposure during specimen transfer. The maps of Mg and Si confirm the uniform distribution of the elements across the surface of the MIMP-synthesised powder (Fig. S1b and c, ESI†).

The low-magnification TEM images in Fig. 1e showed that typical micron/sub-micron Mg₂Si particles were rich in grain boundaries. At higher magnification (Fig. 1f), it was evident that the Mg₂Si particles were composed of a multitude of crystalline nanograins, each *ca.* 5–10 nm across. On closer inspection (Fig. 1g), TEM images provided evidence of: (i) a disordered surface layer of *ca.* 1–2 nm in thickness, which potentially stemmed from a surface reaction when exposed to oxygen/water in air. This is consistent with the reactivity of Mg₂Si, especially in powder form, and the formation of a passivation layer³¹ and (ii) highly crystalline regions beneath the surface layer, where lattice fringe spacings of 0.371 nm predominated, matching well with the (111) planes in Mg₂Si (and consistent with PXRD results; Fig. 1a).³⁹ Fig. 1h shows a typical SAED pattern from the sample and as taken from the region shown in Fig. 1g. The pattern is typical of a polycrystalline material, with diffraction rings that can be indexed to Mg₂Si. These data affirm that the crystalline material is bulk Mg₂Si encapsulated with a thin layer of oxide that likely forms instantaneously when handled in air (Table S1, ESI†).

The oxidation states and binding energies of Mg and Si in the Mg₂Si *Zintl* phase were further investigated by measuring high-resolution Si2p and Mg1s XPS spectra (Fig. 2). Compared to a reference spectrum taken for Si powder, which also featured distinct peaks for SiO₂ in addition to those for Si(0), the spectrum from a sample of as-synthesised Mg₂Si powder showed the co-existence of two broad peaks covering binding energies corresponding to SiO₂ (SiO_x), Si(0) and Si species that appeared more anionic in character as would befit Mg₂Si (at 98.58 eV) (Fig. 2a).^{49,50} Impurity peaks might be expected from the surface oxidation of Mg₂Si in air (just as the Si reference sample was surface-oxidised). The sample was subsequently etched with an Ar-ion beam and although the treatment could not completely remove all the oxidised surface species, the predominant Si peak was identified at a binding energy of 97.77 eV, which is significantly lower than that expected for elemental Si (99.29 eV), revealing the nominally negative oxidation state of Si in Mg₂Si (Fig. 2a).^{49,50} One peak was discovered in the Mg1s XPS spectrum (Fig. 2b) and this shifted to lower binding energy post-etching. The initial observation suggests the presence of a passivating surface layer of MgO, as could be inferred from electron microscopy. Post etching, however, the Mg peak is located at a binding energy intermediate between MgO (1304.5 eV) and Mg (1303.0 eV), suggesting an oxidation state of Mg between formally +2, as in MgO, and of 0 in Mg metal.⁵¹ The XPS data indicated that the bonding in Mg₂Si was by no means purely ionic (*i.e.* in which Mg valence electrons were entirely transferred to Si) but possessed significant covalent character.^{13,14,52,53} The spectra and inferences are entirely consistent with comprehensive studies of (oxidised) Mg₂Si on Si (111) made more than 2 decades ago.⁵⁴ Interestingly, the refined Mg–Mg distance in Mg₂Si was only 3.1726(1) Å, which is rather shorter than the equivalent distance in Mg metal (3.1967(4) Å). This presents the possibility of “free” electrons within the cubic Mg₈ sublattice in Fig. 1b.^{40,52} Our XPS and PXRD results concur with previous studies on Mg₂Si when a charge transfer from Mg to Si was calculated as 0.16 units by applying a potential model to XPS data; this corresponds to an Mg–Si bond with an ionicity of 8%.^{50,55} Subsequent Bader charge analysis implied that Mg carries a charge of +1.45 and Si could be attributed a charge of –2.90.⁵² The vacant cavity at the body centre of the unit cell is proposed to form a concentration of electron

**Fig. 2** High-resolution (a) Si2p and (b) Mg1s XPS spectra of MIMP-synthesised Mg₂Si powders (irradiated for 60 s).

density originating from the overlapping Mg 3p states, which in turn are primarily responsible for the conduction band minimum (CBM) (at the X point in the Brillouin zone) in the electronic structure of Mg₂Si. This is a point that we will return to when discussing the Mg₂X phases below.

MIMP synthesis and characterisation of Mg₂Ge

The MW exposure of Mg and Ge powders to an incident MW power of 200 W for 30 s was able to generate a product dominated by Mg₂Ge (94.3(3) wt%). The remainder of the sample was composed of a small amount of unreacted starting materials (Mg: 4.1(3) wt% and Ge: 1.5(1) wt%), as indicated by the Rietveld refinement profile shown in Fig. 3a (see also ESI† Tables S2 and S3). PXRD confirmed that irradiation of the elements at 200 W for double the duration (60 s) led to their complete reaction, with one very weak diffraction peak at 42.8° 2θ suggesting the presence of MgO.⁴⁴ Correspondingly, the Rietveld refinement revealed a phase purity of 98.1(1) wt% for Mg₂Ge with the remainder of the sample corresponding to MgO (1.9(1) wt%) (Fig. 3b; Table 3). As with the Mg₂Si sample, the presence of MgO as a minor phase could originate from handling during sample transfer and measurement, with the additional caveat that the nanoporous Ge reactant is quite likely to also react with air to oxidise at its surface, presenting a potential source of oxygen at the outset.¹⁷ The Rietveld refinement confirmed Mg₂Ge to be isostructural with Mg₂Si, with a lattice parameter of *a* = 6.3940(1) Å and an Mg–Mg distance of 3.1970(1) Å, equivalent to that in Mg metal (3.1967(4) Å) within 1σ.⁴⁰ In contrast to Mg₂Si, we found no evidence of non-stoichiometry at the Mg 8c site; attempts to refine the SOF led to no significant departure from unity and did not improve the overall fit to the profile or the *R* factors (Table 4).

Fig. 4a and b show SEM images taken for the Mg₂Ge powder synthesised at 200 W for 60 s. For comparison, the size and morphology of the nanoporous Ge reactant powder are indicated in the SEM images in the ESI† (Fig. S2). The Mg₂Ge powders take the appearance of individual micron-sized particles, which can be viewed as pieces of a nanoporous “bulk” matrix composed of nano ligaments

ranging from *ca.* 85–300 nm across. An appraisal of the SEM images from both the nanoporous Ge reactant powder and the nanoporous Mg₂Ge product demonstrates the close resemblance of the former and latter. This similarity signals the pseudomorphic nature of the MIMP reaction. In many ways, this is not an unreasonable result. For example, there are many examples of nanoporous matrices of p-block metals/metalloids possessing the capability for Li⁺, Na⁺ or Mg²⁺ ion insertion during electrochemical alloying reactions in rechargeable-ion batteries; such processes can have minimal effects on the nanostructure, extending cyclability over equivalent bulk materials.^{22–26} One can also further infer from this result that the MIMP process, at least in the case of Mg₂Ge, is one that involves a solid-plasma phase reaction between Ge and Mg respectively, reinforcing the hypothesis made above concerning the MW reaction mechanism in the Mg–Si system.^{3,5} This premise was reinforced by conducting a supplementary MIMP synthesis of Mg₂Ge from a mixture of Mg and commercial, bulk Ge powers (99.999%, Acros Organics). Revealingly, this experiment led to the production of non-porous, micron-sized Mg₂Ge particles (ESI† Fig. S3).

Fig. 4c shows a representative EDX spectrum, yielding an atomic Mg:Ge:O ratio of 60.39:23.81:15.80. Fig. 4d–f show that elemental distributions of Mg, Ge and O were uniform across the surface of the specimen, demonstrating the homogeneity of the MIMP-synthesised product. In light of the known reactivity of Mg₂Ge with water,^{5,31,56} the EDX data suggest that a surface passivation occurs following exposure to air as the sample was transferred to the SEM chamber:

Fig. 4 SEM characterisation of Mg_2Ge powders synthesised from Mg and Ge at 200 W with an irradiation time of 60 s, showing: (a and b) SEM images at different magnification; (c) a representative EDX spectrum taken from the area shown in the image in (b); and (d–f) elemental maps of Mg, Ge and O, respectively, taken from the same area shown in (b).

Indeed, we tested the reactivity of samples of Mg_2X ($\text{X} = \text{Si}$, Ge and Sn) with deionised water (*ca.* 100 mL in a beaker; Mg_2Sn was prepared as per ref. 5). Mg_2Ge reacted rapidly with water, generating a white precipitate within a few seconds. Mg_2Si reacted with water less vigorously, forming a white precipitate over the course of several minutes. By comparison, the reaction of Mg_2Sn was slow (*i.e.* reaction continued to occur after 24 h), forming a dense grey/white powder. Moreover, reactions of Mg_2Si and Mg_2Ge with 0.1 M HCl aqueous solutions formed gaseous bubbles which could be ignited in air, assumed to be SiH_4 and GeH_4 gases, respectively, in accord with previous observations for Mg_2Si and Mg_2Ge .^{31,56}

The surface composition and the oxidation states of Mg and Ge in Mg_2Ge were further investigated by the measurement of high-resolution Ge3d and Mg1s XPS spectra (Fig. 5). Spectra confirmed the presence of the oxide passivation layer suggested by SEM/EDX results. The Ge3d XPS spectra (Fig. 5a) showed that Ar-ion beam etching can effectively remove this surface oxide layer (which likely formed during the transfer of the XPS specimen to the vacuum chamber). The experimental spectra for Mg_2Ge were compared to those from a reference of Ge powder. Prior to Ar-etching, the Ge3d spectra for Mg_2Ge showed little evidence for Ge(0) and only a relatively small peak corresponding to a binding energy typical for GeO_2 (at 32.21 eV). This peak was effectively removed from the spectrum post-etching. As

Fig. 5 High-resolution (a) Ge3d and (b) Mg1s XPS spectra of the MIMP-synthesised Mg_2Ge powders with an irradiation time of 60 s.

witnessed for Si in the equivalent Si2p XPS spectra taken for Mg_2Si , the main Ge peak shifts significantly to lower binding energy as compared to that in the elemental spectrum (of Ge(0)). The shift of >1 eV (from 29.29 eV to 28.2 eV) indicates a nominal negative oxidation state for Ge in Mg_2Ge .⁵⁷ The Mg1s spectrum is rather similar to that seen for Mg_2Si . Fig. 5b shows that, post-etching, the Mg1s peak is centred at *ca.* 1303.5 eV, which is located between the binding energies expected for MgO (1304.5 eV) and Mg (1303.0 eV), suggesting an oxidation state of Mg between +2 in MgO and 0 in Mg metal.^{51–53} In similarity to Mg_2Si , therefore, XPS reveals that the bonding in the germanide is likely to be predominantly covalent.

Trends in the structures of MIMP-synthesised Mg_2X ($\text{X} = \text{Si}$, Ge, Sn) and common features of the MIMP syntheses

Selected structural data for the Mg_2X ($\text{X} = \text{Si}$, Ge, Sn) antifluorite compounds, as determined from Rietveld refinement, are presented in Fig. 6. As would be expected, Mg_2Sn has a larger cubic lattice parameter ($a = 6.7653(1)$ Å), Mg–X bond length (2.9295(1) Å) and Mg–Mg distance (3.3827(1) Å) when compared to Mg_2Si and Mg_2Ge .⁵ Mg_2Ge exhibits a very similar cubic lattice parameter to Mg_2Si , reflecting the rather similar covalent radii of the elements. Consequently, and given that both Mg and X are located on

Fig. 6 Plot of refined lattice parameter, a (black), Mg–X (blue) and Mg–Mg (red) distances⁵ for MIMP-synthesised Mg_2X ($\text{X} = \text{Si}$, Ge, Sn) (200 W, 1 min) against covalent radius of X.⁶⁰ The horizontal line and value represents the Mg–Mg distance in Mg metal.⁴⁰

special positions (of $(1/4, 1/4, 1/4)$ and $(0,0,0)$, respectively), the Mg–X ($X = \text{Si, Ge}$) bond lengths and Mg–Mg distances vary by only *ca.* 0.02 Å. It should also be noted that the Mg–Mg distances (within the cubane-like Mg_8 cluster) is only 3.1762(1) and 3.1970(1) Å for Mg_2Si and Mg_2Ge , respectively and therefore equal or less than the Mg–Mg distance in Mg metal (3.1967(4) Å).^{40,52,58} This implies potential metal–metal interactions and the presence of “free” electrons within the central cavity of the cubic Mg_8 sub-lattice in both Mg_2Si and Mg_2Ge . The recent computational study that identified such electrons as being associated with the CBM (through both σ and π bonding Mg 3p_y states interacting with Si 3d states) suggested that these cavity electrons are likely mobile and associated with the intrinsic n-type semiconductivity of Mg_2Si (and, in fact, these cavity states are deep lying enough to resemble those in inorganic electrides).⁵² The structural data would suggest that Mg_2Ge is likely to behave in a similar way and that the transport properties of both compounds could be tuned by modifying the size of the central cavity. Interestingly, single crystal X-ray structural studies had previously suggested that Mg_2Si could accommodate additional interstitial Mg in the vacant body centre $(1/2, 1/2, 1/2)$ position, albeit at very low levels (<1%).⁵⁹ Simultaneously, there was a tendency for the crystals to exhibit Mg vacancies of up to 1% at the 8c $(1/4, 1/4, 1/4)$ position and that as these vacancies increased so the electrical conductivity decreased (and the Seebeck coefficient increased). Our structural data suggest Mg vacancy levels of *ca.* 2% at the 8c site in Mg_2Si , but lab PXRD could not resolve the presence of electron density at the 1–2% level at the body centre. The presence of analogous vacancies in MIMP-synthesised Mg_2Ge and Mg_2Sn ⁵ could not be so readily established. There is clearly a need for a still more comprehensive understanding of the links between structure, composition and electronic properties in Mg_2Si and to explore to what extent these are replicated or otherwise in other Mg_2X Zintl phases. The links between “cation” vacancies and the presence of either interstitial Mg or electrons could also have profound implications for ionic transport and the application of Mg_2X as anodes in Mg-ion batteries.^{19–21}

The observed plasma generation during our MIMP syntheses of Mg_2X ($X = \text{Si, Ge}$) and for Mg_2Sn ⁵ was very similar, *i.e.* a transition from an initial purple coloured plasma (within *ca.* 10 s) to a steady green plasma. This is despite the very different physical and chemical properties of Sn, Si and Ge as reactants, where semiconducting Si and Ge have much higher melting points and hardness factors, for example, than metallic Sn.^{5,17} Given the volatility of Mg, it is not altogether surprising that Mg plasma formation is pivotal in the synthesis of Mg_2X ($X = \text{Si, Ge, Sn}$) Zintl phases in a microwave field under vacuum.^{3,5} The pseudomorphic reaction of Mg with nanoporous Ge underlines the premise that Mg is in the plasma state during each of these MW syntheses. Given that plasma is essentially a gas formed from ions and electrons, the Mg_2Si and Mg_2Ge synthesis processes can be likened to many conventional high temperature solid–

Scheme 1 Schematic of the principal Mg plasma-enabled reaction route proposed for the MIMP synthesis of Mg_2Si and Mg_2Ge .

gas reactions, which are often similarly pseudomorphic.^{61,62} The principal difference in the MIMP case is that it is the *metal* starting material that reacts ostensibly in the gaseous phase. Any contrast, therefore, between the MIMP Mg_2X reactions mainly lies in the state of X. For Si and Ge, with high melting points and vapour pressures, the non-metal remains in the solid state (Scheme 1). For $X = \text{Sn}$, which has very different physical properties and where Sn interacts considerably with the MW field itself, the situation is rather different and a range of possible reaction processes are possible, as discussed previously.⁵

Performing the Mg_2X MW syntheses under vacuum has profound effects on not only the way in which the reaction proceeds, but also on reaction efficiency and product purity. Comparing the purity of MIMP-synthesised Mg_2Si with that prepared using MW in the *solid state* in a nitrogen atmosphere under otherwise similar conditions previously (175 W, 120 s), the latter contained both Si and Mg as impurity phases among the products.³⁶ Given that the coupling of solid Si with the magnetic component of the field was proposed as the primary heating mechanism towards reaction with Mg, it is perhaps not unexpected that the products lacked homogeneity. By contrast, the study noted that the fine powdered Mg starting material did not couple effectively with either component of the 2.45 GHz MW field.³⁶

In the MIMP reactions, the coupling and direct heating of both of the Mg and X reactant powders with MWs is clearly important and this is especially true for Mg, as the initial heating stage is the vital precursor to Mg plasma formation. This can be observed in the opening seconds of the MIMP reactions when from an initial state of no plasma formation, the colour of the evolving plasma transforms from purple (residual trace gas in the tube) to green (magnesium). This almost immediate and steady formation of reactant metal plasma *in vacuo* contributes hugely to the rapid reaction kinetics, as the motions of the charged particles in the plasma phase are enhanced by the 2.45 GHz electromagnetic field.^{3,5} The possibility of producing Mg_2X ($X = \text{Si, Ge, Sn}$) within 60 s contrasts enormously with equivalent conventional high-temperature solid-state approaches which typically require in excess of 10 h to complete.^{5,17} While the results also demonstrate the powerful potential to fabricate bespoke nanostructured intermetallic materials *via* the

judicious selection of precursors, it will likely be the ability to scale up the MIMP method that will have the biggest impact on large scale materials production for applications such as rechargeable ion batteries and biomedical therapeutics.

Conclusions

In summary, the MIMP approach has proved highly effective in the synthesis of the high purity, polycrystalline Mg_2Si and Mg_2Ge *Zintl* phases. Application of an incident power of merely 200 W to the solid elemental reactants *in vacuo*, led to each product within 60 s. The reaction of Mg with Ge was revealed as pseudomorphic, with nanoporous Mg_2Ge attainable from Mg powder and nanoporous Ge starting material. The experiments shed further light on the mechanisms of the MIMP process, demonstrating that the formation of metal (Mg) plasma is fundamental to its success. The plasma facilitates rapid reaction rates and the physical state of the other reactant, X, with which the plasma interacts, is pivotal in determining the microstructure of the products. The synthesis of high purity Mg_2X has also enabled further investigations of the structure–composition relationships of the silicide, germanide and stannide *Zintl* phases. The implications of Mg–Mg interactions within the Mg_8 sub-lattices and the (non)existence of vacancies at the 8c (1/4, 1/4, 1/4) site are manifestly likely to be pivotal in determining the electronic (and possibly ionic) transport properties. Further systematic studies (including neutron diffraction combined with electrical and thermal conductivity measurements, for example) should be able to test these hypotheses further. Meanwhile, further investigations should be conducted to extend the MIMP method towards the rapid energy-efficient synthesis of other *Zintl* phases, intermetallics and alloys.
