# The states that hide in the shadows: the potential role of conical intersections in the ground state unimolecular decay of a Criegee intermediate†

Barbara Marchetti,<sup>\*a</sup> Vincent J. Esposito,<sup>id b</sup> Rachel E. Bush<sup>a</sup> and  
Tolga N. V. Karsili<sup>id \*a</sup>

Criegee intermediates are of great significance to Earth's troposphere – implicated in altering the tropospheric oxidation cycle and in forming low volatility products that typically condense to form secondary organic aerosols (SOAs). As such, their chemistry has attracted vast attention in recent years. In particular, the unimolecular decay of thermal and vibrationally-excited Criegee intermediates has been the focus of several experimental and computational studies, and it is now recognized that Criegee intermediates undergo unimolecular decay to form OH radicals. In this contribution we reveal insight into the chemistry of Criegee intermediates by highlighting the hitherto neglected multi-state contribution to the ground state unimolecular decay dynamics of the Criegee intermediate products. The two key intermediates of present focus are dioxirane and vinylhydroperoxide – known to be active intermediates that mediate the unimolecular decay of CH<sub>2</sub>OO and CH<sub>3</sub>CHOO, respectively. In both cases the unimolecular decay path encounters conical intersections, which may play a pivotal role in the ensuing dynamics. This hitherto unrecognized phenomenon may be vital in the way in which the reactivity of Criegee intermediates are modelled and is likely to affect the ensuing dynamics associated with the unimolecular decay of a given Criegee intermediate.

## Introduction

Criegee intermediates are a class of highly reactive organic compounds, known most prominently as reactive atmospheric oxidants. They are distinguishable by their carbonyl oxide functional group that contains Zwitterionic (or biradical) character. Criegee intermediates are an important source of non-photolytic OH radicals,<sup>1–5</sup> and are well-known for their role in promoting the oxidizing capacity of the troposphere and for forming low volatility products that typically condense to form secondary organic aerosols (SOAs). In the atmosphere, Criegee intermediates are formed *via* the oxidation of volatile alkenes with ozone.<sup>6–9</sup> The nascent Criegee intermediates are formed highly internally excited and may undergo prompt unimolecular decay or vibrational energy relaxation *via* collisions with bath molecules in the troposphere (*e.g.*, N<sub>2</sub>).<sup>10–13</sup> If the latter prevails, the resulting state is known as a stabilized Criegee intermediate, which may then undergo unimolecular decay or bimolecular reaction with trace tropospheric gas molecules (notably H<sub>2</sub>O,

SO<sub>2</sub> and organic acids).<sup>14–17</sup> Both processes are implicated in enhancing the oxidizing capacity of the troposphere and in forming SOAs.

The chemistry of Criegee intermediates of varying molecular complexities have been at the centre of several experimental and computational studies.<sup>11,18–23</sup> It is now recognized that the unimolecular decay of Criegee intermediates is an important source of OH radicals – which is the main oxidizer in the troposphere. The simplest Criegee intermediates, formaldehyde oxide (henceforth CH<sub>2</sub>OO) undergoes unimolecular decay to form OH radicals – as well as CO, CO<sub>2</sub> and formic acid.<sup>24,25</sup> This unimolecular decay is summarized in Scheme 1 and is driven by isomerization of CH<sub>2</sub>OO to form a dioxirane intermediate, which then undergoes ring-opening to form formic acid *via* a bisoxy biradical intermediate.<sup>24</sup> Recent work has detected formic acid, CO, CO<sub>2</sub> and OH products from CH<sub>2</sub>OO. The Criegee intermediates in this case is formed by initial photolysis of CH<sub>2</sub>I<sub>2</sub> and subsequent reaction of the nascent CH<sub>2</sub>I radical with seed O<sub>2</sub> gas molecules – forming CH<sub>2</sub>OO + I products.<sup>25</sup>

The simplest alkyl substituted Criegee intermediates, acetaldehyde oxide, CH<sub>3</sub>CHOO, may also undergo unimolecular rearrangement to form acetic acid, *via* rearrangement of an methyldioxirane intermediate. This however constitutes a minor channel in CH<sub>3</sub>CHOO and the dominant unimolecular

Scheme 1 Reaction mechanism associated with the unimolecular decay of  $\text{CH}_2\text{OO}$  to form the bisoxy biradical.

Scheme 2 Reaction mechanism associated with the unimolecular decay of  $\text{CH}_3\text{CHOO}$  to form the  $\text{CH}_2\text{CHO} + \text{OH}$  radicals via a VHP intermediate.

decay pathway is intramolecular H-atom transfer to form vinylhydroperoxide (VHP), followed by unimolecular decay to form  $\text{CH}_2\text{CHO} + \text{OH}$  radicals.<sup>4,26–31</sup> This latter process is highlighted in Scheme 2 and is now understood to be a key contributor to the OH radical yield in the troposphere. Criegee intermediates with  $>\text{C}_2$  are also known to undergo unimolecular decay to form OH radicals.<sup>29,32</sup> In such Criegee intermediates the mechanism is the same as that outlined in Scheme 2 for  $\text{CH}_3\text{CHOO}$ .

In the present study, we use state-of-the-art multi-reference quantum chemical methods to access the extent to which coupling between multiple electronic states contributes to the ground state (thermal or vibrationally excited) unimolecular decay dynamics of Criegee intermediates. In so doing, we assess the ground and excited state energy profiles of two key intermediates, dioxirane and VHP, which are known to mediate unimolecular decay in Criegee intermediates. The recognition that the ensuing dynamics occurs on multiple energy profiles may potentially influence the dynamics – including altering the product branching ratios and yields.

## Computational methodology

All optimizations (ground state minima and conical intersections) were performed in the Gaussian 16 computational package.<sup>33</sup> The (X)MS-CASPT2 computations were undertaken in the Molpro computational package.<sup>34,35</sup>

The ground state minimum energy geometry of dioxirane was optimized with Density Functional Theory (DFT), using Grimme's B2PLYP-D3<sup>36</sup> functional coupled to the 6-311+G(d,p) basis set.<sup>37,38</sup> This functional has been shown to perform well in optimizing geometries and obtaining normal modes in Criegee intermediates.<sup>29,31</sup>

Relaxed potential energy profiles along the O–O stretch coordinate ( $R_{\text{OO}}$ ) were constructed by fixing  $R_{\text{OO}}$  at various values and optimizing the remainder of the nuclear with the Møller-Plesset second-order perturbation theory<sup>39,40</sup> or the complete active space second-order perturbation theory (CASPT2), method coupled to the aug-cc-pVTZ basis set.<sup>41</sup> At each relaxed geometry, multi-state complete active space second-order perturbation theory (MS-CASPT2),<sup>42</sup> coupled to the aug-cc-pVTZ basis set, was used to obtain the ground and lowest three electronically excited state energies. The lowest four states of singlet spin-multiplicity were mixed in the MS-CASPT2 calculations and were based on a state-average complete active space self-consistent field (SA4-CASSCF) reference wavefunction. An active space consisting of twelve electrons in ten orbitals was used in the CASSCF and MS-CASPT2 calculations. The active orbitals are displayed in Fig. S1 of the ESI.†

A conical intersection between the ground and first electronically excited state of dioxirane was located at the CASSCF/6-31G(d) level of theory. In this case a smaller active space of six electrons in five orbitals was used. This smaller active space (*cf.* PE profiles) is adequate for describing the two-state interaction between the  $S_0$  and  $S_1$  states at a localized region, while in the PE profiles, the larger active space is required to describe the long-range PE profiles of the four coupled electronic states (*vide infra*).

The ground state minimum energy geometry of VHP was optimized using Grimme's B2PLYP-D3 functional coupled to the 6-311+G(d,p) basis set. Unrelaxed (rigid body) potential energy profiles along the  $R_{\text{OO}}$  coordinate were constructed by elongating the  $R_{\text{OO}}$  bond length and performing single-point calculations of the four lowest singlet electronic states at each geometry. All other coordinates were fixed at their equilibrium geometry. The single-point calculations were performed using Extended Multi-State complete active space second-order perturbation theory (XMS-CASPT2)<sup>43</sup> in conjunction with the aug-cc-pVTZ basis set. All 4 states were mixed in the XMS-CASPT2 wavefunction and were based on a 4 state-averaged CASSCF (SA4-CASSCF) reference wavefunction using the same basis set. An active space of twelve electrons in nine orbitals was used, the latter of which are visualized in Fig. S2 of the ESI.† CASPT2 relaxed scans were also conducted along  $R_{\text{OO}}$ , by fixing  $R_{\text{OO}}$  at various values and allowing the remainder of the nuclear framework to relax to their ground state minimum energy configurations.

The active spaces for both dioxirane and VHP were selected in order to describe all significant electronic effects while maintaining an appropriate computational expense. The reactant and product vertical excitation energies were benchmarked with various active

spaces. These results are displayed in Table S1 and S2 of the ESI† and show that variations in the active space show only modest changes to the excitation energies.

## Results and discussion

### Ground state structures and vertical excitation energies

Fig. 1 presents the ground state minimum energy geometry of dioxirane and VHP – calculated at the B2PLYP-D3/6-311+G(d,p) level of theory. As previously noted,<sup>26,44</sup> the ground state minimum energy geometry of both dioxirane and VHP are with all carbon and oxygen atoms in a common plane. In dioxirane, the carbon atom is at the centre of a pseudo-tetrahedral geometry, in which the carbon-hydrogen and carbon-oxygen bonds form a symmetric arrangement around the central carbon-atom. In VHP the hydrogen atom on the terminal OH moiety is out of the molecular plane – forming a staggered conformation. This is consistent with the molecular geometry of hydrogen peroxide which also shows a staggered conformation.<sup>45,46</sup>

Fig. 2 presents the dominant electronic configurations associated with the ground and excitation to the lowest three electronically excited singlet states of dioxirane and VHP.

In dioxirane the ground state involves an expected electronic configuration in which all bonding and non-bonding valence orbitals are doubly occupied. The first and second vertically excited states involve single-excited electronic configurations, involving promotion from an out-of-plane valence orbitals to a common in-plane  $\sigma^*$  virtual orbital. This  $\sigma^*$  orbital is localized along the O–O bond of the dioxirane. The third excited state also arises by electron transition to the same  $\sigma^*$  orbital but in this case the configuration is doubly-excited – with the  $\sigma^*$  orbital doubly occupied.

In VHP the ground state also involves an expected electronic configuration in which all orbitals are doubly occupied. The excited electronic states all involve promotion of an electron to a common  $\sigma^*$  orbital localized along the O–O bond. The first, second and third electronically excited state configurations are distinguishable by the different  $\pi$  orbital from which the electron is promoted.

## Unimolecular decay paths

### Dioxirane

Fig. 3 presents the adiabatic MS-CASPT2 potential energy (PE) profiles along the O–O stretch coordinate (henceforth  $R_{OO}$ )

Fig. 1 Ground state minimum energy geometry of dioxirane and VHP – calculated at the B2PLYP-D3/6-311+G(d,p) level of theory.

Fig. 2 Orbitals and orbital promotions associated with the vertically excited electronic states of (a) dioxirane and (b) VHP.

of dioxirane. Panels (a) and (b) are distinguishable by the relaxation of the nuclear framework with MP2 or CASPT2, respectively. These will henceforth be referred to as MS-CASPT2/AVTZ//MP2/AVTZ and MS-CASPT2/AVTZ//CASPT2/AVTZ, respectively. Additional details are given in the methodology section. The geometry at  $R_{OO} = 1.56$  Å corresponds to the dioxirane reactant whilst that at  $R_{OO} \sim 2.4$  Å corresponds to the bisoxy biradical – which is the intermediate precursor for forming formic acid. As shown, the PE profiles of the adiabatic ground state (blue curve in Fig. 3) follows that of a typical ground state reaction, wherein the reactant dioxirane and the product bisoxy biradical are separated by a PE barrier at *ca.*  $R_{OO} \sim 2.2$  Å. The molecular structures of the reactant, product and saddle point (of dioxirane and the bisoxy diradical) accord well with previous single point computations by Guo and co-workers.<sup>44</sup> Fig. 3 also displays the adiabatic  $S_1$ ,  $S_2$  and  $S_3$  states along the  $R_{OO}$  coordinate. In both the MS-CASPT2/AVTZ//MP2/AVTZ and MS-CASPT2/AVTZ//CASPT2/AVTZ PE profiles, all three excited states show a net decrease in PE upon increasing  $R_{OO}$  from that of the ground state equilibrium value. This can be understood by recognizing that all vertically excited electronic states correspond to excitations to a common  $\sigma^*$  orbital, localized on the O–O bond (as outlined in the previously section). This will inevitably lead to a long-range repulsive interaction upon decreasing  $R_{OO}$  when viewed from the bisoxy biradical geometry. The relative gradients along  $R_{OO}$ , of the excited electronic states at the Franck–Condon region, qualitatively increases from  $S_1$  to  $S_3$ . This steepest gradient of the  $S_3$  state (*cf.*  $S_1$  and  $S_2$  states) can be understood by recognizing that the electronic state arises *via* promotion of an electron-pair to the  $\sigma^*$  orbital (see Fig. 3) – leading to a doubly excited state configuration. This manifests in a lower bond order for  $S_3$  (*cf.*  $S_1$  and  $S_2$  states). Instead, the  $S_1$  and  $S_2$  states arise *via* a

**Fig. 3** Relaxed PE profiles along the O–O stretch coordinate of dioxirane of the lowest four singlet states, calculated at the (a) MS-CASPT2/AVTZ//MP2/AVTZ and (b) MS-CASPT2/AVTZ//CASPT2/AVTZ levels of theory. The orbitals represent the highest doubly occupied molecular orbital and various points, two of which are indicated by arrow. The orbital displayed in the yellow box is the highest doubly occupied molecular orbital of the  $S_3$  state (yellow profile) at  $R_{OO} = 1.56$  Å. The step change between  $R_{OO} = 2.18$  Å and  $R_{OO} = 2.2$  Å represents a change in the C–O bond distance from 1.44 Å to 1.31 Å. Panel (c) shows a LIIC between this step change in energy between the relaxed  $R_{OO} = 2.18$  Å and  $R_{OO} = 2.2$  Å geometries displayed in (b).

single excitation to the  $\sigma^*$  orbital – leading to a singly occupied configuration and thus a greater O–O bond order when compared to  $S_3$ .

The  $S_1$  state becomes degenerate with the  $S_0$  state at *ca.*  $R_{OO} = 2.2$  Å, at which point the  $S_2$  and  $S_3$  states are also close in energy to the  $S_0$  state. This is particularly noteworthy as  $R_{OO} \sim 2.2$  Å also corresponds to the transition state geometry associated with the ground state unimolecular decay of dioxirane to the bisoxy biradical. From the dioxirane parent molecule, progressive elongation of  $R_{OO}$  leads to an adiabatic change in the ground state electronic configuration from the dioxirane to the bisoxy biradical. This change in the electronic wavefunction is illustrated by the change in the highest occupied molecular orbital upon forming the bisoxy biradical from dioxirane. The highest occupied molecular orbital of the bisoxy biradical is of anti-bonding ( $\sigma^*$ ) character and is therefore unoccupied in the ground state dioxirane. The ground state electronic configuration of the bisoxy biradical product therefore correlates with an excited electronic state configuration of the reactant dioxirane structure that is distinct from that of ground state dioxirane.

Although the PE profiles calculated at the MS-CASPT2/AVTZ//MP2/AVTZ and MS-CASPT2/AVTZ//CASPT2/AVTZ level are similar in the region between  $R_{OO} = 1.56$  Å and  $R_{OO} = 2.18$  Å, we note an important distinction at long  $R_{OO}$ . As shown in Fig. 3(b), the MS-CASPT2/AVTZ//CASPT2/AVTZ PE profiles show a step discontinuity in the energy profiles between  $R_{OO} = 2.18$  Å and  $R_{OO} = 2.2$  Å, which arises *via* the reduction of the C–O bond distance from *ca.*  $R_{CO} = 1.44$  Å (at  $R_{OO} \leq 2.18$  Å) to  $R_{CO} = 1.31$  Å (at  $R_{OO} \geq 2.2$  Å). This behaviour is not captured in the MP2 relaxation due to its inherent single-reference nature. To investigate this step change in energy further, additional MS-CASPT2 PE profiles connecting the CASPT2 relaxed geometries at  $R_{OO} = 2.18$  Å to  $R_{OO} = 2.2$  Å were constructed using a Linear interpolation in internal coordinates (LIIC). Fig. 3(c) presents the resulting LIIC between the CASPT2 relaxed geometries at  $R_{OO} = 2.18$  Å and  $R_{OO} = 2.2$  Å, which shows the smooth barrierless variation of the ground state from  $R_{OO} = 2.18$  Å to  $R_{OO} = 2.2$  Å. When comparing the bisoxy biradical relative energy (*cf.* to the dioxirane parent molecule), calculated at the MS-CASPT2/AVTZ//MP2/AVTZ and MS-CASPT2/AVTZ//CASPT2/AVTZ levels, the latter is in excellent agreement with previous high-level CCSD(T)-F12 calculations of the energy difference between dioxirane and bisoxy.<sup>44</sup> The variation is noteworthy since it shows that MP2 relaxation does not sufficiently describe the multi-reference nature of the bisoxy biradical (beyond  $R_{OO} = 2.18$  Å).

With these topographic details in mind, the ground state reaction from dioxirane to the bisoxy biradical may involve substantial non-adiabaticity as the change in the electronic wavefunction is associated with a transition state that is close in energy to the several excited states. This is reinforced by recognizing that the transition state and degeneracy at *ca.*  $R_{OO} = 2.2$  Å is associated with a conical intersection. Fig. 4 displays the optimized  $S_0/S_1$  conical intersection geometry, which although performed with a different level of theory (*i.e.*, smaller active space, basis set and CASSCF method) than the PE profiles in Fig. 3 (see Methodology section), is consistent with the same point at  $R_{OO} = 2.2$  Å. Any changes in the geometry are minor – as revealed by  $R_{OO} = 2.157$  Å in the optimized

Fig. 4  $g$  and  $h$  vectors associated with the optimized  $S_0/S_1$  conical intersection of dioxirane.

structure vs.  $R_{OO} = 2.2 \text{ \AA}$  (MP2 relaxed) and  $R_{OO} = 2.16 \text{ \AA}$  (CASPT2 relaxed) in Fig. 3(a) and (b), respectively. Fig. 4 also displays the  $g$  and  $h$  vectors associated with the optimized conical intersection. It is reassuring that the  $g$ -vector – *i.e.*, the gradient-difference vector (or tuning coordinate) – is associated with the reactive coordinate. The  $h$ -vector – *i.e.*, the derivative-coupling vector (or coupling coordinate) requires anti-symmetric wagging of the oxygen and hydrogen atoms in order to lift the degeneracy associated with the conical intersection.

The transition state at  $R_{OO} = 2.2 \text{ \AA}$  in Fig. 3 is the lower part of a conical intersection and is therefore expected to undergo non-adiabatic coupling with the excited electronic states. Motion around the lower cone of the conical intersection may give rise to the geometric phase (GP) effect as the electronic wavefunction bifurcates around the point of degeneracy. The GP effect is a characteristic signature of conical intersections and arises when the adiabatic electronic wavefunction changes sign when transported around the conical intersection. The inherent GP effect may then control the exit channel energy dissipation and thus the ensuing chemistry for formic acid formation. Such effects are common in molecular reactions that are analogous to the current system of interest and it is known that such effects persist even in cases in which the conical intersection is much higher in energy than the initially excited vibrational resonance of the ground state.<sup>47</sup> Ample studies

have demonstrated that the GP needs to be considered in treating the adiabatic dynamics around a conical intersection.<sup>47–53</sup>

We make one caveat that since dioxirane is likely prepared highly vibrationally excited, the subsequent O–O bond fission to form the bisoxy biradical may not necessarily follow the minimum energy path as given by the relaxed PE profiles. Although these side routes are possible at high internal energies, the most energetically probable route is the minimum energy path.

### Vinyl hydroperoxide (VHP)

Similar behaviour is observed in our next case study vinyl hydroperoxide (VHP). VHP is formed when thermalized or vibrationally excited  $\text{CH}_3\text{CHOO}$  undergoes intramolecular 1,4-H-atom transfer. The nascent VHP is formed with high internal excitation – which is excess of the energetic limit for forming  $\text{CH}_2\text{CHO} + \text{OH}$  products. This process is the dominant unimolecular decay path for alkyl-substituted Criegee intermediates.

Fig. 5 presents the adiabatic PE profiles along the O–O stretch coordinate ( $R_{OO}$  – identified in the molecule inset in Fig. 5(a)) of VHP. Panels (a) and (b) indicate the PE profiles along  $R_{OO}$  at geometries at which the CCOO torsional angle ( $\tau_{\text{CCOO}}$  – identified in the yellow highlight on the VHP in Fig. 5(a)) is at  $\tau_{\text{CCOO}} = 0^\circ$  and  $90^\circ$ , respectively.  $\tau_{\text{CCOO}} = 0^\circ$  is a planar configuration and corresponds to the minimum energy geometry displayed in Fig. 1 while  $\tau_{\text{CCOO}} = 90^\circ$  corresponds to an out-of-plane configuration.

Focussing on Fig. 5(a), the energy at  $R_{OO} = 1.45 \text{ \AA}$  corresponds to the VHP parent molecule, while the asymptotic region beyond  $R_{OO} > 2.5 \text{ \AA}$  corresponds to the  $\text{OH} + \text{CH}_2\text{CHO}$  radical products. The ground state PE profile shows a characteristic topology associated with a bond dissociation process – wherein the energy rises upon increasing  $R_{OO}$  and then plateaus as the PE profile becomes asymptotic. In the asymptotic region and under gas phase conditions, the OH and  $\text{CH}_2\text{CHO}$  fragment partners are at a terminal separation. As with dioxirane, the ground state PE profile along  $R_{OO}$  shows an avoided crossing with the  $S_1$  state at *ca.*  $R_{OO} = 2.3 \text{ \AA}$ . As Fig. 3 implies, the degeneracy observed at  $R_{OO} = 2.3 \text{ \AA}$  and  $\tau_{\text{CCOO}} = 0^\circ$  is lifted by motion along  $\tau_{\text{CCOO}}$  which is consistent with coupling mode behaviour at a conical intersection. The lowest three excited states of VHP are dissociative with respect to  $R_{OO}$ , which can be understood by considering that all three electronic states correspond to excitation into a common  $\sigma^*$  orbital localized along the O–O bond.

To investigate the minimum energy path associated with VHP further, fully relaxed PE profiles along the  $R_{OO}$  coordinate were undertaken. These are presented in Fig. 5(c). The CASPT2 relaxed PE profile shows that the parent VHP molecule is planar at short range  $R_{OO}$  and undergoes progressive motion out of plane at  $1.9 \text{ \AA} \geq R_{OO} \geq 2.4 \text{ \AA}$ . This aligns with the unrelaxed PE profiles which show that the most stable configuration of VHP is planar, while motion around the crossing  $R_{OO} = 2.3 \text{ \AA}$  along  $\tau_{\text{CCOO}}$  shows a lower energy route to OH elimination. Although motion along  $\tau_{\text{CCOO}}$  manifests in the ground state minimum energy path at  $1.9 \text{ \AA} \geq R_{OO} \geq 2.4 \text{ \AA}$ , the  $S_1$  state is unstable with

Fig. 5 Unrelaxed adiabatic PE profile of VHP along the O–O stretch coordinate at (a)  $\tau_{\text{CCOO}} = 0^\circ$  and (b)  $\tau_{\text{CCOO}} = 90^\circ$ , calculated at the XMS-CASPT2/aug-cc-pVTZ level of theory. (c) XMS-CASPT2/AVTZ//CASPT2/AVTZ relaxed PE profiles along the  $R_{\text{OO}}$  coordinate.

respect to increasing  $\tau_{\text{CCOO}}$  in this  $R_{\text{OO}}$  range. This is highlighted by the step increase in energy from  $R_{\text{OO}} = 1.8 \text{ \AA}$  to  $R_{\text{OO}} = 1.9 \text{ \AA}$  in Fig. 5(c) and supported by the unrelaxed PE profiles in Fig. 5(a) and (b). At  $R_{\text{OO}} = 2.6 \text{ \AA}$ , the ground state minimum energy path shows a planar geometry and a rotation of the OH moiety so as to undergo hydrogen bonding of the H-atom with the nascent vinyloxy centred O-atom. Such a geometry along  $R_{\text{OO}}$  is consistent with earlier study by Kidwell *et al.*<sup>54</sup> and is attributed to a frustrated submerged transition state.

As with dioxirane, we note however that since VHP is prepared highly vibrationally excited and undergoes intramolecular vibrational energy redistribution, the subsequent OH elimination may not necessarily follow the minimum energy path as given by the relaxed PE profiles.

As shown in the PE profiles in Fig. 5 the lowest energy asymptote corresponds to OH ( $D_0$ ) + CH<sub>2</sub>CHO ( $D_0$ ) products and correlates with an excited state electronic configuration – as indicated by the change in the highest occupied molecular orbital of the ground state VHP at  $R_{\text{OO}} = 4.0 \text{ \AA}$  relative to the ground state. Again, unimolecular decay of ground state VHP clearly involves coupling of energy surfaces en route to forming OH + CH<sub>2</sub>CHO. Although motion along  $\tau_{\text{CCOO}}$  lifts the degeneracy at  $R_{\text{OO}} = 2.3 \text{ \AA}$  and provides a lower energy route around this crossing point, the ensuing dynamics is likely perturbed by the intersection at  $R_{\text{OO}} = 2.3 \text{ \AA}$  as the evolving wavepacket bifurcates as it traverses the region around the crossing point. Unimolecular decay is therefore likely to involve substantial non-adiabaticity upon dissociation, wherein the GP effect may play a role in the ensuing dynamics as described above for dioxirane. This feature is analogous to the ground state unimolecular decay of vibrationally excited hydroxymethyl radical which is known to occur non-adiabatically.<sup>47</sup>

## Conclusions

In this study, we have demonstrated the multi-state character associated with two well-known unimolecular decay paths available to Criegee intermediates. This hitherto unrecognized multi-state character, in the context of the products of Criegee intermediates, is an important recognition as it may control the nascent product yields formed upon unimolecular decay of Criegee intermediates. In 2018, Guo and co-workers discovered the role of conical intersections in the unimolecular decay of the hydroxymethyl radical and demonstrated that the geometric phase effect plays a role in controlling the rovibrational energy dissipation of the nascent formaldehyde product.<sup>47</sup> In the context of the systems explored here, similar behaviour may effect on the product state branching in the nascent intermediates and fragments formed during the unimolecular decay of dioxirane or VHP. Providing that the nascent products react on timescales that are shorter than collisional energy relaxation, the preselected rovibrational energy distribution may have an implication on the resulting reactions of these atmospherically relevant products, but we note that these most likely undergo vibrational energy relaxation and thermalization prior to bimolecular chemistry. Notwithstanding, we demonstrate that such multi-state behaviour should be considered in future computational studies of molecular reactions that are relevant in the atmosphere or in combustion – especially in the context of Criegee intermediates.

Given the details of the PE profiles above, our future plan is to generate full-dimensional energy profiles and to undertake time-dependent quantum wavepacket dynamics simulations on the subsequent energy surfaces. Such simulations will reveal

the extent to which the unimolecular dynamics involves coupling to the excited state energy surfaces and thus if the reaction occurs non-adiabatically. One of the key questions that such simulations will answer is if the GP effect plays a role in the product state energy distributions of the nascent products.

The most exciting prospect is to explore how such electronic state couplings associated with the unimolecular decay of a dioxirane or a hydroperoxide change upon increasing molecular complexity of the starting Criegee intermediate. Future studies on the geometric and electronic effects of increasing molecules complexity are therefore also anticipated.
