Core–shell and heterostructured silver–nickel nanocatalysts fabricated by γ -radiation induced synthesis for oxygen reduction in alkaline media†

Yi Yang, ^{*a} Gerard Montserrat-Sisó, ^b Björn Wickman, ^b Pavel Anatolyevich Nikolaychuk ^c and Inna L. Soroka ^{*a}

To reach commercial viability for fuel cells, one needs to develop active and robust Pt-free electrocatalysts. Silver has great potential to replace Pt as the catalyst for the oxygen reduction reaction (ORR) in alkaline media due to its low cost and superior stability. However, its catalytic activity needs to be improved. One possible solution is to fabricate bimetallic nanostructures, which demonstrate a bifunctional enhancement in the electrochemical performance. Here, two types of bimetallic silver–nickel nanocatalysts, core–shells (Ag@NiO) and heterostructures (Ag/Ni), are fabricated using γ -radiation induced synthesis. The Ag@NiO nanoparticles consist of an amorphous, NiO layer as a shell and a faceted crystalline Ag particle as a core. Meanwhile, the Ag/Ni heterostructures comprise Ag particles decorated with Ni/Ni(oxy–hydro)–oxide clusters. Both materials demonstrate similar and increased alkaline ORR activity as compared to monometallic catalysts. It was revealed that the enhanced catalytic activity of the core–shells is mainly attributed to the electronic ligand effect. While in the Ag/Ni heterostructures, a lattice mismatch between the Ni-based clusters and Ag implies a significant lattice strain, which, in turn, is responsible for the increased activity of the catalyst. Also, the Ag/Ni samples exhibit good stability under operating conditions due to the existence of stable Ni³⁺ compounds on the surface.

Introduction

Anion exchange membrane fuel cells (AEMFCs) are considered as next generation fuel cells and show great potential to be an alternative to acidic proton exchange membrane fuel cells (PEMFCs).¹ Alkaline conditions in AEMFCs allow the usage of less expensive, Pt-free catalysts for the oxygen reduction reaction (ORR).² Potential candidates include many abundant transition metals, the use of which drastically reduces the cost per kilowatt of power in fuel cell devices.³ One such candidate is Ag, whose market price is approximately 50 times lower than that of Pt and 90 times lower than the price of Pd and Au.⁴ Moreover, as it has been reported in a number of studies, Ag

can display high electrocatalytic activity for the ORR in alkaline media.^{5–7} Like Pt, the ORR on the silver surface takes place *via* a pseudo four-electron transfer pathway. The Tafel slope for the Ag catalysts shows a similar trend to that for Pt, thus, indicating the similarity of ORR kinetics for both metals.^{8,9} In addition, Ag has good electrochemical stability in alkaline solutions according to the Pourbaix diagram.¹⁰

It is believed that there are two dominant factors that govern the ORR activity in alkaline media: (i) adsorption strength of the oxygen species on the catalyst surface and (ii) O–O bond breakage tendency.^{11,12} However, since the d-band of Ag is completely occupied, it is difficult for pure silver to provide unpaired electrons from the d-band to form bonds with oxygen, thus resulting in low oxygen coverage.¹³ Meanwhile, Ag shows slow kinetics of the O–O bond split.¹² These factors result in much lower ORR activity of Ag than that of *e.g.*, Pt. One way to improve the ORR activity of Ag is to decrease the d-band charge density, thus, lowering the d-band center. This can be done by introducing another metal with low d-band occupancy, for example, Ni¹⁴ and Co,¹⁰ to form bimetallic composites.

Ni is one of the most widely used elements in metal-based catalysts.¹⁵ It is known for its low d-band occupancy and high

alloying ability with some noble metals and many transition metals. As shown in the literature, the alloying effect may contribute to the enhanced catalytic activity of the constituents.^{10,16} Ag and Ni are thermodynamically immiscible, which makes it quite difficult to form alloys. However, some studies on Ag–Ni alloy nanomaterials can still be found.^{17,18} As shown in the literature, during synthesis and operation, metastable AgNi alloys may undergo structural reorganization followed by atomic segregation.^{19,20} In particular, Ag atoms tend to segregate at the surface of Co, Cu and Ni, to form thermodynamically stable phase-segregated structures.^{21–23} Nanocatalysts with phase segregated structures such as near-surface alloys,²⁴ core–shells,²⁵ Janus²⁶ and hetero-structures,²⁷ demonstrate improved kinetics mainly due to electronic effects induced from the segregated phases. Electronic effects can be categorized into two major types:^{12,28} (i) the ligand effect originates from the atomic vicinity of two different metal atoms. This leads to a charge transfer between the adjacent atoms and results in the modification of their electronic structures at interfaces. In this way, surface chemical properties can be altered, for instance, O–O breaking is facilitated.^{24,28} (ii) The strain effect, compressive or tensile, is caused by a lattice mismatch between constituents. Upon a compressive strain, the d-orbitals' overlapping index increases. It results in the broadening of the catalysts' d-bands and, consequently, in the lowering of its average energy. Thereafter, the adsorption energies of oxygenated adsorbates are expected to decrease.²⁹ Generally, ligand effects together with strain effects can synergistically alter the ORR activity of catalysts. Both effects usually co-exist and work as cumulative electronic effects.³⁰ Deconvolution of these two effects is feasible using theoretical modeling. However, it is a rather challenging problem for experimentalists.

In addition to the enhanced activity, the stability of the catalyst under operating conditions is equally important. Recently, Back *et al.*³¹ used density functional theory calculations to predict the stability and activity of a series of the noble-metal supported transition metal (oxy-hydro) oxide nanocatalysts. It was shown that the NiOOH|Ag composite is one of the most promising candidates as alkaline ORR catalysts due to both enhanced activity and stability. Given these facts, Ag–Ni nanocomposites with well-defined structures could be promising candidates as catalysts for oxygen reduction in alkaline media.

As a facile technique for producing nanomaterials, γ -radiation induced synthesis has been proved to have some advantages over other methods, such as room temperature processing, minimal use of hazardous chemicals and precise control of the amount of reactive species.^{32,33} In the current study, core–shell Ag@NiO and heterostructured Ag/Ni nanocatalysts for the ORR were produced by using the above-mentioned γ -radiation induced synthesis method. Essential structural, chemical, and electrochemical characterization studies of the synthesized materials are performed to emphasize the effect of compositional and structural modulation on the activity of the nanocatalysts.

Results and discussion

The general concept of γ -radiation induced synthesis of nanoparticles

The synthesis of materials by γ -radiation induced methods involves redox reactions of metal precursor salts with the products of water radiolysis. Upon absorbing ionizing radiation, water molecules undergo decomposition to form free radicals and active molecular species. The main radical products formed as a result of water radiolysis are hydroxyl radicals, OH[·], and solvated electrons, e_{aq}[−]. In neutral water, those radicals are formed in equal amounts of 0.28 $\mu\text{mol J}^{-1}$ and readily react with each other.^{34,35} The hydroxyl radicals are strong oxidants, while the solvated electrons are strong reductants (Table S1†). Thus, in order to tune the redox conditions of the solution to either reductive or oxidative, the undesired radical needs to be scavenged. To produce metallic nanomaterials, reductive conditions are created by adding, for example, propan-2-ol (IPA) as an OH[·] scavenger. The reaction between IPA and OH[·] results in the formation of reductive 2-hydroxy-2-propyl radicals, whose standard potential *vs.* the SHE is −1.8 V.³⁶

These radicals and solvated electrons are the main agents responsible for metal atom formation from monovalent metal ions.³⁷

For divalent ions the reduction may occur in the following sequence:

Considering the oxidation state of Ag and Ni in the precursor solutions, the reduction of Ag⁺ ions and Ag atom formation occur *via* reaction (2), while the reduction of Ni²⁺ to Ni⁰ may follow the route shown in reaction (3). The details of the γ -radiation induced synthesis of metallic Ni are given elsewhere.³⁸ Since the binding energy between the metal atoms is stronger than that between the atom and solvent, the metal atoms tend to form dimers and subsequently clusters. The metal ions in the solution can also adsorb to the clusters and be reduced on the cluster surface.³⁹ The size of the metal clusters can be controlled by adding polymers and surfactants.⁴⁰ The final size of the clusters or nanoparticles is dependent on the initial polymer/ion ratio and, thus, polymer concentration in solutions.

Fabrication of bimetallic Ag–Ni nanoparticles

The synthesis procedures of the Ag@NiO and Ag/Ni nanoparticles are illustrated in Fig. 1a. Core–shell Ag@NiO nanoparticles were synthesized by the co-reduction method where an aqueous solution containing both Ag and Ni salts was subjected to γ -radiation. The types of Ag and Ni species and the interaction between them under the synthesis conditions are

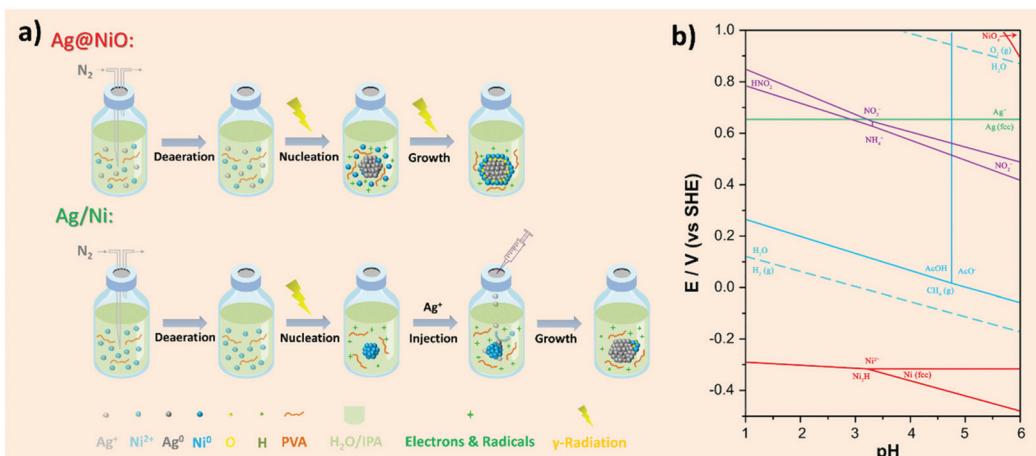

Fig. 1 (a) Synthesis procedure and formation process of Ag@NiO and Ag/Ni nanoparticles. (b) The potential–pH diagram calculated for the $\text{Ni}-\text{Ag}-\text{NO}_3-\text{AcO}-\text{H}_2\text{O}$ system containing 5 mM of Ni^{2+} and Ag^+ ions at $T = 298.15\text{ K}$ and an atmospheric pressure of 1 bar.

predicted by using the calculated potential–pH diagram for the $\text{Ni}-\text{Ag}-\text{NO}_3-\text{AcO}-\text{H}_2\text{O}$ system (Fig. 1b). The calculation details and parameters are presented in the ESI Chapter 3.† The chosen pH range in the diagram covers the experimental pH values, between 5.5 and 3, measured before and after irradiation, respectively. As seen in the diagram, no hydrolysis of the metal cations occurs in the chosen pH range. No bimetallic $\text{Ag}-\text{Ni}$ particles or mixed oxides are formed due to the homogeneous reactions in solutions, indicating that the interactions between the Ag and Ni species occur heterogeneously *via* the surface reactions.

The redox potential values for Ag and Ni calculated using actual experimental conditions correspond to 0.67 and -0.29 V , respectively, which are close to the theoretical values (see Table S1†), indicating the affinity of the ions for the electrons and the species' tendency to be reduced is much higher in Ag as compared to that in Ni. Therefore, there will be a thermodynamic driving force to a selective reduction of Ag ions first, and the reduction of Ni will take place only when the system is depleted by the Ag^+ ions.⁴¹ Hence, the reduction of Ni^{2+} in solution and the homogeneous nucleation of the Ni cluster occur to a lesser extent. The nucleation of the Ag particles takes place according to the following reactions:³⁹

The dimers formed in reaction (4) later merge into larger clusters. The unreacted remaining Ag ions adsorb on the cluster surface (reaction (5)) and are reduced provided that the reducing agents are continuously supplied into the solution. Moreover, the reduced Ag particles act as seeds over which the Ni-rich phase nucleates and grows. The resulting particles will have a core with the noble metal (Ag) and a shell layer with the less noble metal (Ni). It agrees with the mechanism of bimetallic nanoparticle formation in solutions exposed to γ -irradiation proposed by Belloni *et al.*,^{39,42} which implies that at a low dose

rate an electron transfers from the less noble metal to the more noble one and, thereby, core–shell structures form. The strong oxidative ability of Ag^+ leads to the oxidation of metallic Ni in the shell and Ni oxide formation, which is confirmed by X-ray photoelectron spectroscopy (XPS) studies. The reaction between Ni and Ag can be described as reaction (6)

The formation of Ni oxide can occur due to the reaction of the Ni species with molecular oxygen, and the latter is formed as a result of the decomposition of H_2O_2 (one of the products of water radiolysis) on the solid surface.

Heterostructured Ag/Ni have been synthesized by a successive reduction where the Ni nanoparticles were obtained first by γ -radiation induced reduction from the corresponding precursor solution. The details about the γ -radiation induce synthesis of Ni nanoparticles performed under similar conditions to those used in the current study are given in our previous work.³⁸ Thereafter the AgNO_3 solution was added, and no further irradiation has been performed. Thus, the Ni-containing clusters can act as seeds for the heterogeneous nucleation and further growth of the Ag nanoparticles. The charge transfer between Ag and Ni, reaction (6) that results in the oxidation of Ni surface layers, leads to the formation of Ni (oxy-hydro) oxide clusters.

Structural and compositional investigation of the Ag–Ni nanocatalysts

To achieve the aim of the current study, the following samples were produced and analysed: monometallic nanoparticles (Ag, Ni) and bimetallic Ag–Ni nanocatalysts: core–shell Ag@NiO , and heterostructured Ag/Ni. The morphology and structure of the obtained nanomaterials are investigated using transmission electron microscopy (TEM) and X-ray diffraction (XRD), respectively, and the surface atomic composition is obtained by XPS. Detailed analyses and descriptions of the monometallic Ag, Ni nanoparticles are shown in the ESI.†

Structure and morphology revealed with TEM. Core-shell Ag@NiO nanoparticles were obtained in the form of a black precipitate by irradiating a mixture containing Ag and Ni salts in an equal amount. The morphology of the precipitate was studied using TEM, and the results are presented in Fig. 2. The core-shell structure is confirmed by energy dispersive X-ray spectrometry (EDS) mapping shown in Fig. 2(e–g), where both Ag and Ni are present, but there is much more Ni in the outer layer. The Ag@NiO nanoparticles consist of large (162 nm on average) faceted particles (core) surrounded by a thin layer/shell (of about 2 nm thick), as demonstrated in Fig. 2(a and b). The composition of the core corresponds to metallic Ag that has a fcc structure as determined from the selected area electron diffraction (SAED) pattern (Fig. 2c). The presence of fcc Ag is confirmed by XRD studies (Fig. 4a). The interatomic distances determined from the high-resolution image and fast Fourier transform (FFT) pattern, shown in Fig. 2b, correspond to the (111) and (200) planes in metallic Ag. The lattice parameter of the Ag core calculated using the XRD pattern is 4105 ± 0.007 Å, (all lattice parameters of Ag obtained from XRD and SAED are presented in Table S2†). The shell represents an adjacent Ni atom containing an amorphous layer/shell of about 2 nm at the surface of the Ag core. As demonstrated in Fig. 2b, the interfaces between the crystalline Ag core and amorphous Ni-based shell are continuous and do not contain any pores or voids.

Heterostructured Ag/Ni nanoparticles are composed of single crystal Ag nanoparticles (the average size of 45 nm) and adjacent Ni-containing polycrystalline clusters, as seen in

Fig. 3. These clusters, whose diameters are ranging from 10 to 20 nm, consist of primary particles (with the size of 3 nm). The SAED pattern shown in Fig. 3c corresponds solely to the diffraction pattern from metallic fcc Ag. No clear signal from the Ni compounds is registered by the electron diffraction technique. However, the interatomic distances of the Ni-containing crystals, determined from the HRTEM image (Fig. 3b), are $d = 0.231$ nm that may correspond to either the (101) planes in $\text{Ni}(\text{OH})_2$, or the (102) planes in $\text{Ni}_2\text{O}_3/\text{NiOOH}$, while $d = 0.197$ nm corresponds to Ni (111).^{43,44} Thus, the epitaxial relationship between Ag and Ni (oxy-hydro) oxide can be shown in the following: Ag [100]// $\text{Ni}(\text{OH})_2$ [101] or/and Ag [100]// $\text{Ni}_2\text{O}_3(\text{NiOOH})$ [102]. The calculated lattice mismatch is about 11%, where Ni (oxy-hydro) oxide undergoes a compressive strain at the surface of Ag. Except for the conventional lattice plane, a Moiré pattern is observed (the area is labeled with a rectangle in Fig. 3b). The Moiré pattern is an optical phenomenon that indicates the coexistence of two sub-lattices that are either disoriented with respect to each other or have slightly different lattice constants.⁴⁵ Thus, the appearance of the Moiré pattern can be ascribed to the interferences from two randomly oriented Ag crystals and/or from the heterostructure formed at the interfaces between the Ag nanoparticles and the Ni-based nanoclusters.

Phase composition of the bimetallic samples studied with XRD. The XRD patterns of the Ag@NiO, Ag/Ni and reference Ag samples are presented in Fig. 4. The high-intensity diffraction peaks corresponding to fcc Ag⁴⁶ are visible for all

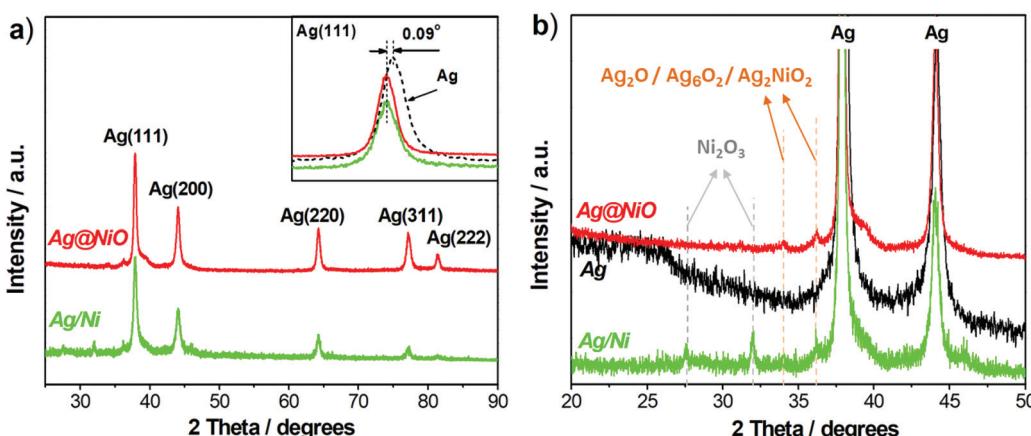

Fig. 4 (a) XRD patterns of Ag@NiO, core–shells and Ag/Ni heterostructures. Miller indices of the corresponding Ag peaks are denoted. The details of the Ag (111) peaks are shown in the inset. The black dashed curve corresponds to the XRD pattern recorded for the Ag nanoparticles. (b) The magnified ($2\theta = 20\text{--}50^\circ$) part of the XRD patterns containing low intensity peaks, recorded from the Ag@NiO, Ag/Ni and Ag nanoparticles. Possible compounds with low density peaks are labeled in b.

samples. Meanwhile, several low intensity peaks in the 2θ range from 20 to 37° have been observed only on the diffractograms recorded from the bimetallic samples but not from the reference ones. Although, the main crystalline phase formed during the synthesis is metallic Ag, the low-intensity XRD peaks recorded for both Ag@NiO and Ag/Ni samples indicate

the presence of other Ag- and/or Ni-based compounds. Thus, the XRD peaks at $2\theta \approx 34^\circ$ and 36.2° , shown in Fig. 4b, can be ascribed to Ag oxides Ag_2O_6 ⁴⁷ and Ag_2O (Ag₂F type)⁴⁸ and/or to a mixed oxide Ag_2NiO_2 .⁴⁹ While in the Ag/Ni sample, the low-intensity peaks at $2\theta = 27.6^\circ$ and 31.9° can be attributed to rhombohedral Ni_2O_3 .⁵⁰ Possible compounds detected with

XRD are listed in Table S3.† Note that the diffraction peaks neither from metallic Ni nor from NiO are observed. This may be due to the fact that the main XRD peak positions for fcc Ni⁵¹ and fcc NiO⁵² are overlapping with those for Ag. Thus, the diffraction peak from Ni (111) appears at $2\theta = 44.5^\circ$ almost overlapping with that from Ag (200) ($2\theta = 44.3^\circ$). As confirmed by TEM, the Ni-based compounds in our samples have much poorer crystallinity than the Ag:Ni-based compounds present in the samples either as thin amorphous layers (Ag@NiO) or as clusters that consist of primary particles with 2–3 nm in diameter. Therefore, X-ray diffraction is less sensitive to the Ni-based compounds in our samples. In addition, as seen in the insert in Fig. 4a, the positions of the Ag(111) peaks recorded from Ag@NiO and Ag/Ni are shifted by 0.09° towards lower 2θ with regard to that recorded from the metallic Ag sample (used as a reference). This indicates the presence of small crystal lattice distortions in the Ag–Ni samples. These distortions correspond to the Ag crystal lattice expansion of 0.65% in Ag@NiO and Ag/Ni as compared to the reference Ag sample. Thus, the X-ray diffraction study reveals that both bimetallic Ag–Ni nanoparticles consist of crystalline Ag and phases with low crystallinity which contain Ag- and Ni-based oxides.

Surface chemical composition of Ag and bimetallic Ag–Ni validated with XPS analysis. To further verify the composition and structure of the studied samples, XPS analysis was performed, and the resulting spectra are shown in Fig. 5. The binding energies (BE) of the O 1s, Ag 3d and Ni 2p core levels and the atomic ratio of Ag and Ni in the samples measured with XPS are given in Table S4.† The structural and compositional studies of free-standing Ni nanoparticles, produced by γ -radiation induced synthesis, were shown in our previous work.³⁸ Detailed XPS analysis of the Ag nano-

particles is shown in the ESI (Table S4† and the text below it).

For core–shell Ag@NiO sample, analysis of the XPS spectra reveals the Ag 3d_{5/2} BE peaks located at 368.6 eV and 368.2 eV. Note that the lower value is close to the BE of the Ag–Ag bonds in bulk.⁵³ Since the diameter of the Ag@NiO core–shell structures is much larger than that of the Ag nanoparticles, the size effect on the electronic structure can be neglected. Hence, the BE of 368.2 eV is attributed to metallic Ag. The higher energy peak may belong to Ag in the bimetallic compounds. As reported in the literature, the binding energies for Ag 3d in the Ag–Ni(OH)₂ composites may shift from 0.2 eV to 0.55 eV towards higher energies with respect to those in pure Ag.^{54,55} The Ni 2p_{3/2} photoelectron lines exhibit a shoulder towards high BEs, which is characteristic of NiO.⁵⁶ The asymmetry of the peak originates from the partial overlapping of the multiplet splitting of NiO and its 2p_{3/2} peaks found at 854.7 eV and 856.5 eV, together with its 2p_{1/2} peaks at 872.4 eV and 874.2 eV are in good agreement with the literature.⁵⁷

The deconvoluted spectrum of Ni 2p for the Ag/Ni sample shows several photoelectron peaks, both primary and secondary. There are three primary peaks resulting from the ejection of a core level electron located at 852.4 eV, 854.3 eV, and 856.5 eV. The first peak is attributed to the 2p_{3/2} spectral line from metallic Ni,⁵⁸ while the second and third peaks may belong to the Ni (oxy-hydro) oxides (Ni₂O₃ and/or NiOOH).^{59,60} Likewise, the primary peaks at 869.7 eV, 871.8 eV, and 874 eV are attributed to the 2p_{1/2} peaks of the same compounds. Higher energy singlet broad peaks at 859.4 eV, 863.1 eV, 877.6 eV and 881.8 eV are reported to correspond to a plasmon-loss peak from metallic Ni and shake-up satellite peaks emerge from the Ni–O–H compounds.⁶⁰ Integration of the primary peaks reveals that 90% of Ni found within the probing depth, of about

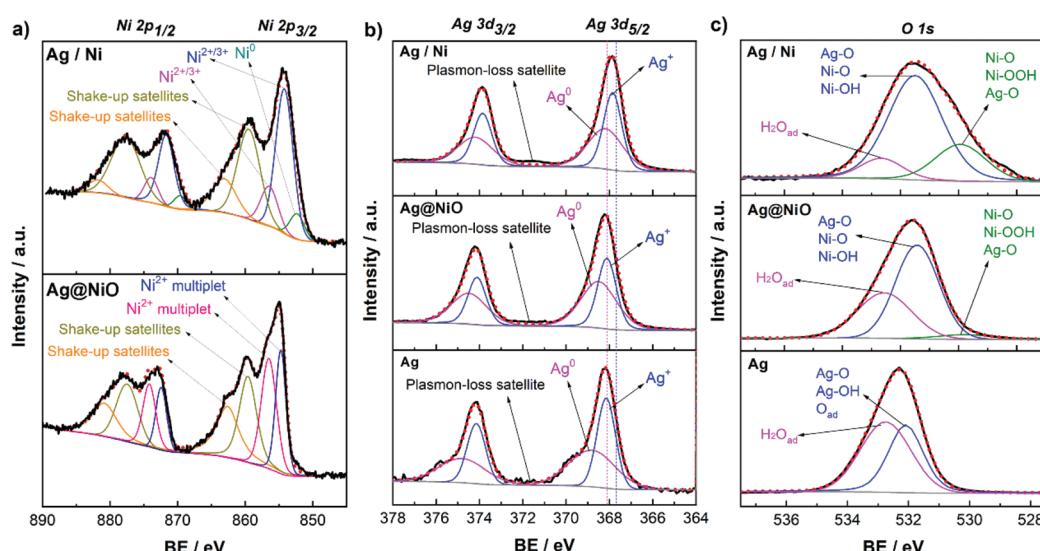

Fig. 5 XPS spectra of the Ag@NiO and Ag/Ni samples for Ni 2p (a), Ag, Ag@NiO, and Ag/Ni NPs for Ag 3d (b) and O 1s (c). The black solid lines represent the original spectra and red dot lines represent the fits to the data. The dash lines in (b) at 368.1 eV and 367.7 eV correspond to the BEs of bulk Ag⁰ and Ag⁺, respectively.

6 nm, corresponds to $\text{Ni}^{2+}/\text{Ni}^{3+}$ and the remaining 10% to metallic Ni. It is known that Ni is readily oxidized by water and, consequently, the $\text{Ni}^{2+}/\text{Ni}^{3+}$ oxide/hydroxide layers cover the surface of the metallic Ni particles.³⁸ Note that other Ni compounds such as Ni_2O_3 ⁶¹ or mixed oxides $\text{Ag}-\text{Ni}-\text{O}$,^{49,62} whose Ni 2p BEs are within the same range as those for $\text{Ni}-\text{O}$ and $\text{Ni}-\text{O}-\text{H}$, may also be present in both $\text{Ag}@\text{NiO}$ and Ag/Ni nanomaterials. The peaks at BEs of 367.9 and 368.2 eV are attributed to $\text{Ag} 3\text{d}_{5/2}$ of Ag_2O and metallic Ag, respectively.⁵³ The plasmon-loss satellites at 371.5 and 377.4 eV confirmed the existence of metallic Ag as described above. The presence of the Ag_2O may be ascribed to the adjacent Ni (oxy-hydro) oxides ($\text{Ni}(\text{OH})_2/\text{Ni}_2\text{O}_3/\text{NiOOH}$) with strong electronic affinity which would promote the electron-depleted Ag to be oxidized.⁶³

Electrochemical performance of the $\text{Ag}-\text{Ni}$ nanocatalysts

Cyclic voltammetry (CV). CV measurements were conducted in N_2 saturated 0.1 M KOH solution at a scan rate of 50 mV s⁻¹. After 20–50 activation cycles, stable CV curves were recorded (Fig. 6a). The CV curves of both bimetallic samples show distinct double oxidation peaks: the one that appears at 1.35 V corresponds to the formation of Ag_2O , and this peak coincides with the oxidation peak observed for the Ag sample;⁶⁴ the peak at 1.48 V can be attributed to the formation of Ni(III) (NiOOH).^{65,66} It should be noted that the CV curve recorded for the Ni sample shows the same feature. This indicates that, in the bimetallic $\text{Ag}-\text{Ni}$ samples, both Ag and Ni are involved in the electrochemical reactions. Thus, in the core-shell $\text{Ag}@\text{NiO}$ sample, the Ag core is partially exposed to the electrolyte rather than being fully covered with the NiO shell layers. The electrochemical surface areas (ECSAs) of the Ag, $\text{Ag}@\text{NiO}$ and Ag/Ni samples determined from the Pb_{upd} -stripping voltammogram are shown in Fig. 6b, where a pair of typical Pb-stripping peaks appears between 0.2 and 0.5 V. The ESCA for Ag/Ni and $\text{Ag}@\text{NiO}$ is found to be $41.90 \text{ m}^2 \text{ g}^{-1}$ and

$30.38 \text{ m}^2 \text{ g}^{-1}$, respectively. The ECSA of monometallic Ag is a bit larger ($43.6 \text{ m}^2 \text{ g}^{-1}$), which could be ascribed to the small particle sizes (a bimodal particle size distribution with 7.4 nm and 18.0 nm) in the monometallic Ag sample (Table S5† shows the ECSA of Ni and detailed calculation parameters). Besides this, the five-fold twinned structure of the Ag nanoparticles may also contribute to their electrochemical activity due to the increased amount of active sites because of the additional edges appearing between the twins and induced lattice strain.⁶⁷

Oxygen reduction reaction. The electrocatalytic performance for the ORR of the obtained catalysts was investigated and the polarization curves are shown in Fig. 7a. The measurements were done at a scan rate of 10 mV s⁻¹ and a rotation speed of 1600 rpm. The ORR onset potential, E_{onset} , and half-wave potential, $E_{1/2}$, derived from the polarization curves are presented in Fig. 7b. The data are summarized in Table 1. The E_{onset} value of both bimetallic $\text{Ag}-\text{Ni}$ samples (around 0.82 V) is higher than that of monometallic Ag and Ni, although it is lower than that of commercial Pt/C. This result can be confirmed with the onset oxidation potentials of $\text{Ag}@\text{NiO}$ and Ag/Ni (shown in the insert in Fig. 6a). The onset oxidation potentials of bimetallic $\text{Ag}-\text{Ni}$ are lower than those of pure Ag, thereby indicating that the surface of the bimetallic $\text{Ag}-\text{Ni}$ nanoparticles is oxidized more readily than that of Ag. The increased E_{onset} for $\text{Ag}@\text{NiO}$ and Ag/Ni could be attributed to the enhanced water-activation ability of the Ni compounds (NiO and Ni (oxy-hydro) oxides in the $\text{Ag}@\text{NiO}$ and Ag/Ni samples, respectively).^{28,68} Similarly, the two bimetallic samples also show larger $E_{1/2}$ values than the monometallic materials. However, the difference is not as distinct as that in E_{onset} .

The ORR kinetics have been investigated by recording the polarization curves at various rotation speeds (Fig. S2(a–d)†). Based on the polarization curves, the electron transfer number (n) is then calculated at 0.5 V using the Koutecky–Levich (K–L)

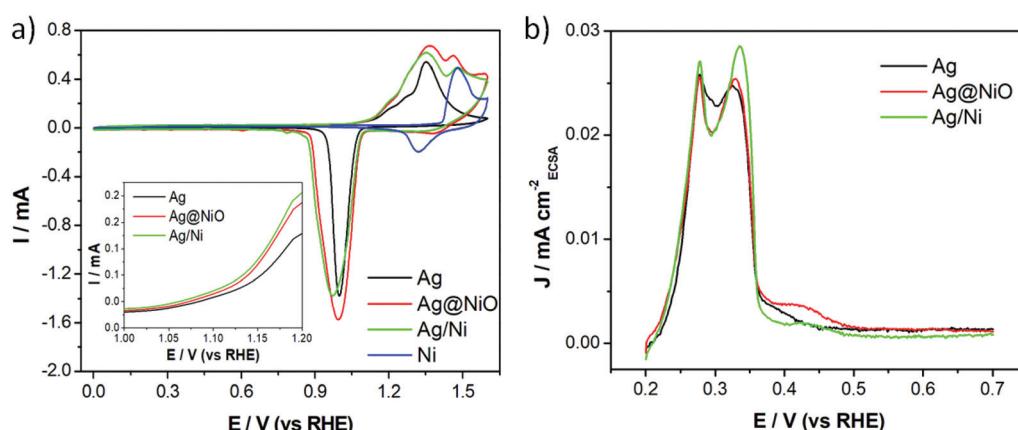

Fig. 6 (a) Cyclic voltammetry curves of Ag, $\text{Ag}@\text{NiO}$, $\text{Ag}-\text{Ni}$ and Ni recorded in 0.1 M N_2 saturated KOH solution at a scan rate of 50 mV s⁻¹; the inset shows the magnified curves showing the onset oxidation potential of Ag, $\text{Ag}@\text{NiO}$, and $\text{Ag}-\text{Ni}$. Ni	0.62	0.52	0.7	0.4	2.2
Pt/C	0.94	0.81	5.0	161.7 (@0.9 V)	4.0

^a The experimental uncertainty of E_{onset} , $E_{1/2}$ is 0.01 V; j_d and the SA are 0.1 mA cm⁻² and $\mu\text{A cm}^{-2}$, respectively; n is 0.1.

equation.⁶⁹ The K-L plots at 0.5 V for the studied samples, including commercial Pt/C (20 wt%, ETEK) used as a reference, are shown in Fig. 7d. The calculation details and K-L plots at different potentials (inserts in Fig. S2(a-d)†) are shown in the ESI.† The calculated electron transfer number is presented as a histogram in Fig. 7c and listed in Table 1. As seen in the table, all Ag-based samples including Ag, Ag@NiO and Ag/Ni possess an electron transfer number greater than 3.5, demonstrating a mainly four-electron transfer pathway. However, the n -values of the Ag and Ag/Ni samples are slightly lower than those of Ag@NiO and Pt/C, indicating that some peroxide is formed on the Ag and Ag/Ni catalysts. Thus, the ORR for these samples proceeds at least partially *via* the 2 + 2 electron pathway.⁷⁰ For commercial Pt/C, our previous study confirmed that the obtained electrochemical parameters were within the normal range for the Pt/C catalyst ($E_{\text{onset}} = 0.94$ V, $E_{1/2} = 0.82$ V).⁷¹ The diffusion limiting current density, j_d , values (shown in Table 1) of bimetallic Ag@NiO and Ag/Ni are

higher (4.9 mA cm⁻²) than those of the monometallic catalysts and pretty close to those of Pt/C.

The specific activity, SA, the current per unit catalyst surface area, is commonly used to reflect the intrinsic activity of the catalysts.⁷² To make a clear comparison, the SA for all prepared samples is calculated at 0.65 V instead of the commonly used potential 0.8 V,^{10,73} and the result is shown in Fig. 7c. The bimetallic Ag–Ni samples display an enhanced SA with around 3 times improvement relative to monometallic Ag, which is much higher than that of Ni prepared under the same conditions. The SA for Pt/C is calculated to be 161.7 $\mu\text{A cm}^{-2}$ _{Pt} at 0.9 V. The catalytic performance of the samples presented in the current study is not high enough as compared to that of Pt/C, however, the calculated activity is quite consistent with the previous results for the Ag-based catalysts.^{6,9} As shown in the literature, the ORR activity of Ag is about an order of magnitude lower than that of Pt due to the low d-band centre and filled d band of Ag.⁷⁴ Moreover, the catalytic

performance could be affected by the surfactant poly(vinyl alcohol) (PVA), which is difficult to remove completely from the surface of the catalyst (Fig. S3†). An example of similar effects on the ORR caused by surfactants was reported by Lu *et al.*, and they found that the ORR current density of the Ag nanorods was significantly increased after the surfactant was removed from the material surface.⁷⁵ Therefore, the intrinsic ORR activity of our samples is likely to be a bit higher if the surfactants are completely removed. The surfactant removal is a complicated procedure that could influence the physical and chemical parameters of the materials, which might be a matter of a separate study.⁷⁶ Therefore, to minimize the systematic uncertainty in the experiment, we perform a similar post-irradiation treatment for all the samples in the current work.

The Tafel plots, used for further analysis of the ORR kinetics of all catalysts, are presented in Fig. 7e. The Tafel slope values decrease in the following sequence: Ag > Ag@NiO ≈ Ag/Ni > Pt/C, and are in the range from -80 to -100 mV dec $^{-1}$ for all Ag-based samples. Since the slope values will be different if different potential ranges are used for data analysis, there is still a debate about how to interpret the Tafel slope trends for the kinetics of oxygen reduction.⁷³ However, considering the values of the potential range shown in Fig. 7e and comparing them to the values reported in the literature (from -80 to -120 mV dec $^{-1}$),⁷⁷⁻⁸⁰ we may assume that the slow transfer of the first electron to the O₂ molecule could be a rate-determining step (RDS) for the ORR process for all three Ag-based samples presented in the current study.

From the point of view of practical applications, in addition to superior activity, catalysts should possess good stability under operating conditions. The chronoamperometry (CA) method was used to evaluate and compare the stability of the two types of bimetallic Ag–Ni samples. As seen in Fig. 7f, Ag/Ni showed good stability with only 4.8% current decay after 20 hours at 0.65 V in O₂-saturated 0.1 M KOH, which is around 4 times lower than that of Ag@NiO (19.5% decay). The atomic ratio of the constituents of two bimetallic Ag–Ni samples was determined by inductively coupled plasma optical emission spectroscopy (ICP-OES) before and after the electrochemical stability test (Table S5†). The Ag-to-Ni ratio in the Ag/Ni samples is found to be 3 : 1 before and after the test, while in the Ag@NiO samples it changes from Ag₄Ni₁ to Ag_{4.5}Ni₁ under the same test conditions.

Discussion

The electrochemical studies reveal that both bimetallic Ag–Ni and monometallic Ag catalysts demonstrate a pseudo four-electron transfer pathway. The bimetallic Ag–Ni nanocatalysts show an enhanced specific activity compared to both pure Ag and Ni catalysts. Evidently, the modulation of the catalysts' structures carried out in the current study is the main reason for the enhanced electrochemical performance. Although the electrochemical parameters measured for both bimetallic

samples are quite close to each other, the reasons behind the enhanced ORR activity may be different.

As shown above, core–shell Ag@NiO consists of metallic Ag nanoparticles covered by the amorphous NiO layers. The interactions at the Ag–Ni interfaces imply changes in the atomic surrounding, which leads to either partial alloying or the formation of new structures, like mixed oxide Ag–Ni–O. The introduced modifications of the electronic structure of the constituents may lead to a ligand effect, which would accelerate the charge transfer between Ag and NiO, thus changing the interfacial chemical properties. Since the Ni-based shell layers are amorphous, the introduced Ag lattice strain at the interfaces is negligible. However, the individual atoms around the interface may still experience a strain-like environment and therefore display a different activity from a crystalline film, as has been observed on Pt in acidic solution.⁸¹ Besides, an amorphous film will have very different interactions with species on the surface as compared to a crystalline one, which can affect the rate of catalytic reactions. To sum up, in the Ag@NiO sample, both electronic effects are assumed to contribute to the improved ORR activity, while the strong ligand effect induced by the amorphous Ni–O layers may play a prominent role.

Heterostructured Ag/Ni, as revealed by the structural analysis, contain clusters of metallic Ni covered by Ni (oxy-hydro) oxides. These clusters are attached to the surface of the Ag nanoparticles. Since both Ag and Ni-based clusters are crystalline, they may grow epitaxially with respect to each other. The large lattice mismatch, of about 11%, established between Ag and the Ni₂O₃/NiOOH (oxy-hydro) oxides may result in a tensile lattice strain of the silver surface layers which, in turn, leads to changes in the electronic structure of Ag. Note that an interface-induced ligand effect in the Ag/Ni sample would also contribute to the catalytic performance even though the interface sites are disrupted. Moreover, a high-valence Ni (≥ 2) with even fewer d-electrons forming in an Ag/Ni sample would imply changes in the electronic structure of metal-adsorbate type and, thus, might also contribute to the enhanced ORR activity.⁸² The latter would need a detailed investigation that is beyond the scope of the present study. Therefore, in the Ag/Ni sample, the improved ORR activity could also be attributed to a cumulative effect of both the ligand and strain effects. Because of the large lattice mismatch between Ag and the Ni (oxy-hydro) oxides, the strain effect may be considered as a dominant contribution to the activity enhancement.

The superior ORR stability of heterostructured Ag/Ni as compared to core–shell Ag@NiO, could be ascribed to the possible presence of a stable crystalline NiOOH compound in the former. As confirmed by ICP-OES, the Ag-to-Ni atomic ratio in the Ag/Ni sample does not change before and after the stability test. However, in the Ag@NiO sample, it changes from Ag₄Ni₁ to Ag_{4.5}Ni₁ under the same test conditions, indicating that some of the Ni ions are lost. This result is consistent with the findings reported by Back *et al.*, where the authors claimed that the presence of a stable NiOOH compound results in the enhanced stability of the catalyst for the ORR.³¹

Conclusions

Two types of bimetallic silver–nickel (Ag–Ni) nanocatalysts, core–shells (Ag@NiO) and heterostructures (Ag/Ni), have been fabricated for the first time using γ -radiation induced reduction. Ag@NiO consists of an amorphous Ni oxide layer of about 2 nm thickness as a shell, and a faceted Ag particle as a core. Meanwhile Ag/Ni comprise polycrystalline Ni-based clusters adjacent to the surface of metallic Ag particles. The composition of the clusters corresponds to metallic Ni covered with Ni (oxy-hydro) oxides, $\text{Ni(OH)}_2/\text{Ni}_2\text{O}_3/\text{NiOOH}$. Electrochemical analysis reveals that both materials proceed with a pseudo four-electron transfer pathway and show a similar but increased alkaline ORR activity compared to monometallic catalysts. The enhanced ORR activity of the core–shell Ag@NiO nanoparticles is attributed mainly to a ligand effect originating from the changing atomic surroundings at the Ag–Ni interfaces. In contrast, the strong strain of about 11%, arising from the significant lattice mismatch between the Ni (oxy-hydro) oxides and Ag, is mainly responsible for the enhanced activity of the Ag/Ni catalyst. The comparative study of two different types of nanocatalysts enables us to resolve the contributions of the ligand and strain effects on the activity of the Ag–Ni catalysts.³⁰ In addition, due to the existence of the stable Ni³⁺ compounds (Ni₂O₃/NiOOH) on their surfaces, Ag/Ni exhibit good stability under operating conditions.

The findings presented in the current study demonstrate, among others, the advantages of using γ -radiation induced approaches for the engineering of bimetallic nanocatalysts with a well-defined interfacial structure. The results presented in this study can be used as the starting point for optimizing the morphology, composition, and structure of Ag–Ni nanocatalysts to achieve their characteristics suitable for industrial use. Due to their special structure and composition, the obtained Ag–Ni nanomaterials can potentially be used as effective catalysts for the peroxide electroreduction and oxygen evolution reaction.

Experimental

Chemicals

Ag nitrate, AgNO₃ ($\geq 99.0\%$), nickel(II) acetate tetrahydrate, Ni(CH₃COO)₂·4H₂O (98%), poly(vinyl alcohol), $[-\text{CH}_2\text{CHOH}^-]_n$ (PVA, M_w 70 000, 87–90% hydrolyzed), propan-2-ol, (CH₃)₂CHOH (IPA, 99.9%), potassium hydroxide, KOH (pellets, 99.99%), lead(II) nitrate, Pb(NO₃)₂ (99.999%), potassium chloride solution KCl solution (for Ag/AgCl electrodes, ~ 3 M KCl, saturated with silver chloride (~ 0.16 M AgCl)), and Nafion-117 (5% in a mixture of lower aliphatic alcohols and water) were purchased from Sigma Aldrich. Milli-Q water (Millipore, 18.2 M Ω cm at 25 °C) was used in all experiments.

Synthesis of core–shell Ag@NiO

Ag@NiO was prepared by a one-step γ -radiation induced synthesis method. A mixture of 5 mM AgNO₃, 5 mM Ni

(CH₃COO)₂·4H₂O, 2 M IPA and 1.0 wt% PVA was purged with N₂ (99.999% purity, Linde) for 30 min and sealed with a septum in a glass vial. The solution was then irradiated for 40 hours which corresponds to the total irradiation dose of 21.6 kGy. The obtained black suspension solution was centrifuged at 8000 rpm for 15 min, then washed with IPA/Milli-Q water three times and dispersed in IPA for further use.

Synthesis of heterostructured Ag/Ni

Ag/Ni was synthesized by a successive reduction process. Ni nanoparticles in the form of a suspension were obtained first by γ -radiation induced reduction. The synthesis procedure is the same as that for the synthesis of Ag@NiO. The only difference is that 5 mM Ni(CH₃COO)₂·4H₂O dissolved in water is used as a precursor. Thereafter, 1.5 mL of the AgNO₃ stock solution (0.1 M) was injected dropwise into the sealed vial with a Ni suspension, and the concentration of Ag⁺ in the suspension solution was 5 mM. The vial was then gently shaken and placed into the glovebox for 20 hours. The Ag/Ni precipitates were washed by centrifugation under the same conditions as described above and dispersed in IPA.

For comparison, monometallic Ag and Ni nanoparticles were synthesized by irradiating the aqueous solution of AgNO₃ (20 hours) and Ni(CH₃COO)₂·4H₂O (40 hours), respectively. The other experimental conditions remained unchanged. More detailed information about the synthesis is described in the ESI.†

Material characterization

XRD patterns were recorded on a PANalytical X'Pert PRO diffractometer with CuK α radiation ($\lambda = 1.5418$ Å). SAED patterns, and TEM, HRTEM, and HAADF-STEM images were obtained on FEI Tecnai G2 F20 equipped with energy dispersive X-ray spectrometry accessories. The composition of bimetallic samples, and the actual amount of metals on the glassy carbon (GC) electrode were determined by ICP-OES measurements with an iCAP 6000 series instrument (Thermo Fisher Scientific). XPS was performed with a PerkinElmer PHI 5000C ESCA system. Al K α radiation ($h\nu = 1486.7$ eV) was used as an excitation source, and the chamber pressure was kept below 6×10^{-10} Torr. The binding energy of the spectra was calibrated at the C 1s core level at 284.8 eV from adventitious carbon. Characterization and analysis details of XPS and ICP-OES are described in the ESI.†

Electrochemical test

The catalyst ink was prepared by mixing 10 μL of Nafion-117 with a specific volume of the as-prepared nanoparticle dispersions. The metal concentration in the nanoparticle dispersions was measured by ICP-OES before the ink preparation. A specific volume of the ink (10–20 μL) was taken with a pipette and cast on mirror polished GC electrodes with a surface area of 0.196 cm². The electrodes were then dried in an ambient environment. The catalyst loadings were aimed at 70 μg_{Ag} cm⁻² for the Ag-based catalysts (Ag, Ag@NiO and Ag/Ni), 15 μg_{Pt} cm⁻² for commercial Pt/C and 250 μg_{Ni} cm⁻² for the Ni

sample. The actual amount of the catalyst on modified GC was quantified by ICP-OES as well. All electrochemical measurements were performed in a three-electrode system using a potentiostat (BioLogic SP-300) with a graphite rod as a counter electrode and Ag/AgCl in saturated KCl solution as a reference electrode. According to the *iR*-compensation instructions and suggestions by BioLogic, all the potentials reported here were corrected with 85% *iR*-compensation and calibrated to a reversible hydrogen electrode (RHE) according to $E(\text{RHE}) = E(\text{Ag/AgCl}) + 0.964 \text{ V}$ in 0.1 M KOH. Before the ORR activity test, the catalysts were activated with CV for 20–50 cycles at 50 mV s⁻¹. A potential at which the current density exceeds a threshold value of 0.1 mA cm⁻² was used to determine the E_{onset} .⁸³ Reproducibility tests with the same experimental procedures were conducted on each sample 3 times to avoid any chances of serendipity.
