Hierarchically porous 2D carbon from bio-waste: a sustainable, rapid, and efficient oxidase mimic for the colorimetric detection of ascorbic acid†

Chandra Jeet Verma,‡ Priya Singh,‡ Ravi Prakash Ojha‡ and Rajiv Prakash *

In the present work, a porous 2D carbon-based sustainable, rapid, and efficient oxidase mimic for ascorbic acid (A.A.) detection has been discussed. Here, *Eichhornia crassipes* (water hyacinth) biomass waste was used as a precursor, which resulted in advanced N, O-doped hierarchically porous 2D carbon. In this, the heteroatom-like N, O are well-dispersed while 2D carbon has a high surface area. For this, a one-step carbonizing technique was used in an inert environment without any surfactant/activating chemical aid. The structural parameters of such a 2D carbon material were characterized by Fourier transform infrared spectroscopy, X-ray diffraction, and X-ray photoluminescence spectroscopic techniques. The morphological investigations of 2D carbon were done by field emission scanning electron microscopy and transmission electron microscopy. Nanozymes, also called nanomaterials having the behaviors of enzymes, are promising materials for biomedical fields. Due to the absence of corrosive H_2O_2 in the reaction path, oxidase-like nanozymes are gaining more importance and attention. Due to the high surface area and N, O-doped hierarchical pores, the 2D carbon possessed more catalytic active sites and facilitated rapid oxidase-like activity for the chromogenic substrate 3,3',5,5'-tetramethylbenzidine (TMB). The oxidation culminated in a charge-transfer product with an absorbance peak at 652 nm. Ascorbic acid is a biomolecules that displays concentration-dependent inhibition property over the oxidase activity of a nanozyme. We developed a colorimetric technique based on a 2D carbon oxidase nanozyme for A.A. sensing. Based on this principle, the presented colorimetric method showed an excellent linearity range from 1 to 70 μM with a 0.26 μM detection limit and the fastest A.A. detection among the other reported colorimetric methods. This work demonstrates a simple approach for preparing a complete metal-free and efficient nanozyme, and explored its use for A.A. detection in orange, lemon, grapes, and human serum. Also, it presents a new avenue to design a sustainable mimetic substrate and further a road map for transforming biowastes into new technology.

1. Introduction

Ascorbic acid (A.A.) is one of the crucial biochemical molecules of the vitamins group and plays a vital role in many biological functions, such as a free radical scavenger and in cancer inhibition and prevention.^{1–6} Unfortunately, the human body cannot produce A.A., so daily diet supplements are the only source to complete such needs. The standard range of A.A. in healthy humans is between 0.6–2 mg dL⁻¹. However, disturbances in their concentration can cause various complications, like stomach pain, muscle pain, and diseases.² Thus, a regular

diagnosis of the A.A. content becomes paramount for a fair and healthy body and has received increasing worldwide attention. In this connection, various techniques, including electrochemical techniques,^{1,6,7} chromatography,^{8,9} chemiluminescence,^{10,11} enzyme-linked immunosorbent assay (ELISA),¹² fluorescence,^{13,14} and colorimetric techniques,^{1,15} have been well studied and established. Biosensing platforms have a broad range of technological arrays and have been explored to detect various small biomolecules, tumor markers, the A.A. level, *etc.*^{16–20} Among these, the colorimetric technique has positioned itself as an excellent method to expedite a simple, quick, cost-effective, visual detection.^{21–25} The colorimetric method is based on a chromogenic substrate, which produces color upon oxidation under the effect of the enzymes. Therefore, the chromogenic substrate or reagents selection is a key point to manifest the colorimetric performance and to achieve an effective detection of the color transformation.²⁶ Natural enzymes are particularly

‡ All authors have equally contributed to this work.

ultra-sensitive to their working environments, and if a bit of change occurs in their environmental conditions (pH, pressure, and temperature), they can lose their catalytic activities. Therefore, the regular application of natural enzymes faces a set of difficulties and creates a significant challenge in medical assays for performing enzyme-dependent reactions or processes.²⁷ To counter such situations, researchers have started developing some new materials that can show enzyme-like activity.²⁷ Based on the catalytic concept, the high surface area and reaction centers are the main factors that shift the equilibrium toward their completion. Since the nanostructure has a high surface area and unique properties, nano-science provides a unique platform for integrating the desired artificial enzymes (also called nanozyme or nano-enzyme). With the development of nanotechnology, several nanomaterials, including transition metals,^{22,28–30} noble metals,^{31,32} polymers,^{33,34} and carbons material,³⁵ have been developed and have been reported for mimic or colorimetric sensing purposes. Artificial enzymes having large surface areas are easy to store and employ. In addition, they can adapt to harsh circumstances for denaturation, high substrate concentration, and low cost, and therefore, are getting prime attention as an alternative to the natural enzymes.^{36,37}

There are four types of nanozymes: oxidase, peroxidase, catalases, and superoxidases have been reported to have advantages and disadvantages. Much research literature has been reported so far for the detection of A.A. *via* oxidase and peroxidase activity. According to the reaction mechanism, the oxidase nanozyme is denoted as a better means than the peroxidase because of the absence of corrosive H₂O₂,²² even though very little literature is available on oxidase nanozymes for A.A. detection. Thus, there is a high demand for sustainable, green, and efficient oxidase nanozymes for A.A. recognition. The colorimetric detection of biomolecules is based on electronic-transfer processes and co-related with the substrate surface area, porosity, and heteroatom in the lattice.^{38–40} Since porous 2D carbon has a vast surface area and unique electronic structures, it can play an exciting role in artificial enzymes. Presently, biowaste-derived 2D carbon nanomaterials are attracting much more attention in various recommended technological projects,^{41,42} *e.g.*, supercapacitors,^{43–45} batteries,⁴⁶ and adsorbents.⁴⁷ Despite this, some work has been published on carbon-based substrates for mimetic purposes, but still, there is a need for more explorations.

In this work, we derived N, O-doped highly porous 2D carbon (BET surface area is 781 m² g⁻¹) from a biowaste *Eichhornia crassipes* plant using a carbonization technique under an inert environment. *Eichhornia crassipes* (locally called jalkumbhi) is an unwanted aquatic herb that causes harm to aquatic agricultural, fisheries, and water transportations. To improve the marine agricultural-based economy, much manpower is consumed unnecessarily for netting such herbs, which are then usually dumped around water ponds and pools, causing environmental contamination. Thus, some scientific approaches are needed to convert this biowaste herb into a valuable material. Since, *Eichhornia crassipes* has massive moisture (~9.95), volatile matter (~56.30), fixed carbon

(~17.40), and ash content (wt 16.35%), respectively, the water and volatile matter content probably act as a self-activating means and provide high surface area 2D carbon.⁴⁴ Motivated by the above facts, *Eichhornia crassipes* was used as a source for developing porous 2D carbon materials in this work, which satisfied both the techno- as well as socio-economical features. The structural parameters of the carbon materials were characterized using Fourier transform infrared spectroscopy (FTIR), X-ray diffraction (XRD), and X-ray photoluminescence spectroscopy (XPS). The surface morphology of the materials was analyzed under field emission scanning electron microscopy (FESEM) and transmission electron microscopy (TEM). The presented 2D carbon material showed an efficient affinity toward the chromogenic substrate 3,3',5,5'-tetramethylbenzidine (TMB), forming a characteristic oxidized blue-colored product. A.A. delivered a concentration-dependent inhibition property over the 2D carbon oxidase activity and resulted in a decrease in color intensity. We developed a colorimetric method for sensing A.A. based on this principle, producing a color contrast with its different concentrations. The technique was further explored to detect A.A. in actual samples (orange, lemon, grapes juice, and human serum) with good recovery percentages obtained.

2. Materials and methods

2.1 Chemicals and reagents

The 3,3',5,5'-tetramethylbenzidine (TMB), ascorbic acid (A.A.), hydrochloric acid (HCl), hydrofluoric acid (H.F.), copper(II) chloride (CuCl₂), calcium chloride (CaCl₂), potassium chloride (KCl), citric acid, glucose, glutathione (GSH), sodium acetate, and glacial acetic acid were purchased from Sigma Aldrich. *N*-Ethylmaleimide (NEM, 98%) was purchased from Avra. All the solutions were prepared in Milli-Q water (resistivity = 18.0 MΩ, pH 7) during the experiments. The human serum samples for the A.A. determination and recovery study were collected from the university hospital “the Institute of Medical Sciences, Banaras Hindu University” (courtesy Prof. D. Dash, IMS, BHU, Varanasi, India).

2.2 Characterization techniques

TEM micrographs of the drop-cast 2D carbon suspension in water were investigated on an FEI system, at an accelerating voltage of 200 kV on the TECHNAI G² 20 TWIN (Czech Republic) TEM instrument. The absorption spectra of the 2D carbon mimetic activity and colorimetric assay were obtained on a Biotek spectrophotometer (Epoch 2, USA). FT-IR analysis was carried out in the spectral range of 450–4000 cm⁻¹ on a Thermo Scientific Nicolet 6700 FTIR spectrometer. X-Ray photoelectron spectroscopy (XPS) was performed on a Kratos analytical instrument (Shimadzu, Amicus XPS, U.K.) equipped with MgKα ($\lambda = 1.254 \text{ \AA}$) radiation. A Rigaku miniflex 600 X-ray diffractometer with Cu Kα1 radiation ($\lambda = 1.54056 \text{ \AA}$) was used for X-ray powder diffraction measurements of the prepared 2D carbon. The surface property of the material was investigated on a Nova Nano SEM-450 system (FEI, USA), and NTEGRA Prima, NT-MDT scanning

probe microscope. For testing the method in an actual sample, orange, lemon, and grapes were used as bought from a Varanasi supermarket.

2.3 Synthesis of the porous carbon

The oxidase mimic porous 2D carbon was synthesized using our previous protocols as reported.⁴⁴ In brief, *Eichhornia crassipes* leaves were washed thoroughly after collection in running water and dried in an oven at 80 °C. The dried leaves were deformed into fine powder form using a mortar and pestle. The obtained powder was allowed to carbonize at 800 °C under inert N₂ conditions followed by an acid–base–water washing process. The carbon obtained was stored at R.T. for further application.

3. Results and discussions

3.1 Structural analysis

Since 2D carbons have a porous architecture and heteroatom doped sp² and sp³ hybridized atom, which are fundamental for any activated carbon. In this work, XRD, FTIR, and XPS techniques were used to confirm a successful material synthesis. The obtained results showed great similarity with our earlier work.⁴⁴ Fig. 1(a) shows the FTIR spectrum of 2D carbon, exhibiting a vibration band corresponding to a hydroxyl group, C=C/C–C stretching vibrations, and advocates the occurrence of the sp²-hybridized graphitic system. A broadband (1000–1100 cm⁻¹) was observed, indicating the C–O functionalities existence. Further, the XRD of such 2D carbon, as shown in Fig. 1(b), reflected two characteristic peaks as one broad peak around 2θ ~ 25° consequent to the (002) plane, and the second peak at 2θ ~ 43° for the (100) plane. Such XRD data (broadening spectra) revealed that the prepared carbonic material was amorphous. In order to understand the surface architecture of the 2D carbon, TEM and SEM image investigations were performed (as shown in Fig. 1(c and d) and ESI† file as Fig. S1(a and b)), respectively, which disclosed that the as-synthesized 2D carbon had a typical porous arrangement. As presented in Fig. 1c, the TEM image indicated that the reported 2D carbon was made up of very tiny particles.

Further at high-resolution, the HRTEM image, as shown in Fig. 1d, reflected some prototype fringes, which suggests that the 2D carbon construction was not fully amorphous but had a few crystalline domains also in their matrix. This observation could be correlated to the presence of some sp³ hybridized centers and a heteroatom. The enlarged images of the fringes are given in the ESI† in Fig. S3. For additional insurance about the contamination-free 2D carbon, mapping (Fig. 1e–h) and EDX (see in Fig. 1(i)) were performed, which were further supported by the XPS observation⁴⁴ (also can be seen in Fig. S2, ESI†) and vice-versa. The XPS survey spectrum study of 2D carbon, as represented in Fig. S2(a), (ESI†) showed three consequent peaks of C, N, and O elements. Further, with deconvolution of the XPS data, the C1s peak of the 2D carbon (see Fig. S2(b), ESI†) was disassembled into the following three peaks as 284.9, 286.3, and 288.7 eV, related to the C–C–C,

C–N/C–O, and O–C=O bonds, respectively. Further, the O1s deconvoluted spectrum (see in Fig. S2(c), ESI†) exhibited three different oxygen moieties at 530.9, 532.7, and 534.7 eV for C–O–C of carboxyl groups, C=O, and chemisorbed O₂, respectively. Finally, Fig. S2(d) (ESI†) showed the N1s peak disassembled into three sub-peaks at 398.7 eV for imine nitrogen, at 400.9 eV for pyrrolic, and 406.3 eV for quaternary nitrogen. These data confirmed that the reported 2D carbon had only C, N, and O elements as its constructing component and was free from contaminating features. The mapping showed that heteroatoms like N and O were distributed homogeneously throughout the carbon matrix (see Fig. 1e–h). Summing these consequences, like the heteroatom, porous structure, and high surface area, the synthesized 2D carbon can be utilized as a fascinating mimetic substrate for establishing biosensors with high performances, which is explored in the next paragraph in the colorimetric detection of A.A.

3.2 Oxidase mimetic activity of 2D carbon and A.A. inhibition

For the H₂O₂ free colorimetric sensing of A.A., the development of oxidase-like nanozymes is an essential call for researchers. Ensuing this, we have presented a sustainable 2D carbon material derived from biowaste, which demonstrated an excellent oxidase mimetic activity in the presence of dissolved O₂. To investigate the oxidase property of 2D carbon material, the absorption spectra of TMB were recorded in the absence of 2D carbon (see Fig. 2 curve (a) and in the presence of 2D carbon (see Fig. 2 curve b)). The absorption spectra result, as in Fig. 2 curve (a), suggested that the TMB aqueous solution alone was colorless because there was no involvement of any charge-transfer reaction. Then upon the addition of 2D carbon into the TMB aqueous solution, a strong absorption peak appeared at 652 nm (Fig. 2 curve (b)). This peak occurrence at 652 nm is crystal-clear proof of a charge-transfer complex (CTC) between the oxidized and unoxidized TMB. TMB molecules get oxidized with the help of the added 2D carbon due to the oxidase activity. Further, upon the addition of A.A. into the reaction mixture of TMB + 2D carbon, the absorption intensity of 652 nm band gets diminished (see Fig. 2 curve (c)). This validated the inhibition of the oxidase activity of 2D carbon. Lastly, when the stop solution H₂SO₄ was added, the absorption band at 652 nm corresponding to CTC gets diminished, and a new peak was generated at λ_{max} = 450 nm, as shown in Fig. 2 curve (d). A detailed discussion is provided in the later Section 3.5).

3.3 Role of the material and optimization toward the oxidase

Since the colorimetric sensing response of the nanozyme is concentration-dependent; therefore, 2D carbon material concentration optimization is compulsory. For the test of variation in the oxidase activity of 2D carbon toward TMB, a range of concentrations between 0.1 to 1 mg mL⁻¹ of 2D carbon was applied. During the experiments, the absorbance at 652 nm was recorded after an incubation period of 15 min, as shown in Fig. 3. The absorbance result was verified in an approximately linear manner, and the response suggested that the saturation level happened after 0.8 mg L⁻¹. Based on this observation, the optimum concentration

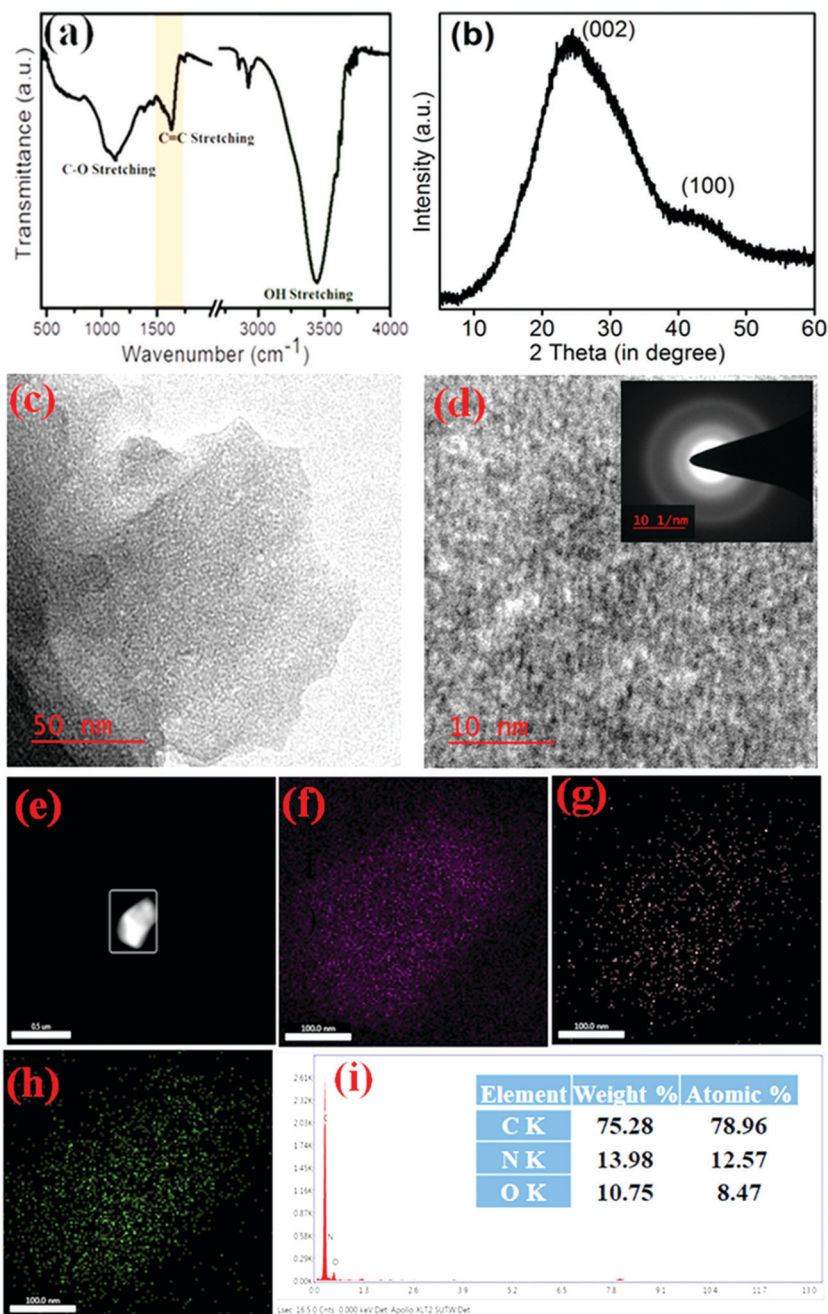

Fig. 1 Characterization of 2D carbon. (a) FTIR spectrum, (b) XRD, (c) TEM image at 50 nm scale, (d) at 10 nm scale (Inset shows the SAED pattern), (e) HAADF image area for mapping, (f) mapping image corresponding to C, (g) N, (h) O, respectively.

of 2D carbon *e.g.*, 0.8 mg mL⁻¹, was chosen for the further experiments. In this way, even at a low concentration of 2D carbon (*i.e.*, 0.08%), we could get an excellent catalytic response.

3.4 TMB optimization and its Lineweaver–Burk plot

In order to investigate the nature of the nanozyme kinetics, the oxidase activity was studied under different TMB concentrations from 100 μM to 1000 μM. In this, the absorbance at 652 nm was recorded at pH 4 (which was adjusted by adding the acetate buffer). Fig. 4(a) depicts the absorbance plot at

652 nm *vs.* TMB concentration, indicating a saturation point after 800 μM. This data showed that the intensity was directly proportional to the TMB concentration, but after 800 μM TMB, the peak intensity was almost constant. Fig. 4(b) shows the Lineweaver–Burk plot of the 2D carbon nanozyme having an *R*-square value of 0.99, which indicated a good linear response. Beer–Lambert's law was utilized to calculate the initial reaction rate using eqn (1).

$$A = \epsilon bc \quad (1)$$

Fig. 2 Absorption spectra for the oxidase activity of 2D carbon and the inhibition property of A.A.

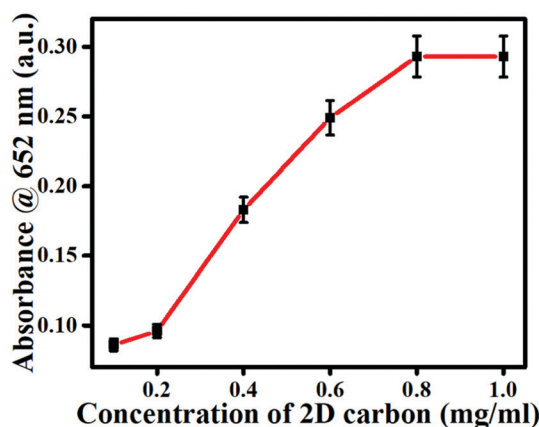

Fig. 3 Endpoint spectrum for 2D carbon optimization.

where C is the solution concentration, A represents the absorbance, b represents the thickness of the solution or path length, and ϵ is the molar absorptivity coefficient, having a value of $39\,000\text{ M}^{-1}\text{ cm}^{-1}$. The Lineweaver–Burk plot for the nanozyme catalysis reaction was plotted against the reciprocal velocity and

TMB concentration reciprocal. The Michaelis–Menten constant (K_m) value for the 2D carbon as the nanozyme was calculated from the Lineweaver–Burk plot. The corresponding value of k_m was $0.121\ \mu\text{M}$, and V_{max} was $5.3\ \mu\text{M s}^{-1}$. The lower value of k_m of the proposed 2D carbon-based nanozyme showed the stronger affinity between the nanozyme and TMB substrate, resulting in a more efficient catalytic property of the 2D carbon. This relationship was because this 2D carbon had a high surface area ($781\ \text{m}^2\ \text{g}^{-1}$), giving more exposure for chromogenic substrate interactions and enhanced molecular interaction and electron transfer. For validating our appeal of the significance of the reported 2D carbon-based nanozyme, a comparison table was made with other carbon-based materials and natural enzymes, showing the superior catalytic properties of the 2D carbon (see Table S1, ESI[†]).

3.5 Principle of the colorimetric detection of A.A.

Joseph *et al.* (1982) well established the oxidation phenomenon of TMB in the presence of a catalyst using optical and EPR spectroscopy.⁴⁸ In line with this, we demonstrated the reaction progress of the oxidation of the TMB molecule to di-imine (see Scheme 1). Since TMB in its reduced form absorbs electromagnetic radiation around the $\lambda_{\text{max}} = 285\ \text{nm}$ region, the solution of TMB has no color. However, with the existence of dissolved oxygen and an oxidase nanozyme, the solution of TMB turned blue color. This is because a cation-free radical was generated, forming a CTC with unoxidized TMB giving a blue color product with absorbance peaks at $\lambda_{\text{max}} = 370$ and $652\ \text{nm}$ (see Scheme 1(i)). The radical cation was less stable and in rapid equilibrium with CTC. Upon the addition of the stop solution (H_2SO_4) (see Scheme 1(ii)), which lowered the pH from 4 to around 1, the enzymatic reaction became terminating. The lowering of the pH caused a shift in the equilibrium from CTC to its radical cation, favoring the formation of the yellow di-imine product with $\lambda_{\text{max}} = 450\ \text{nm}$ and a significantly higher molar absorptivity.⁴⁹

Now understanding the oxidation reaction of TMB, we are in a position to elucidate the nanozyme activity of the proposed

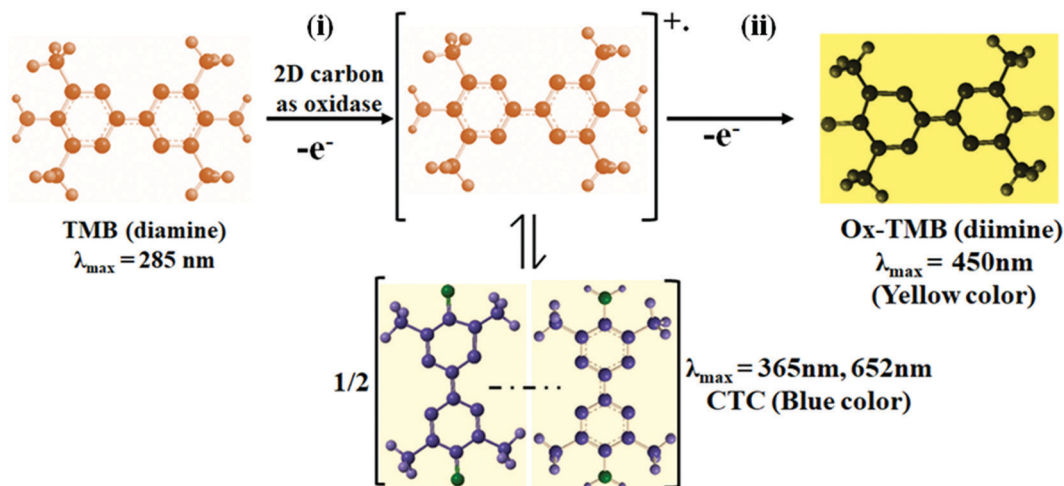

Fig. 4 Steady-state kinetic assay of 2D carbon as a nanozyme: (a) the variation of the enzyme velocity with the TMB concentration, (b) Lineweaver–Burk plot.

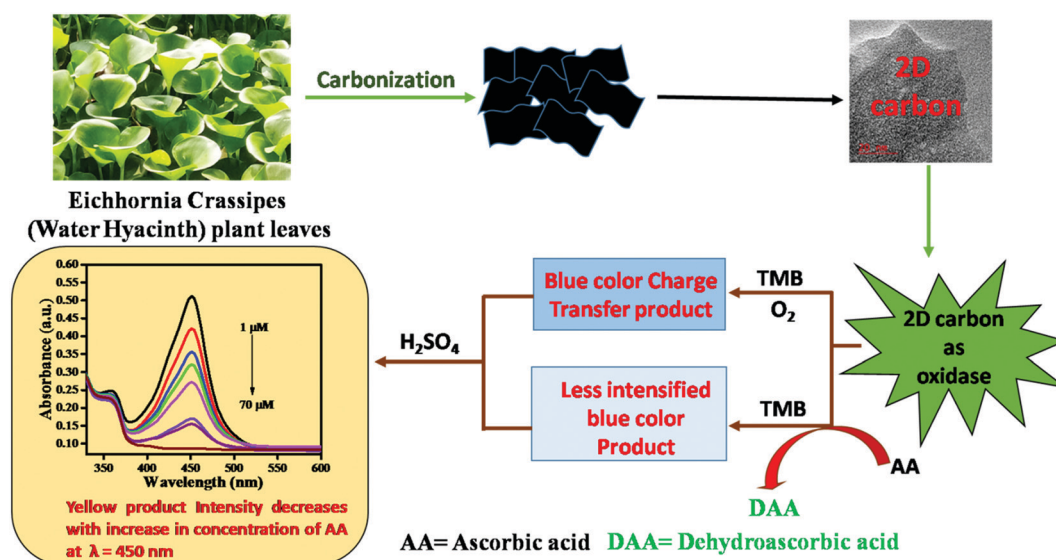

Scheme 1 Schematic representation of the oxidation of TMB.

2D carbon. The 2D carbon was synthesized from *Eichhornia crassipes* leaves by the carbonization technique, as shown in Scheme 2. Since the nanozyme mimicking oxidase functions as a catalyst that accelerates TMB oxidation by mediating the electron transfer from TMB to dissolved oxygen,^{50,51} this is a better means than from the peroxidase because of the absence of corrosive H_2O_2 .²² So our interest was focused on the investigation of the oxidase-like nanozyme. The offered 2D carbon possessed an excellent surface area with profound oxidase activity corresponding to the chromogenic substrate TMB. Due to the large surface area, more TMB and O_2 molecules get adsorbed over the 2D carbon. Due to such proximity, the reacting molecules become closer together, facilitating the electronic or redox reactions. There is a net transfer of electrons from TMB to the catalyst (2D carbon), forming oxidized TMB; further, oxygen receives an electron from the catalyst and gets reduced. 2D carbon bears another advantage as it has O, N

heteroatoms, allowing making H-bonding and acting to better mimic the activity. A.A. is an antioxidant and has competitive inhibition properties concerning the oxidase activity of 2D carbon toward TMB. Therefore, with the addition of A.A., the oxidation of TMB was inhibited, resulting in a lowering of the peak intensity at 450 nm and producing yellow color contrasts. A linear response was achieved for absorbance at 450 nm for different A.A. concentrations. This oxidation reaction between 2D carbon and TMB is a corrosive H_2O_2 -free process and has excellent sensitivity, stability, and reproducibility, which were due to the reported 2D carbon material.

3.6 Optimal pH and temperature parameters

The catalytic properties of enzymes are susceptible to different parameters, such as pH and temperature. So, optimizing these parameters is crucial for developing an efficient sensor with better accuracy and precision. For temperature optimization,

Scheme 2 Schematic representation of the principle for the colorimetric detection of A.A.

Fig. 5 Spectra for the optimization of the parameters for the nanozyme: (a) temperature, (b) pH.

the oxidase activity experiments were performed at different temperatures ranging from 10 °C to 50 °C. Fig. 5a shows that 2D carbon exhibited good mimetic activity over a broad temperature spectrum with maximum activity at 20 °C. Further, to optimize the pH, the oxidase activity experiment was performed in buffer solutions with varying pH (2, 3, 4, 5, 6, 7), as shown in Fig. 5b. In Fig. 5b, it is shown that 2D carbon had a maximum activity at pH 4, which is consistent with earlier reports.²² Such results show the resistance of the 2D carbon catalytic property to pH and temperature compared to the natural enzyme and suggest the better stability and efficiency of the developed nanozyme.

3.7 Sensing

Under all the optimized conditions of temperature, pH, material concentration, and TMB, the developed methods were explored for the sensing of A.A. Since A.A. shows an inhibition property over the oxidase activity of 2D carbon and is concentration-dependent, this can be tested as 2D carbon induces the oxidation reaction of TMB and displays a blue color as the charge-transfer complex is formed. This blue color is transformed to yellow upon adding the stop solution and gives a

characteristic absorbance peak at 450 nm. The addition of A.A. gives a color contrast with its different concentrations. Fig. 6a represents the sensing of A.A., and shows the developed sensor had good linearity in the range of 1 to 70 μM with a regression coefficient of 0.99. Fig. 6b shows the linear calibration plot, which was plotted taking the average of ten replicates. The developed sensor showed good linearity with a detection limit of 0.26 μM calculated using the formula $LOD = 3 \times \text{standard deviation of the blank/slope of the calibration plot}$.

3.8 Reproducibility and cycle stability

In order to elucidate the reproducibility of the developed sensor, we have repeated the experiment several times using freshly prepared solutions for all components as described in Fig. 7(a). It can be inferred from the result that the sensor's relative activity was similar over ten days with inefficient differences. Further, the recyclability test of the nanozyme has been tested by recovering it after the test through centrifugation at 8000 rpm for 10 min. For this purpose, 30 min incubation time has been reserved. As can be observed in Fig. 7(b), the relative activity of the nanozyme shows good cycle stability over six cycles with more than 94%. This minor

Fig. 6 (a) UV-Vis absorption spectra for A.A. sensing (1 to 70 μM). (b) Endpoint calibration plot at 450 nm.

Fig. 7 (a) Reproducibility study over different days, (b) cycle stability of catalytic activity of 2D carbon.

reduction may be due to the sample loss during centrifugal treatment.⁵²

3.9 Interference study

For any sensor, the specificity and selectivity are essential parameters. Before commercialization, an interference study is necessary to ensure the selectivity of sensors toward the targeted molecules. The real sample can encounter several molecules, which may interfere with the sample analysis and mislead the data interpretation. In this work, the method was examined with various interferences that may be encountered, like glucose, citric acid, glutathione, Cu^{2+} , Ca^{2+} , K^+ , and Cl^- , taking their concentration as ten times as high as A.A. Since GSH has a reductive nature like A.A., it gives a very similar response to the reported method. The comparative responses of the interferences as mentioned above with A.A. are shown in Fig. 7. Thus, there is a critical step needed for investigation of GSH's effect. To understand this, similar experiments for the oxidase activity were performed in the absence and presence of NEM. NEM is an alkylating compound commonly used to protect the thiols group (-S.H.) of GSH. Thereby, we negotiated the effect of GSH in our A.A. sensing.^{53,54} The histogram of Fig. 8 depicts that the present method is particular for A.A., and

can be effectively applied as a selective technique for sensing A.A. in actual samples.

3.10 Real sample analysis

Three different A.A.-rich fruits, like oranges, lemons, and grapes, and human serum were used for the objective sample analysis as tabulated in Table 1. In order to do this, the juices of oranges, lemons, and grapes were collected and centrifuged at 8000 rpm to get the extract. Consequently, each extract was diluted up to 50-fold (using the buffer) and used for the further experiments. The A.A. analysis was performed by spiking different A.A. concentrations (10 and 20 μM) for each fruit extract and the absorbance was recorded at $\lambda_{\text{max}} = 450 \text{ nm}$. By using the absorbance data, the concentration of A.A. was calculated from the calibration plot, and their respective concentrations are given in ESI† Table S1. The observed result clearly showed the potential of our method with excellent recovery between 97% to 106%. However, human serum (samples obtained from IMS-BHU Hospital) was diluted up to 10-fold using acetate buffer and an experiment was performed *via* spiking different A.A. concentrations (20 and 40 μM). The observed result clearly showed the potential of our method with an excellent recovery response between 93% to 103% (see Table 2). The comparative data of the projected colorimetric method with the previously reported nanozyme are also tabulated as ESI† Table S2. Thus, the present technique based on the 2D carbon

	20	42.54	103.2
	40	57.36	93.5

nanozyme possessed good linearity and a lower LOD. Therefore, we can say that Eichhornia crassipes-derived 2D carbon-based colorimetric detection provides a reliable, highly sensitive, and convenient approach for detecting A.A.

4. Conclusions

Herein, we presented a biomass waste-derived 2D carbon-based sustainable, rapid, and efficient oxidase mimic for A.A. colorimetric detection from Eichhornia crassipes. Such 2D carbon has a high surface area ($781 \text{ m}^2 \text{ g}^{-1}$) with self-doped O, N heteroatoms, which gives unique electronic or redox properties. The developed 2D carbon-based sensor showed an excellent linear response (R -square = 0.99) over the range of 1 to 70 μM . The detection limit was found to be 0.26 μM , by introducing a sensitive platform for the sensing of A.A. in real samples. Further, the reported oxidase 2D carbon-based sensor quantified the A.A. concentration in orange, lemon, and grape juice, and human serum with good recovery values. In conclusion, this work presents a complete metal-free and efficient nanozyme based on Eichhornia crassipes biowaste. It presents a new avenue to design a sustainable mimetic substrate for ascorbic acid detection from biowastes.
