# Insights into the multifunctional applications of strategically Co doped MoS<sub>2</sub> nanoflakes†

R. Rahman,<sup>a</sup> S. Chaudhuri,<sup>a</sup> D. Samanta,<sup>b</sup> A. Pathak<sup>id</sup>\*<sup>b</sup> and T. K. Nath<sup>id</sup>\*<sup>a</sup>

Simultaneous tuning of magnetic, transport and electrochemical properties through strategic doping of cobalt (Co) ions in hydrothermally treated multi-layered MoS<sub>2</sub> nanoflakes (NFs) without having a secondary phase has been regarded as cutting-edge research. In our study, we have successfully incorporated Co into MoS<sub>2</sub> NFs at various percentages (0%, 2%, 4%, 6%, 8%) with a significant presence of defects, strain and sulfur vacancies, enabling prompt transformation of the surrounding 2H-MoS<sub>2</sub> local lattice into a trigonal (1T-MoS<sub>2</sub>) phase. Effective amplification of magnetic property (ferromagnetic coupling on the scale of  $p_{\text{eff}} \sim 4.37\mu\text{B}$ ) in 8% Co-doped MoS<sub>2</sub> NFs has been evidenced from VSM measurements. The key reasons are probably attributed to the doping induced 1T phase, the presence of zigzag edges well-established from TEM and Raman measurements, and exchange interactions between ferromagnetically ordered sulfur vacancies and Mo<sup>4+</sup> and Co<sup>2+</sup> ions. The experimental observations on magnetic measurements have been fitted well with the well-known density-functional theory (DFT) computation. Further, the effect of intentional doping on transport property has been evaluated by employing a four probe linear geometry setup. The increased carrier concentration and decreased resistance result in improved transport properties. Various transport models such as variable range hopping (VRH) and nearest neighbour hopping (NNH) of the Co-doped MoS<sub>2</sub> systems have been successfully fitted in different temperature regimes with a tunable temperature coefficient of resistance (TCR)  $\sim 3.0 \times 10^{-2} \text{ K}^{-1}$ . Additionally, electrochemical measurements revealed a significant increase in electrochemical activity with the highest proportion of Co doping (8% Co), which is likely due to increased defect levels and active surface area with expanded interlayer separation, as well as exposure of the electrochemically more active metallic (1T phase) Mo atoms in the edge planes. Therefore, our approach in achieving mixed-phase defect-rich (1T and 2H) Co-doped MoS<sub>2</sub> NFs exhibiting room-temperature ferromagnetism, high TCR and improved electrochemical performance makes them an excellent multifunctional candidate in spintronics, infrared (IR) detection and energy storage devices.

## 1. Introduction

Molybdenum disulfide (MoS<sub>2</sub>), as one typical candidate of graphene analogues and a member of the transition metal dichalcogenides (TMDs), has recently drawn tremendous attention in a wide range of novel applications such as field-effect transistors,<sup>1</sup> flexible devices,<sup>2</sup> digital electronics,<sup>3</sup> and nano- and opto-electronics<sup>4,5</sup> as well as in basic research<sup>6-7</sup> due to its unique electrical, optical, mechanical and electronic properties. Based on the demanding application of diluted magnetic semiconductors (DMS), manipulating the magnetic properties

of MoS<sub>2</sub> nanoflakes is crucial for expanding their applications in nanoelectronics and spintronics. However, pristine MoS<sub>2</sub> nanoflakes are intrinsically nonmagnetic. Therefore, the realization of stable magnetism in MoS<sub>2</sub> is highly desirable.

Motivated by the potential applications and the great demand for magnetic MoS<sub>2</sub> nanostructures, a variety of methods have been developed and explored in the past few years. However, there are many effective ways in which the magnetism of 2D materials can be realized such as the introduction of defects,<sup>8,9</sup> surface functionalization (*i.e.*, hydrogenation),<sup>10</sup> cutting 2D nanoflakes into one-dimensional (1D) nanoribbons (NRs),<sup>11,12</sup> and transition-metal (TM) doping.<sup>13</sup> Moreover enormous ferromagnetism in MoS<sub>2</sub> nanoflakes requires the introduction of a large number of defects which in turn results in the reduction of carrier mobility because of the formation of scattering centres or charge-trapping sites in the MoS<sub>2</sub> sheets. Although surface functionalization is capable of producing stable magnetism, experimentally it faces a big challenge. For

† Electronic supplementary information (ESI) available. See DOI: <https://doi.org/10.1039/d2ma00738j>

example, surface hydrogenation requires the implementation of external stress in MoS<sub>2</sub> nanoflakes. The introduction of ferromagnetism in MoS<sub>2</sub> NRs is very crucial and the edge type of the nanoribbon needs to be well-controlled as zigzag NRs are ferromagnetic whereas armchair NRs are nonmagnetic. Structure and vacancy-related ferromagnetism contributed by zigzag edges of MoS<sub>2</sub> nanoribbons and sulfur vacancies in MoS<sub>2</sub> flakes has been reported in several theoretical calculations.<sup>11,14,15</sup> In this regard, TM doping is a facile and conventional way to achieve stable magnetism in 2D semiconductor materials. Moreover, the magnitude of magnetism and the dopant concentration of MoS<sub>2</sub> nanoflakes can be controlled in the doping process. Ferromagnetism in layered TMDs *via* substitutional doping of magnetic 3d transition-metal atoms has been reported by Ramasubramaniam *et al.*<sup>16</sup> and possible ferromagnetism in MoS<sub>2</sub> by single absorption of the Co atom has been claimed by Chen *et al.*<sup>13</sup> for the first time. Evidence of room temperature ferromagnetism in Mn, Fe, Co and Ni-doped MoS<sub>2</sub> in monolayer and bulk form, initiated by substitutional defects and defect complexes, has been reported by Wang *et al.*<sup>17</sup> Additionally, proton beam irradiation<sup>8</sup> and doping with non-metal elements<sup>18</sup> are considered to produce ferromagnetism in few-layer non-magnetic MoS<sub>2</sub>. It has been shown in previous studies that localized nonbonding 3d electrons of TM atoms produce charge polarization in TM substituted 2D systems.<sup>19–21</sup> The extra nonbonding valence electrons present in the TM metal ion compared to Mo contribute magnetic moment with substitutional doping in layered materials. For example Mn-MoS<sub>2</sub> = 1 $\mu_B$ , Fe-MoS<sub>2</sub> = 2 $\mu_B$ , Co-MoS<sub>2</sub> = 3 $\mu_B$ , Ni-MoS<sub>2</sub> = 4 $\mu_B$ , Cu-MoS<sub>2</sub> = 5 $\mu_B$  moments possess 1, 2, 3, 4 and 5 extra electrons in nonbonding orbitals.<sup>22</sup> It is worth noting that a maximum of only 5 electrons can be accommodated by the 3d orbital in the single-filled states. Hence, based on the above theory, the magnetism of the TM doped MoS<sub>2</sub> structure can be tuned successfully by the internal TM engineering which plays a crucial role in the functionalization of MoS<sub>2</sub> nanomaterials in possessing a defined magnetic moment. However, Co being a member of the transition metal ion group possesses a comparable ionic radius (0.70 Å) to molybdenum (0.68 Å). Doping of the Co-ion in MoS<sub>2</sub> NSs can effectively modulate the structural properties by introducing vacancies, defects and strain which are also responsible for the ferromagnetism. The magnetism in MoS<sub>2</sub> nanostructures can be much influenced by the zigzag edges, and the experimental and computational study has shown that the magnetism in Co-doped MoS<sub>2</sub> nanoflakes is sensitive to the edges as well.<sup>23</sup> Theoretically it has been shown that Co substitution at the Mo site leads to a spin-polarized state<sup>24</sup> contributing three electrons in the 3d orbital in the single-filled states. The partial replacement of Mo with the transition metals like Co creates magnetism in MoS<sub>2</sub> making it a suitable candidate as a new kind of diluted magnetic semiconductor.

Moreover, other effects such as coupling between the adjacent layers are known to stabilize the magnetism and can enhance the overall magnetization originating from the grain boundaries.<sup>25</sup> The ferromagnetic signal was attributed to

localized electronic states at grain boundaries in other non-magnetic layered systems such as graphite.<sup>26</sup> Even though the interlayer coupling might enhance the ferromagnetic signal, such coupling is not a necessary condition for the existence of ferromagnetism as the presence of zigzag edges is sufficient and magnetization measurements certainly confirms that the magnetization originating from zigzag edges.<sup>11,27</sup> Nevertheless, studies on the tuning of magnetic and transport properties of MoS<sub>2</sub> simultaneously by doping of transition metal (TM) atoms are extremely critical in experimental work.

In earlier reports, it has been shown that n-type MoS<sub>2</sub>-based field-effect transistors (FETs) face limitations in certain applications due to having high contact resistance. However, to reduce contact resistance, metallic MoS<sub>2</sub> with a lithium-solution treatment has recently been introduced<sup>28,29</sup> which is dissimilar to the conventional methods, such as chemical doping and ion implantation, used for the reduction of contact resistance in other devices. Li-treatment of MoS<sub>2</sub> results in the coexistence of various MoS<sub>2</sub> phases and consequently develops significantly different electronic and magnetic properties.<sup>30,31</sup> Kim *et al.* reported the transport properties of Li-ion treated polymorphic MoS<sub>2</sub> with a large temperature coefficient of resistance (TCR), enabling efficient IR detection at room temperature.<sup>32</sup> Meanwhile recent studies on transport suggest that some factors such as charged impurities<sup>33–35</sup> and localized states<sup>34,36,37</sup> play a crucial role in controlling the dominant scattering processes that limit the carrier mobility in mechanically exfoliated samples, and this remains unexplored. Recent studies on CVD-grown MoS<sub>2</sub> suggest that the contact resistance due to Schottky barriers needs to be carefully considered. The adverse impact of dominant scattering processes that limit the carrier mobility should be critically evaluated.<sup>38,39</sup> The advantage of incorporation of the 1T metallic phase in the semiconducting 2H phase through Li-ion treatment or TM ion doping is that it controls the junction barrier resistance in TMD-based devices. In this work, we investigate the nature of various dominating charge transport mechanisms which come into play in the high- and low-temperature region of multi-layered undoped (0% Co) and doped (with various amounts of cobalt, *i.e.*, 2% Co, 4% Co, 6% Co and 8% Co) MoS<sub>2</sub> nanoflakes. Doping-induced sulfur vacancies (SVs) and cobalt dopants act as electron donors and induce localized states in the band gap leading to the narrowing of the band gap.<sup>40</sup> In undoped MoS<sub>2</sub> the electron transport is dominated by thermally excited nearest-neighbour hopping (NNH) throughout the entire temperature region (50–300 K) due to the lack of doping-related defect induced localized electrons. The localized electron transport in the cobalt doped MoS<sub>2</sub> sample is dominated by thermally excited NNH from moderate to high temperature and variable-range hopping (VRH) at sufficiently low temperatures. In this report, doping-induced ferromagnetism by cobalt ion doping in MoS<sub>2</sub> nanoflakes has been explored and verified both experimentally (VSM, EPR) and theoretically (DFT). Additionally, the presence of zigzag edges has been verified by TEM measurements corresponding to 8% Co-doped MoS<sub>2</sub> NFs which probably gives rise to the ferromagnetic behaviour

synergistically in association with the doping effect. The ferromagnetic behaviour of 8% Co-doped MoS<sub>2</sub> NFs having saturation magnetization ( $M_s$ )  $\sim$  1.2 emu g<sup>-1</sup> and coercivity  $\sim$  70 Oe at 5 K has been observed. The role of the substituted Co dopant and the doping induced 1T phase in enhancing ferromagnetism has been explained through the bound magnetic polaron (BMP) model. According to the BMP model, only those nearby Mo<sup>4+</sup> ions in the 1T phase and Co<sup>2+</sup>/Co<sup>3+</sup> ions in octahedral geometry located within the effective radius of the same polaron (around a sulfur vacancy center) could interact with each other ferromagnetically giving rise to ferromagnetism in 1T@2H-MoS<sub>2</sub> nanoflakes. A detailed first principle DFT study on undoped and cobalt doped systems reveals the increasing nature of ferromagnetism assuming substitutional Co doping in a pure 2H MoS<sub>2</sub> matrix. Therefore, we have successfully incorporated zigzag edges, defects and vacancies in a controlled way by doping Co in MoS<sub>2</sub> NFs while improving their electrical properties.

Layered TMDs, such as MoS<sub>2</sub>, have proven their efficacy in the electrochemical energy storage/conversion field, owing to their large surface area that allows maximum exposure of surface active sites, high mechanical strength, and flexibility in the atomic scale dimension.<sup>41</sup> The heterogeneous electron transfer (HET) on the edge planes of MoS<sub>2</sub> is predicted to be higher than that on the basal planes, and thus the edge sites are catalytically and electrochemically more active than the basal planes.<sup>42</sup> Hence, it is always encouraged to fabricate MoS<sub>2</sub>-based electrodes with the edge-exposed surface rather than with the basal planes exposed, and of these the former improves the catalytic and electrochemical performances.<sup>43,44</sup> Moreover, the electrical conductivity of MoS<sub>2</sub> is another key factor that influences the catalytic and electrochemical performance of MoS<sub>2</sub>-based electrodes. Our strategy of systematic Co-doping in MoS<sub>2</sub> increases the number of active sites in the edge planes, enhances the conductivity by introducing the metallic 1T phase and increases interlayer separation aiding in the intercalation of ions easily and defect states with modulation of the band gap. Such salient features facilitate the Co-doped MoS<sub>2</sub> to function as a better electrode material ( $\sim$ 1.7 times higher specific capacitance observed in 8% Co doped MoS<sub>2</sub> compared to the undoped one) having an improved charge storage mechanism. Our work provides a detailed investigation of the manipulation of magnetic property for achieving room-temperature ferromagnetism and of transport property by varying Co ion dopant content in MoS<sub>2</sub> NFs as well as by introducing the 1T phase, defects, and edges with simultaneous enhancement in electrochemical property for future application in energy storage devices.

## 2. Experimental details

### 2.1. Chemicals used

High purity (99.9% purity) chemicals such as sodium molybdate dihydrate (Na<sub>2</sub>MoO<sub>4</sub>·2H<sub>2</sub>O), thiourea (CH<sub>4</sub>N<sub>2</sub>S), and cobalt acetate tetrahydrate (Co(CH<sub>3</sub>COO)<sub>2</sub>·4H<sub>2</sub>O) were procured from

Sigma-Aldrich. All the reagents were of analytical reagent grade and used without further purification.

### 2.2. Synthesis of ultra-thin Co-doped MoS<sub>2</sub> NFs

The undoped and Co-doped (with various percentages of Co) MoS<sub>2</sub> NFs were synthesized using the facile one-step hydrothermal technique using Na<sub>2</sub>MoO<sub>4</sub>·2H<sub>2</sub>O, Co (CH<sub>3</sub>COO)<sub>2</sub>·4H<sub>2</sub>O and CH<sub>4</sub>N<sub>2</sub>S as starting reagents. In a typical preparation process, 2 mmol of Na<sub>2</sub>MoO<sub>4</sub>·2H<sub>2</sub>O and 5 mmol of CH<sub>4</sub>N<sub>2</sub>S were taken and dissolved in 40 mL of deionized water and the pH value of the solution was adjusted to 5.0 by adding 0.02 mol L<sup>-1</sup> of acetic acid (CH<sub>3</sub>COOH). Then the mixed solution was transferred into a 50 mL Teflon-lined stainless-steel autoclave for hydrothermal treatment at 200 °C for 24 h and cooled down to room temperature naturally. MoS<sub>2</sub> in the form of a black powder was obtained by centrifugation at 3000 rpm for 10 min. Then the black powder was washed with deionized water and ethanol several times and dried in a vacuum oven at 60 °C for 12 h. For the synthesis of 2 at wt%, 4 at wt%, 6 at wt% and 8 at wt% cobalt doped MoS<sub>2</sub> NFs, the two precursors Na<sub>2</sub>MoO<sub>4</sub>·2H<sub>2</sub>O and Co (CH<sub>3</sub>COO)<sub>2</sub>·4H<sub>2</sub>O were taken in the ratio of 0.98 : 0.02, 0.96 : 0.04, 0.94 : 0.06 and 0.92 : 0.08 (in mmol) while using the same amount of CH<sub>4</sub>N<sub>2</sub>S in the aqueous solution and the synthesis process was repeated.

The MoS<sub>2</sub> NFs with various amounts of cobalt doping (0 at wt%, 2 at wt%, 4 at wt%, 6 at wt% and 8 at wt%) were labelled as undoped, 2% Co, 4% Co, 6% Co and 8% Co, respectively.

### 2.3. Characterization techniques

The instrumental specifications of X-ray diffraction (XRD), Raman measurement, scanning electron microscopy (SEM) and high-resolution transmission electron microscopy (HRTEM) techniques to understand the existing crystalline phase and different vibrational modes present in our samples have already been reported.<sup>40</sup> The room temperature EPR spectra of the samples were recorded using an X-band Bruker ELEXSYS 580 EPR spectrometer with 9.8492 GHz of X-band frequency. A 7400 series vibrating sample magnetometer (VSM) (Lake Shore Cryotronics, USA) was used to measure the magnetic property based on the  $M$  vs.  $H$  (applied field  $\sim$  -2 T to +2 T) and  $M$  vs.  $T$  plot (10–300 K, 500 Oe). The characterization of the transport property of the samples was carried out using a Lake-shore four-probe linear geometry setup using a low-temperature closed-cycle helium refrigeration cryostat. The powder form MoS<sub>2</sub> samples with various amounts of Co dopants were pelletized and conducting silver contacts were made for transport property measurements.

### 2.4. Electrode preparation

Electrochemical measurements like cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) and ac impedance were performed using a CHI600E Electrochemical Workstation (CH Instruments, USA) at room temperature containing a glassy carbon electrode loaded with undoped and Co-doped MoS<sub>2</sub> samples, Ag/AgCl (in standard 3 M KCl aqueous solution), and Pt electrode as the working electrode, reference electrode, and

counter electrode, respectively, using 1 M Na<sub>2</sub>SO<sub>4</sub> aqueous solution as the electrolyte. Before starting all the measurements, the bare glassy carbon electrode (GCE, dia. 3 mm) was polished mechanically with 1, 0.3 and 0.05 μm alumina slurry sequentially to obtain a mirror finish, and then washed with acetone, ethanol and DI water thoroughly. The slurry was a mixture consisting of the active material, activated carbon, and poly(vinylidene fluoride) binder in the weight ratio of 80:15:5 with *N,N*-dimethylformamide as the solvent. Then, a certain amount of the slurry was drop cast on the GCE surface carefully. Finally, the electrodes were dried at 80 °C for 12 h in vacuum.

### 2.5. Computational details

To elucidate the impact of Co dopants on the magnetic properties of MoS<sub>2</sub> nanoflakes, first-principles calculations were performed using the Vienna *Ab initio* Simulation Package (VASP),<sup>45</sup> within the generalized gradient approximation (GGA)<sup>46</sup> considering the Perdew–Burke–Ernzerhof (PBE)<sup>46</sup> parametrization to describe the exchange–correlation interaction. The cut-off energy for the plane-wave basis set was set at 450 eV in all the computations. The relaxation convergence of energy was taken to be less than  $1.0 \times 10^{-6}$  eV and all the atoms were allowed to relax using a conjugate gradient scheme until the inter-atomic forces fell below 0.01 eV Å<sup>-1</sup>. All the structural optimizations and the scf calculations were done using a well-converged Monkhorst–Pack<sup>47</sup>  $11 \times 11 \times 11$  and  $21 \times 21 \times 21$  *k*-point grid, respectively. The electronic structure calculations were done with a much denser *k*-point mesh. In our calculation, we assumed that unit cells have 2H atomic arrangements as the 2H phase is seen to be dominant over the 1T phase in all cases. To account for van der Waals interaction between two layers of the unit cell, the DFT-D2<sup>48</sup> method as implemented within VASP was adopted in all calculations.

## 3. Results and discussion

### 3.1. XRD data analysis

The XRD patterns of the undoped and cobalt-doped (with various percentages of Co) MoS<sub>2</sub> nanostructures recorded over the  $2\theta$  range of 10°–70° have been shown in our previous research paper.<sup>40</sup> Here the XRD peaks of all undoped and Co-doped samples exactly match with hexagonal MoS<sub>2</sub> having

identical peak positions. The XRD graphical plot of the samples with JCPDS card no. 00-037-1492 is shown in Fig. 1(a). The signature of the diffraction peak corresponding to the 1T phase (ESI,† Fig. S1) is more prominently observed in the XRD pattern of 8% Co-doped MoS<sub>2</sub> compared to other samples with low concentration Co doping. This peak shifts to a lower angle 10.6° to 10.5° when the Co dopant percentage is increased from 2% to 8%, possibly due to the appearance of tensile strain within the lattice. The slight shift of the main (002) diffraction peak to a lower angle and increased lattice parameters (*a* and *c*) confirm the existence of uniaxial lattice strain (tensile) in the lattice due to substitutional Co doping.<sup>49</sup> The XRD pattern of the undoped and Co-doped MoS<sub>2</sub> nanoflakes was successfully refined with a 2H-MoS<sub>2</sub> phase (*P63/mmc*, *a* = 3.14 Å, *b* = 3.14 Å, *c* = 12.53 Å,  $\alpha$  = 90°,  $\beta$  = 90°,  $\gamma$  = 120°) having no extra crystalline impurity phase. The lattice parameters as obtained after refinement are found to be *a* = 3.158 Å, *b* = 3.158 Å, *c* = 12.815 Å for undoped and *a* = 3.174 Å, *b* = 3.174 Å, *c* = 12.879 Å for 8% Co-doped MoS<sub>2</sub> NFs. The refined lattice parameters agree well with previous literature.<sup>50</sup> The average crystallite size of all the MoS<sub>2</sub> NFs varies from 8 nm to 6 nm. It has been observed that the crystallite size as obtained by using the Scherrer formula decreased with the increase of the cobalt dopant amount. This can be attributed to the possible appearance of lattice strain and defects induced by doping. The microstrain and dislocation density increased significantly with increasing doping concentration as evidenced by increasing defects and strain reported earlier.<sup>40</sup>

### 3.2. Raman spectroscopy study

Raman spectroscopy was employed to demonstrate the doping effect in MoS<sub>2</sub> NFs using a 532 nm excitation laser with the calibrated silicon Raman peak at 521 cm<sup>-1</sup>. The recorded Raman spectra of MoS<sub>2</sub> and Co-doped MoS<sub>2</sub> are shown in Fig. 2. Furthermore, for the undoped MoS<sub>2</sub> nanoflakes, the Raman spectra display characteristic peaks at 281, 377, 404, and 454 cm<sup>-1</sup> arising from the E<sub>1g</sub>, E<sub>2g</sub><sup>1</sup>, A<sub>1g</sub> and longitudinal acoustic phonon mode (A<sub>2u</sub>) of 2H-MoS<sub>2</sub>.<sup>51,52</sup> The two intense peaks are located at ~377 cm<sup>-1</sup> (E<sub>2g</sub><sup>1</sup> mode) corresponding to the in-plane vibration of S and Mo atoms and at ~404 cm<sup>-1</sup> (A<sub>1g</sub>) attributed to the relative vibration of S atoms in the out of plane direction.<sup>53,54</sup> In addition to these 2H vibrational Raman modes, two other weak vibrational modes at 232 cm<sup>-1</sup> (J<sub>2</sub>) and

Fig. 1 (a) XRD pattern of MoS<sub>2</sub> NFs doped with various percentages of cobalt. Rietveld refinement of (b) undoped and (c) 8% Co doped MoS<sub>2</sub>.

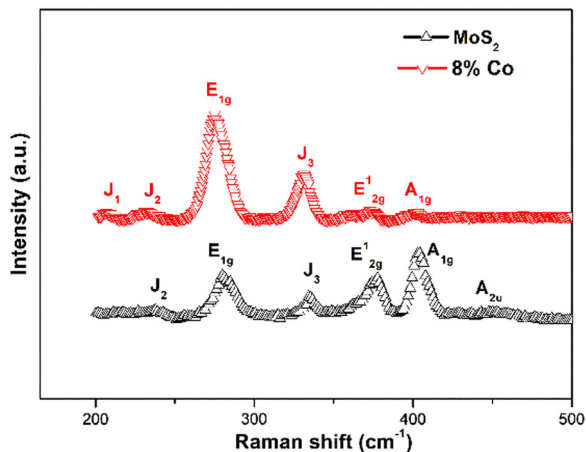

Fig. 2 Different Raman modes showing the presence of 1T and 2H phases in undoped and 8% Co doped MoS<sub>2</sub>.

335 cm<sup>-1</sup> (J<sub>3</sub>) appear in the undoped one assigned to the 1T phase. By contrast, for 8% Co-doped MoS<sub>2</sub> NFs, the intensity of J<sub>2</sub> and J<sub>3</sub> has increased significantly along with the presence of the J<sub>1</sub> phase attributed to the 1T-MoS<sub>2</sub> phase. In 8% Co-doped MoS<sub>2</sub> NFs the suppression of the E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> peak intensity has been observed. This suggests that a high amount of cobalt doping enables phase transformation of the 2H phase to 1T phase in 8% Co-doped MoS<sub>2</sub> NFs. In the case of 8% Co-doped MoS<sub>2</sub> NFs, redshifts of the two peaks (E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub>) were detected from 377.72 cm<sup>-1</sup> to 374.78 cm<sup>-1</sup> and from 404.27 cm<sup>-1</sup> to 402.32 cm<sup>-1</sup>, respectively. Specifically, the absence of sulfur atoms in few-layer MoS<sub>2</sub> would induce redshifts of both Raman peaks as reported by Kim *et al.*<sup>55</sup> Tensile strain appearing in MoS<sub>2</sub>, directly related to the increase of the lattice parameters, redshifts both E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> peaks as observed by Yang *et al.*<sup>56</sup> and Chaudhury *et al.*<sup>57</sup> Thus, a possible explanation is that sulfur vacancies and tensile strain lead to bond softening and increased lattice parameters. Additionally, we found that the redshift of the E<sub>2g</sub><sup>1</sup> mode contributed by the in-plane opposite vibration of two S atoms with respect to the Mo atom is always larger than that of the A<sub>1g</sub> mode caused by the out-of-plane vibration of S atoms.<sup>58</sup> The absence of sulfur atoms would have a larger effect on the E<sub>2g</sub><sup>1</sup> mode due to the in-plane chemical bonds between S and Mo atoms<sup>59</sup> showing a gradual increase in  $\Delta k$  (difference in  $k$ ) between E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> modes. Table 1 shows that there is a gradual increase of  $\Delta k$  between E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> in 8% Co-doped MoS<sub>2</sub> NFs compared to the undoped ones. Additionally, chemical doping induced strain in the lattice changes the bond length and hence an increase in  $\Delta k$

Table 1 Variation of characteristic Raman modes of undoped and 8% Co doped MoS<sub>2</sub> NFs

Co doping percentage (%)	E <sub>2g</sub> <sup>1</sup> (cm <sup>-1</sup> )	A <sub>1g</sub> (cm <sup>-1</sup> )	$\Delta k$ (cm <sup>-1</sup> )	FWHM ratio (A <sub>1g</sub> /E <sub>2g</sub> <sup>1</sup> )
0	377.72	404.27	26.55	0.82
8	374.78	402.32	27.54	1.62

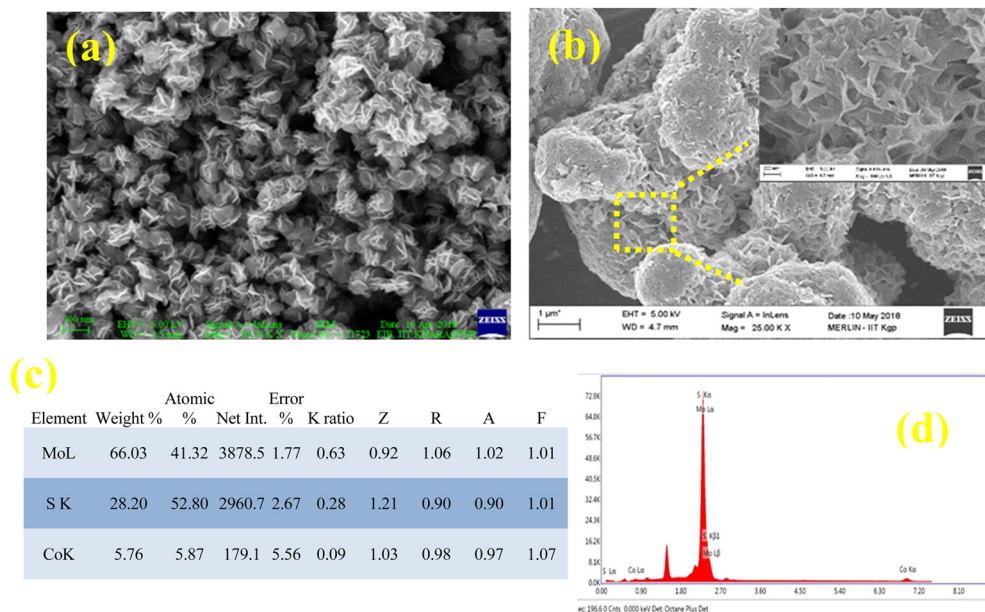

occurs. The observed increase in the E<sub>2g</sub><sup>1</sup>/A<sub>1g</sub> intensity ratio and the increased FWHM of A<sub>1g</sub> in 8% Co-doped MoS<sub>2</sub> compared to the undoped one are an indication of stacking of more number of layers along the in-plane direction and suppression of the out-of-plane movement related to the mode.<sup>60</sup> The significant increase in FWHM and the downshift of A<sub>1g</sub> frequency as observed in the 8% Co-doped MoS<sub>2</sub> case support the presence of zigzag edges forming structural disorder.<sup>61</sup> The shifts and differences between the vibrational Raman E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> peaks with Co doping are presented in Table 1.

### 3.3. Morphology and microstructure study

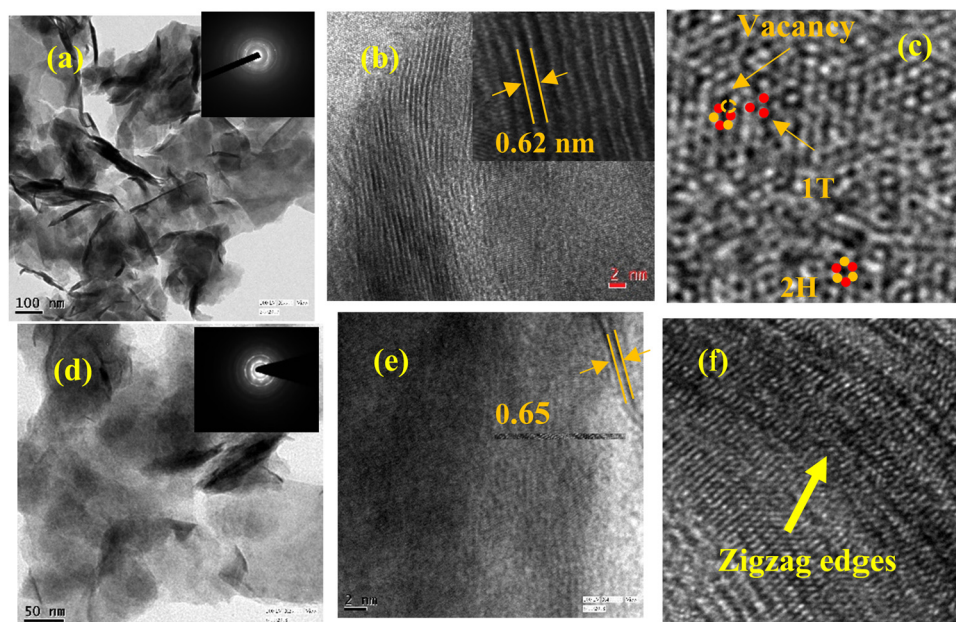

**3.3.1. SEM image analysis.** Fig. 3(a and b) show the FESEM images of the as-prepared 8% Co-doped MoS<sub>2</sub> nanoflakes indicating the formation of a 3D hierarchical fluffy petaloid architecture. Each flower consists of several interconnected nanopetals in the form of nanoflakes. The average diameter of the undoped and 8% Co-doped MoS<sub>2</sub> flowers is about ~200 nm and ~1.5  $\mu$ m, lateral dimensions are ~130 nm and ~240 nm and the thickness lies within 10 nm. The lateral size of the MoS<sub>2</sub> NF increases with the incorporation of more Co dopants. The reason for the formation of larger nanoflowers with higher dopant content may be ascribed to the accumulation of dopant and defect-induced charge on the surface and edge of the lamellar structure contributing to the electrostatic attraction between them which can be validated by zeta potential measurements.<sup>40</sup> Fig. 3(c and d) show the EDAX elemental data analysis and plot indicating the proper distribution and presence of Mo, S and Co in 8% Co-doped MoS<sub>2</sub> NFs. However the theoretically calculated stoichiometric ratio of Co, Mo, and S (0.03:0.31:0.66) for 8% Co-doped MoS<sub>2</sub> matches well with the experimentally found value with a slight variation (0.05:0.41:0.53) possibly due to the presence of S vacancies.

**3.3.2. TEM image analysis.** The detailed information about the microstructure of undoped and 8% Co-doped MoS<sub>2</sub> NFs can be further unfolded by TEM image analysis. The thin interlaced flakes of MoS<sub>2</sub> convert to a bigger nanostructure having sheet-like morphology with larger lateral dimensions which can be well understood in Fig. 4(a and d). The inset of Fig. 4(a) shows diffused rings in the SAED pattern of undoped MoS<sub>2</sub> whereas the inset of Fig. 4(d) shows distinct spots in SAED pattern diffraction planes indicating an increased crystalline nature upon doping in 8% Co-doped MoS<sub>2</sub>. Fig. 4(b) clearly shows the magnified image of interlaced flakes of undoped MoS<sub>2</sub> where the interlayer distance is found to be ~0.62 nm forming a 14–16-layer system. In the case of 8% Co-doped MoS<sub>2</sub>, it has been observed that the number of layers lies within 4–8 layers having an extended interlayer distance ~0.65 nm as shown in Fig. 4(e) due to the appearance of doping-induced lattice strain.<sup>39</sup> Fig. 4(c) shows the prominent presence of 2H and 1T phases and defects in the vicinity of the 1T phase. The presence of edge-terminated zigzag orientation in 8% Co-doped MoS<sub>2</sub> has been indicated by an arrow as shown in Fig. 4(f). According to Tinico *et al.*, such type of zigzag orientation in vertically oriented MoS<sub>2</sub> is responsible for metallic behaviour.<sup>62</sup>

**Fig. 3** SEM images of (a) undoped and (b) 8% Co doped  $\text{MoS}_2$  nanostructures. The inset of (b) shows a zoomed view of the encircled area indicating the microstructure of nanoflakes after doping. (c and d) EDAX analysis of 8% Co doped  $\text{MoS}_2$  indicating the percentage of Mo, Co and S elements present in the sample.

### 3.4. XPS study

The chemical composition and prominent presence of the 1T phase along with the 2H phase in undoped<sup>40</sup> and 8% Co-doped  $\text{MoS}_2$  have been verified by X-ray photoelectron spectroscopic (XPS) measurement. The typical BE peaks of Mo  $3d_{5/2}$  and Mo  $3d_{3/2}$  corresponding to the 2H phase of 8% Co-doped  $\text{MoS}_2$

appeared at 228.37 and 231.75 eV, as shown in Fig. 5(a). Two extra peaks corresponding to Mo  $3d_{5/2}$  and  $3d_{3/2}$  of the 1T characteristic phase were shifted to  $\sim 0.5$ –1 eV. Similarly, the binding energy peaks corresponding to S  $2p_{3/2}$  and S  $2p_{1/2}$  of the 2H phase appeared at 161.63 and 162.79 eV in the case of 8% Co-doped  $\text{MoS}_2$ , as shown in Fig. 5(b). Two other extra peaks

Fig. 5 XPS narrow scan spectra of undoped and 8% Co doped MoS<sub>2</sub> (a) Mo 3d, (b) S 2p and (c) Co 2p of 8% Co MoS<sub>2</sub>. Survey spectra of Mo (3d, 3p, 3s), S 2p, C 1s, and Co 2p are shown in (d) corresponding to undoped and 8% Co doped MoS<sub>2</sub>.

shifted about  $\sim 0.5$  eV from S 2p<sub>3/2</sub> and S 2p<sub>1/2</sub> of the 2H phase are assigned to the 1T phase. It has been observed that the doublets corresponding to Mo<sup>4+</sup> and S<sup>2-</sup> are shifted to lower binding energy with a gradual increase of Co dopant as observed in 8% Co-doped MoS<sub>2</sub> when compared with the undoped one as shown in Fig. 5(a and b), confirming the loss of sulfur atoms in the sample.<sup>58</sup> The difference between Mo 3d<sub>3/2</sub> and 3d<sub>5/2</sub> binding energy peaks corresponding to the 1T phase is 3.1 eV confirming the emergence of Mo<sup>5+</sup> ions in 8% Co-doped MoS<sub>2</sub>.<sup>63</sup> By analyzing the XPS spectra, the S:Mo peak ratio for 4% Co-doped MoS<sub>2</sub> is 37% smaller than that for 2% Co-doped MoS<sub>2</sub> NFs.<sup>64</sup> In addition, based on the analysis of the Mo 3d peak area, it is deduced that the content of Mo<sup>5+</sup> in MoS<sub>2</sub> NFs is around 26%, demonstrating a defect-rich structure.<sup>65</sup> Four main peaks corresponding to Co 2p<sub>3/2</sub> at 780.34 eV (Co<sup>3+</sup>) and 785.27 eV (Co<sup>2+</sup>) and Co 2p<sub>1/2</sub> at 791.33 eV (Co<sup>3+</sup>) and 798.07 eV (Co<sup>2+</sup>) are found in 8% Co-doped MoS<sub>2</sub> as shown in Fig. 3(c) similar to the report in the case of Co species found in CoS<sub>2</sub>.<sup>66–69</sup> Also, another two peaks arising at 790.73 eV and

803.24 eV signify the existence of satellite shake-up peaks. The binding energy peak of Co 2p<sub>3/2</sub> at 780.34 eV resembles the CoMo<sub>2</sub>S<sub>4</sub> phase, confirming the uniform substitution of Mo atoms by Co<sup>2+</sup> along the {002} or the S-edge planes.<sup>70</sup> The presence of the elements C, Mo, S, O and Co is revealed in the survey spectrum (wide scan) of undoped and 8% Co-doped MoS<sub>2</sub> as shown in Fig. 5(d). The BE peaks corresponding to different oxidation states of Mo, S, and Co elements present in our samples are listed in Table 2.

### 3.5. Electronic transport property study

Fig. 6 shows the temperature-dependent resistivity curves for all undoped and Co-doped MoS<sub>2</sub>, exhibiting typical semiconductor behaviour. The resistivity eventually decreases with an increase in doping concentration and it is clearly seen in low-temperature regimes. This supports the increase in carrier concentration with the incorporation of an increased proportion of the 1T phase with Co doping.<sup>71</sup> Thermal excitation of electrons from donor levels to the conduction band takes place

Table 2 Position of binding energy peaks of Mo, S and Co elements corresponding to the 1T and 2H phase of undoped and 8% Co-doped MoS<sub>2</sub>

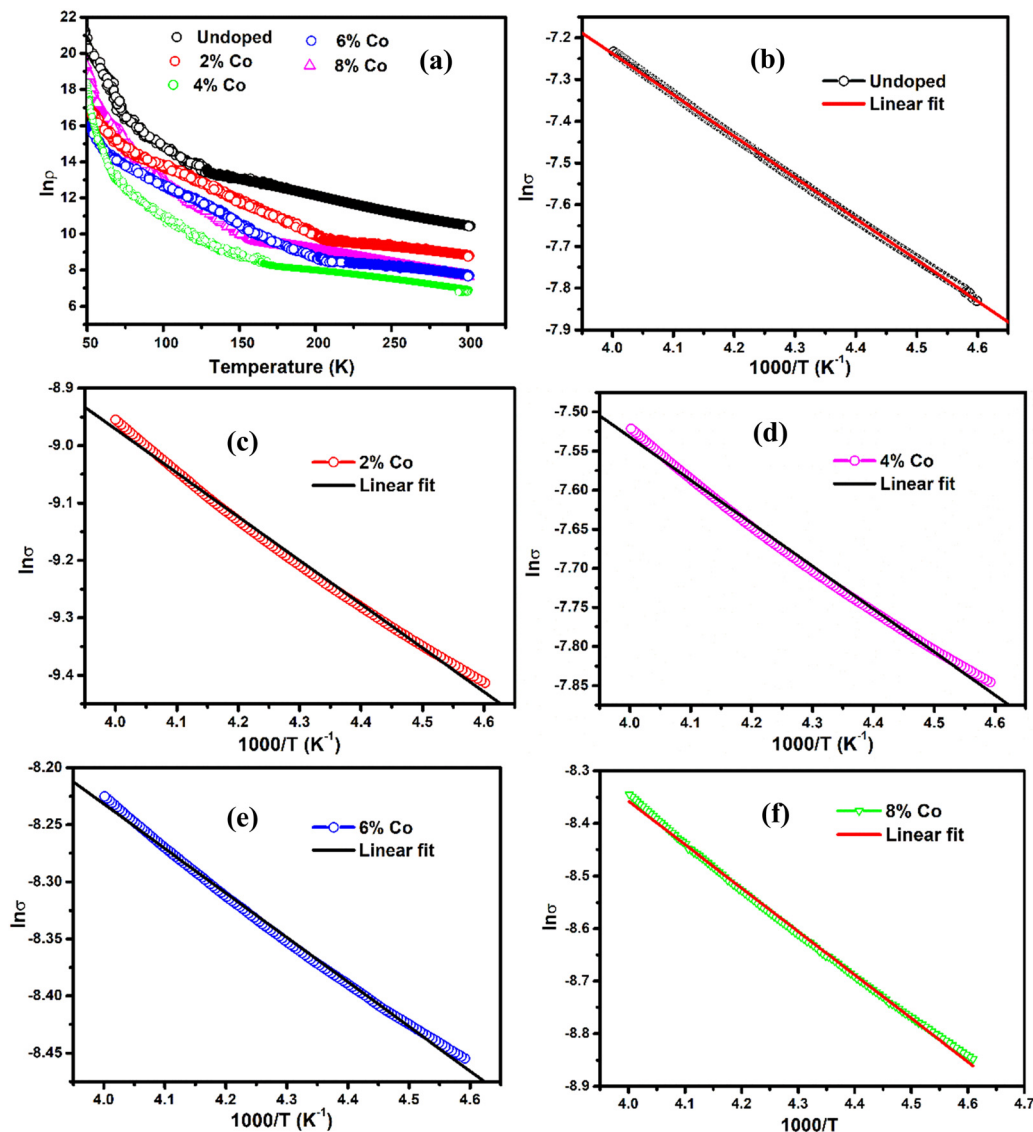

Fig. 6 Logarithmic plot of resistivity with temperature of (a) undoped and Co doped MoS<sub>2</sub>. Linear variation of conductivity with inversion of temperature to test the (b) undoped and (c) 2%, (d) 4%, (e) 6% and (f) 8% Co doped MoS<sub>2</sub> which satisfy the thermal excitation process of transport.

with the increase in temperature. Temperature-dependent resistance can be written in an Arrhenius form:

$$\sigma(T) = \sigma_0 \exp(-E_a/k_B T)$$

where  $\sigma$  is the conductivity,  $\sigma_0$  is the pre-exponential factor,  $k_B$  is the Boltzmann constant, and  $E_a$  is the activation energy. Fig. 6(a–f) shows the plots of the conductivity in log scale as a function of  $1000/T$  from 217 K to 250 K of undoped and 2%, 4%, 6%, and 8% Co-doped samples. Different thermal activation energy regions have been obtained beyond 200 K. The data are fitted to a line with different slopes in this temperature region. The activation energy values for undoped and 2%, 4%, 6% and 8% Co-doped samples are 85.13 meV, 65.73 meV, 47.38 meV, 33.9 meV and 85.3 meV respectively (above 200 K). The activation energy is observed to be much lower than the band gap energy of MoS<sub>2</sub> samples. Such low activation energy

strongly suggests that native defects such as sulfur vacancies and impurities are present in the as-synthesized MoS<sub>2</sub> samples as already verified in the XPS result. The decrease of activation energy with an increase of doping concentration suggests that donor carrier density lifts the Fermi level position in the band gap which supports the result obtained from UV-visible absorption spectra.<sup>40</sup> It has been studied in a doped semiconductor that a major portion of the free electrons is recaptured by donor atoms themselves at low temperatures.<sup>72</sup> The electrons suffer from lack of sufficient energy to jump from donor levels to the conduction band. At this stage, the electrons transport through hopping from one level to another in the impurity band and free-electron band conduction becomes less significant.<sup>72</sup> Thermal activation is due to deep donor level ions contributing to the conduction band. For higher cobalt doped MoS<sub>2</sub> at temperature < 200 K, the activation energy ( $E_a$ ) drops and other

2% Co	$3.932 \times 10^9$	$1.67 \times 10^8$	352.7	30043.28	0.2686	65.73	0.99825	$-3.12 \times 10^{-2}$
4% Co	$5.92 \times 10^{11}$	$1.08 \times 10^7$	6.5023	9583.31	0.4832	47.37	0.99828	$-1.85 \times 10^{-2}$
6% Co	0.7780	2 931 986	7.5341	12 500	0.1267	33.59	0.99871	$-1.29 \times 10^{-2}$
8% Co	5597.07	$2.673 \times 10^7$	1.769	18770.31	0.00647	85.3	0.9997	$-2.93 \times 10^{-2}$

transport mechanisms could play a role in addition to the nearest neighbour hopping. The weak temperature dependence of resistance at low temperatures can be explained by the mechanism of electron hopping through impurity levels formed near the conduction band edge of cobalt-doped MoS<sub>2</sub>. In addition to this, the decrease of temperature is accompanied by a rapid rise of electrical resistivity as electrons hop from the conduction band to the localized impurity states. Therefore, the conduction mechanisms in these Co-doped MoS<sub>2</sub> samples can be explained by the combination of two types of conduction models such as variable range hopping (VRH),  $\sigma_{\text{VRH}} = \sigma_{\text{0VRH}} \exp[-(T_{\text{0VRH}}/T)^{1/4}]$ , and thermal excitation by nearest neighbour hopping (NNH),  $\sigma_{\text{th}} = \sigma_{\text{0th}} \exp[(E_{\text{a}}/kT)]$ , where  $\sigma_{\text{0VRH}}$ ,  $T_{\text{0VRH}}$ , and  $\sigma_{\text{0th}}$  are constants. The first one describes carrier hopping in localized states at a lower temperature range whereas the

second one describes carriers that have been thermally excited from the localized state to the conduction band. The parameters were evaluated from the linear fitting method by plotting  $\ln \sigma \sim T^{-1/4}(\text{VRH})$  and  $\ln \sigma \sim 1000/T(\text{NNH})$  in different temperature regions to investigate the involved temperature-dependent transport processes. These parameters are listed in Table 3. The resistivity rises at low temperature and passes the VRH test for 2%, 4%, and 8% Co-doped samples (50–70 K) and for 6% Co (50–110 K) at a low-temperature range as shown in Fig. 7(a, b, d and c), respectively. It suggests that the conduction in these pellet-formed powder samples is due to the thermally assisted tunneling of the charge carriers through the grain boundary barrier and transition from the donor level to the conduction band. It is observed that at low temperature, the resistivity of 8% Co-doped MoS<sub>2</sub> is very less compared to the

Fig. 7 Temperature dependent conductivity plot of 2%, 4%, 6% and 8% Co doped MoS<sub>2</sub> (a–d) and  $\ln \sigma \sim T^{-1/4}$  plot of 2%, 4%, 6% and 8% Co doped MoS<sub>2</sub> to test the VRH mechanism.

undoped one due to incorporation of the metallic 1T phase in 2H MoS<sub>2</sub> with the increase of cobalt doping concentration. Increasing the Co-doping concentration will reduce the resistance, and in Table 3 it has been observed that the activation energy decreases from 65.73 meV to 33.59 meV as the concentration of Co atoms increases from 2% to 6%. It has been observed that in the case of heavy doping of the Co ion (8% Co) in MoS<sub>2</sub>, the activation energy is increased. This is attributed to the increase in atomic defects which are electrically active at the grain boundary.<sup>73</sup>

### 3.6. EPR analysis

The room temperature electron paramagnetic resonance spectra (EPR) of MoS<sub>2</sub> nanostructures doped with various percentages of cobalt are shown in Fig. 8. The undoped MoS<sub>2</sub> shows a prominent resonant peak of low intensity at a magnetic field of 3446 G with  $g = 2.0005$ . This signal may come from the unpaired electrons generated by unsaturated coordination structures, e.g., vacancies and defects such as S vacancies, acting as paramagnetic centers.<sup>74</sup> The EPR signal in the higher magnetic field is indicated with an arrow in Fig. 8 at  $g = 1.89$ , which is very close to  $g$  values of oxygenated species of Mo<sup>5+</sup> in amorphous or unsupported sulfides.<sup>74</sup> The maximum EPR signal has been observed in 2% Co-doped MoS<sub>2</sub> NFs and decreases gradually with an increase in Co dopant amount. The expression

$$g = h\nu/\beta H_0$$

is used to calculate the electron  $g$  factors, where  $\nu = 9.65$  GHz (frequency),  $h = 4.135 \times 10^{-15}$  eV s<sup>-1</sup> (Planck constant),  $\beta = 5.788 \times 10^{-5}$  eV T<sup>-1</sup> (Bohr magneton) and  $H_0$  is the resonance magnetic field. Co doping at different concentrations in MoS<sub>2</sub> does not induce any new peak or change in the EPR spectra. However, a peak shift towards a lower magnetic field has been observed in all the doped MoS<sub>2</sub> samples. In Fig. 8, the prominent resonance peaks are witnessed at the magnetic field of 3435 G ( $g = 2.007$ ), 3433 G ( $g = 2.008$ ), 3439 G ( $g = 2.005$ ), and 3443 G ( $g = 2.002$ ) for 2 at% Co, 4 at% Co, 6 at% Co and 8 at%

Fig. 8 EPR spectra of MoS<sub>2</sub> NFs doped with various percentages of cobalt.

Co-doped MoS<sub>2</sub> samples, respectively, which are attributed to the enhanced ferromagnetic coupling with the increase in Co concentration. Eventually, the  $g$  value reaches a maximum for 4 at% Co-doped MoS<sub>2</sub>. The 1T regions tend to produce more Mo<sup>4+</sup> spins by expanding in the less dense S vacancy regions. However, in the case of higher cobalt concentration (8 at%), the proportion of the 1T phase has increased up to 48%. In this case, S atoms are surrounded by a majority of the Mo atoms compared to S vacancies whereas a few of Mo atoms exist as isolated Mo<sup>4+</sup> spins. This explains the origin of the ferromagnetic coupling with S atoms, resulting in a rise of ferromagnetism in MoS<sub>2</sub> nanoflakes macroscopically.<sup>31</sup>

### 3.7. VSM data analysis

The magnetic properties ( $M-T$  and  $M-H$  at 10 K, 100 K and 300 K) of undoped and 2% Co, 6% Co and the highest Co (8% at wt.) doped MoS<sub>2</sub> samples were studied through VSM as shown in Fig. 9. Both undoped and 2% Co-doped MoS<sub>2</sub> samples show paramagnetic behaviour originating from free electrons contributed from defects and a small proportion of the 1T phase whereas 2% Co-doped MoS<sub>2</sub> samples show higher magnetic moment compared to the undoped one as shown in the inset of Fig. 9(a). As reported by Nair *et al.* the existence of point defects such as vacancies and the introduction of fluorine adatoms in graphene induce notable paramagnetism.<sup>75</sup> However, a paramagnetic to ferromagnetic transition has been distinctly found above 2% Co doping. The ZFC-FC feature in the  $M-T$  curve of 8% Co-doped MoS<sub>2</sub> NFs, as shown in Fig. 9(b), almost retraces the same path indicating intrinsic single-phase ferromagnetism. The highest saturation magnetization ( $M_s$ ) at 10 K is 0.42 emu g<sup>-1</sup> and 1.2 emu g<sup>-1</sup>, remanence magnetization ( $M_r$ ) is 0.06 emu g<sup>-1</sup> and 0.045 emu g<sup>-1</sup> and coercivity is ~150 Oe and 70 Oe corresponding to 6% Co- and 8% Co-doped MoS<sub>2</sub> nanoflakes respectively as shown in Fig. S2(c) (ESI<sup>†</sup>) and Fig. 9(d). Since our undoped MoS<sub>2</sub> possesses a feeble paramagnetic nature, it is fair to assume that the robust magnetism in 6% Co- and 8% Co-doped MoS<sub>2</sub> arises as a consequence of doping. The magnetism in multilayer MoS<sub>2</sub> and its doped analogues depends on the presence of zigzag edges, defect type, vacancies, lattice strain, and dopant concentration. Theoretical calculations by Wang *et al.*<sup>76</sup> revealed that low concentration Co doping at 4% and 6% in the Mo vacant sites of the basal planes results in stable magnetic moments at room temperature. Yun *et al.*<sup>77</sup> and Saab *et al.*<sup>78</sup> also reported tuning of electronic and magnetic properties due to doping of metal ions in the MoS<sub>2</sub> lattice. The high  $M_s$  observed in Co-doped MoS<sub>2</sub> suggests that the robust ferromagnetism here originates not from the strain in the layer but rather from the ferromagnetically favourable ordering of Co<sup>2+</sup> ions.<sup>50</sup> The effective Bohr magneton number ( $p_{\text{eff(Co)}}$ ) and the value of the Curie constant ( $C$ ) were calculated using the following formulae:

$$(p_{\text{eff(Co)}})^2 = xg^2S_{(\text{Co}^{2+})}(S_{(\text{Co}^{2+})} + 1) + (1 - x)g^2S_{(\text{Co}^{3+})}(S_{(\text{Co}^{3+})} + 1) \quad (1)$$

$$(p_{\text{eff(Co)}})^2 = 3Ck/N\mu_B^2 \quad (2)$$

Fig. 9 (a)  $M$  vs.  $T$  plot of undoped and 2%, 6% and 8% Co doped  $\text{MoS}_2$  at an applied field of 500 Oe; the inset shows the  $M$ – $T$  curve of undoped and 2% Co doped  $\text{MoS}_2$ . (b) Individual ZFC–FC curve of 8% Co doped  $\text{MoS}_2$  indicating  $T_c \sim 139$  K. (c)  $dm/dT$  plot of 8% Co doped  $\text{MoS}_2$  showing  $T_c \sim 139$  K. (d) Linearly fitted  $1/\chi \sim T$  ( $T_c \sim 139$  K) corresponding to 8% Co doped  $\text{MoS}_2$ ; the inset shows a magnified image of the  $M$  vs.  $H$  hysteresis loop of 8% Co doped  $\text{MoS}_2$  at 10 K having 70 Oe coercive field. (e) Hysteresis loop at 10 K, 50 K, 100 K and 300 K. (f)  $M$ – $H$  loop of 8% Co doped  $\text{MoS}_2$  showing room-temperature ferromagnetism at 300 K at a magnified scale.

where  $g = 2$  represents the Lande'  $g$ -factor of the cobalt ions,  $S_{(\text{Co}^{2+})}$  and  $S_{(\text{Co}^{3+})}$  represent the total spin quantum numbers for  $\text{Co}^{2+}$  and  $\text{Co}^{3+}$  ions respectively,  $k$  is the Boltzmann constant,  $N$  is the Avogadro number and  $\mu_B$  is the Bohr magneton. The value of  $p_{\text{eff}(\text{Co})}$  obtained for  $\text{MoS}_2$  NFs doped with various amounts of cobalt lies between the theoretical value of  $p_{\text{eff}(\text{Co}^{2+})} = 3.87$  and  $p_{\text{eff}(\text{Co}^{3+})} = 4.89$  due to the presence of the mixed-valence state of Co in Co-doped  $\text{MoS}_2$  NFs. Again, the value of Curie temperature of 6% and 8% Co-doped  $\text{MoS}_2$  NFs was obtained from the minima of the  $dm/dT$  vs.  $T$  plot. The magnitude of the Curie constant ( $C$ ) for 6% and 8% Co-doped  $\text{MoS}_2$  nanoflakes was calculated using eqn (2) by putting the value of  $p_{\text{eff}(\text{Co})}$ . The variation of saturation magnetization ( $M_s$ ), Curie temperature ( $T_c$ ), Curie constant ( $C$ ),  $p_{\text{eff}(\text{Co})}$  and the percentage amount of  $\text{Co}^{2+}/\text{Co}^{3+}$  ions present in  $\text{MoS}_2$  NFs doped with various amounts of cobalt are listed in Table 4.

To study the origin and variation of the observed ferromagnetism in  $\text{MoS}_2$  NFs with Co doping, it is necessary to point out the role of the 1T phase and cobalt ion incorporation in the 2H

$\text{MoS}_2$  matrix. The fact that Co dopant atoms can effectively introduce ferromagnetism in  $\text{MoS}_2$  nanoflakes has been confirmed by magnetic measurement results. Herein, we only consider the magnetic moment introduced in the  $\text{MoS}_2$  NFs through the substitution of Mo atoms by Co atoms. According to crystal field theory, 4d and 3d orbitals corresponding to  $\text{Co}^{2+}/\text{Co}^{3+}$  remain in different degenerate states in 2H and 1T coordination.<sup>31</sup> The  $\text{Mo}^{4+}$  ions corresponding to 2H coordination split into three energy levels: ( $d_{z^2}$ ), ( $d_{x^2-y^2}$ ,  $d_{xy}$ ), and ( $d_{xz}$ ,  $d_{yz}$ ) while the 1T has two levels: ( $d_{xz}$ ,  $d_{yz}$ ,  $d_{xy}$ ) and ( $d_{x^2-y^2}$ ,  $d_{z^2}$ ) as shown in Fig. 10(a). As described in Fig. 10(a), two 4d electrons occupy the  $d_{z^2}$  orbital of the  $\text{Mo}^{4+}$  ion in a spin-antiparallel manner, thus giving net zero magnetic moments in the 2H phase. In the case of the 1T phase of  $\text{MoS}_2$ , the lower energy levels ( $d_{xz}$ ,  $d_{yz}$ ,  $d_{xy}$ ) are occupied by the two 4d electrons spin-parallelly contributing net magnet moments in the 1T phase of Mo atoms.<sup>79</sup> Therefore, it can be assumed that the presence of ferromagnetism is directly connected to the proportion of both 1T and 2H phases in  $\text{MoS}_2$  nanoflakes. Seven and six 3d

Table 4 Variation of magnetic parameters with various amounts of Co doping (0%, 2%, 6%, 8%) in Co-doped  $\text{MoS}_2$  NFs

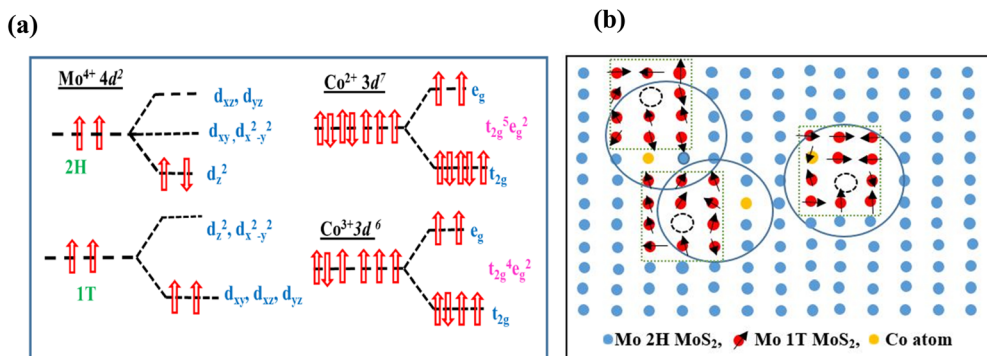

Fig. 10 (a) Electron orbital degenerate states of Mo atoms ( $\text{Mo}^{4+}$  ionic state) in 1T and 2H configuration and Co atoms ( $\text{Co}^{2+}$  and  $\text{Co}^{3+}$  ionic state). (b) Schematic representation of the bound magnetic polaron model mediated by vacancy and Co dopant in  $\text{MoS}_2$  NFs. 1T phases are induced around vacancy and Co atom forming spin polarized states.

electrons corresponding to the  $\text{Co}^{2+}$  and  $\text{Co}^{3+}$  configuration contribute three and four unpaired electrons in the octahedral geometry of the  $\text{Co}^{2+}$  and  $\text{Co}^{3+}$  configuration, respectively. The observed magnetic moment varies monotonically with the proportion of the 1T phase present in the sample. In undoped  $\text{MoS}_2$ , the proportion of the 1T phase was 18% having the lowest magnetic moment as shown in EPR analysis. The proportion of the 1T phase increases gradually with the incorporation of the cobalt dopant. The proportion of the 1T phase in undoped and 2%, 4%, 6% and 8% Co-doped  $\text{MoS}_2$  samples is found to be 18%, 26%, 39%, 42% and 48%, respectively. The magnetic moment value increases as the proportion of the 1T phase increases with an increase in the cobalt dopant as revealed by experimental results.

To further explain the origin of ferromagnetism in Co-doped  $\text{MoS}_2$  systems, the bound magnetic polaron (BMPs) model is utilized.<sup>80–82</sup> Two main results are obtained from the XPS spectra: (i) S vacancies are typical defects in hydrothermally synthesized  $\text{MoS}_2$  nanoflakes and (ii) the substituted Co atoms can contribute two holes. Thus the  $\text{Co}^{2+}$  dopants provide the local magnetic moments in addition to the carriers needed to couple these moments.<sup>80</sup> Under this condition, the electron distribution changes causing a strong interaction among the spin impurities. Unintentional sulfur vacancies are formed in  $\text{MoS}_2$  nanoflakes during the hydrothermal synthesis process. As a result, BMPs could be realized with localized holes and the S vacancies surrounded by a large number of  $\text{Mo}^{4+}$  spins.<sup>80</sup> The  $\text{Mo}^{4+}$  spins and S vacancy spin are aligned parallel, leading to the formation of a BMP. Cai *et al.* observed that the 2H–1T phase transformation always occurs near the defects.<sup>52</sup> Such ferromagnetism appears due to the overlapping of BMPs and their ferromagnetic coupling to each other as shown in Fig. 10(b).

Additionally, with the  $\text{Mo}^{4+}$  ions, the doped Co ions can be bounded by the S vacancies<sup>82,83</sup> as shown in Fig. 10(b). Only those Co ions arranged at suitable distances can interact ferromagnetically possibly through some indirect coupling mechanism.<sup>50</sup> In this manner, numerous BMPs can be created by the Co ions in the vicinity of the S vacancies. They are

ordered ferromagnetically and establish long-range room-temperature ferromagnetism in Co-doped  $\text{MoS}_2$  nanoflakes.<sup>84</sup>

### 3.8. Theoretical result

To simulate 2%, 6% and 8% Co doping in  $\text{MoS}_2$ ,  $5 \times 5 \times 1$ ,  $3 \times 3 \times 1$  and  $3 \times 2 \times 1$  bulk  $\text{MoS}_2$  supercells were created respectively and then one Mo atom from the supercell was substituted with one Co atom, to incorporate the desired doping level, as shown in Fig. 11(a and b). The average Mo–Mo and Mo–S bond length obtained theoretically from our calculation agrees well with the experimental value<sup>85</sup> in the case of undoped and doped samples. In all the doped cases a small variation of the average Co–Mo bond length values and the average Mo–Mo bond length around the dopant site is observed from the Mo–Mo bond length value in the undoped cases. This suggests that the substitutional doping of Co at Mo does not change the symmetry around the dopant site. All the calculations are performed on the semiconducting 2H phase, since this phase is seen to be the dominant one over the metallic 1T phase, in all the cases.

The total and projected densities of states (TDOS and PDOS) of undoped  $\text{MoS}_2$  and 2%, 6%, and 8% Co-doped  $\text{MoS}_2$  are displayed in Fig. S3(a–d) (ESI<sup>†</sup>) and Fig. 11(a–d), respectively. The symmetry of the spin-up and spin-down DOS throughout the energy range, as shown in Fig. 11(a), validates the non-magnetic nature of the undoped  $\text{MoS}_2$  NFs. In the case of doped systems, it is seen that the doping of the Co atom in one layer does not affect the other layer. The reason might be the weak interlayer interaction and the large interlayer separation. The isolated Co atom possesses an electronic configuration of  $3d^7 4s^2$  having three additional valence electrons compared to the Mo atom, and it contributes to the magnetic moment in the Co-doped system. The overall magnetic moment of the supercell with one Co atom substituting one Mo atom and the local magnetic moment of the constituent atoms for 2%, 6%, and 8% Co-doped  $\text{MoS}_2$  NFs are presented in Table 5. The Co atom induces spin polarization in the neighbouring 6 Mo atoms and S atoms. The spins of the six neighbouring Mo atoms are coupled to the Co atom with an average moment of  $0.2\mu_B$  in

**Fig. 11** The atomic structure of (a) the undoped MoS<sub>2</sub> supercell and (b) the 3 × 3 × 1 supercell of 6% Co doped MoS<sub>2</sub> from top view with a Co atom substituting the Mo site. The big purple balls represent Mo atoms, small yellow balls represent sulphur atoms and the blue ball represents the cobalt atom. The projected density of states (PDOS) corresponding to Mo d, S p and Co d states of (c) the undoped MoS<sub>2</sub> supercell, (d) the supercell with 2% Co dopant, (e) the supercell with 6% Co dopant and (f) the supercell with 8% Co dopant (the vertical dashed line indicates the Fermi level).

**Table 5** Local magnetic moments of the dopant Co and the six neighbouring Mo and total magnetic moments in MoS<sub>2</sub> multi-layered systems doped with various percentages of cobalt

Doping percentage (%)	Local magnetic moments ( $\mu_B$ )		Total magnetic moments	
	Mo	Co	( $\mu_B$ )	(emu g <sup>-1</sup> )
0	0	—	0	0
2	0.24	0.91	2.96	4.16
6	0.20	1.10	2.94	5.77
8	0.14	1.34	2.63	7.76

the 6% Co-doped case. An average magnetic moment of  $0.04\mu_B$  is contributed by spin-polarized p orbitals of the S atoms. More

obviously, the Co dopant site remains in trigonal prismatic symmetry even after structural relaxation. As shown in Fig. 11(c–f), with the doping of the Co atom replacing a Mo atom, a distinct spin splitting appears near the Fermi level contributing to large ferromagnetism. This is attributed to the defect states associated with the doped Co atom, p states of the adjacent S atoms, and d states of the nearby Mo atoms, although mainly Co-d and Mo-d states. Due to the overlapping among the Co-d, Mo-d, and S-p orbitals the band edge structures change significantly in comparison with undoped MoS<sub>2</sub>. For the  $C_{3v}$  symmetry around the dopant site, the doping produces five 3d states within the band gap which split into three sub-levels  $e_1$ ,  $e_2$ , and  $a$ , among which one is mono degenerate and two doubly degenerate. The Co  $e_1$  ( $d_{xy}$ ,  $d_{x^2-y^2}$ )

orbitals and  $e_2$  ( $d_{xz}$ ,  $d_{yz}$ ) orbitals are strongly hybridized with S 3p orbitals and remain at relatively low energy levels in the spin-up channel, whereas in the spin-down channel they possess higher energy.<sup>13</sup> The 3 extra non-bonding valence electrons occupy the lowest energy mono-degenerate ( $d_{z^2}$ ) and the first doubly degenerate ( $d_{xy}$ ,  $d_{x^2-y^2}$ ) states in the spin-up channel. The spin-down channel remains vacant at the Fermi level, at least in the low doping regime. The results obtained from the calculation indicate an obvious asymmetry of the DOS around the Fermi level of the cobalt doped MoS<sub>2</sub>, confirming that the substitution of Co at the Mo site gives rise to the spin-polarized state. Interestingly, the DOS indicates that Co-doped MoS<sub>2</sub> exhibits half-metallic behaviour in the 2% doping case, *i.e.*, the DOS shows no gap in the spin-up channel and a semiconducting band gap in the spin-down channel which means being a semiconductor in one spin channel and a metal in another.<sup>13,86,87</sup> It is obvious from the calculation that, the asymmetry around the Fermi level has increased significantly with the increase in Co dopant concentrations, resulting in a net increase of total magnetic moment. Experimentally it has been demonstrated that Co doping up to a certain percentage can enhance ferromagnetism very well. The theoretical calculation for the Co doping in the dominant phase 2H supercell of MoS<sub>2</sub> shows the increasing nature of magnetic moment with an increase in doping concentration which supports the experimental evidence obtained from VSM measurements. This is probably because the small contribution of the 1T phase has been neglected in the calculation since the 2H phase has always been the dominant one over the 1T phase. However, the calculation presents a clear picture of the environment around the dopant site, the local and global magnetism and the induction of magnetism from the dopant to the nearby Mo and S atoms. To visualize the nature of the impurity state initiated by the S defect, Salehi *et al.*<sup>88</sup> discussed the influence of chalcogen defect on the electronic structure of the monolayer MoS<sub>2</sub> by assuming a single sulphur vacancy per supercell. Evidently, at high defect concentration, a midgap band is introduced by the sulphur vacancies near the VBM having a bandwidth of  $\sim 0.6$  eV. Such types of defect states tend to become more delocalized due to the interaction between S vacancies. Additionally, a flat band appears just below the MoS<sub>2</sub> CBM which does not change notably with the concentration changes. The Mo 4d orbitals around the vacancies play the main role in the creation of midgap states, while the S 3p and 3d orbitals do not contribute considerably to the defect states of the gap region. The presence of sulphur vacancies shifts the Fermi level to the bottom of the conduction band due to the unsaturated electrons in the Mo orbitals around the vacancy defect. In the case of multi-layered MoS<sub>2</sub>, the effect of layers and their interactions come into the picture. In the case of multi-layered MoS<sub>2</sub> with S vacancy in each layer, an increase in the electron density of the unremoved S atoms has been observed which increases the repulsion of electrons between layers, increasing the interlayer distance as reported by Zhu *et al.*<sup>89</sup> Additionally, a direct band gap with  $\Gamma \rightarrow \Gamma$  transition is observed in addition to a decrease in the band gap by

introducing mid-gap defect in the forbidden region for the MoS<sub>2</sub> structures with S vacancies. This is quite different from the  $\Gamma \rightarrow K$  transition as observed in bulk MoS<sub>2</sub> without defects. In the MoS<sub>2</sub> structures with S vacancies, the VBM is mainly composed of the 4d orbital of the Mo atom at the  $\Gamma$  point, while the doping band minimum is almost composed of the 4d orbital of the Mo atom and the 3p orbital of the S atom at the  $\Gamma$  point. This can be considered to be responsible for such direct nature of  $\Gamma \rightarrow \Gamma$  transition. Such type of defect and 1T phase enriched Co-doped half-metallic MoS<sub>2</sub> possessing robust ferromagnetism may show greater potential for application in spintronic and detection-based devices.

### 3.9. Electrochemical measurement

To unravel the effect of Co-doping on MoS<sub>2</sub> NFs, the electrochemical performance of undoped MoS<sub>2</sub> and 2% Co, 4% Co and 8% Co-doped MoS<sub>2</sub> as electrode materials was characterized by cyclic voltammetry (CV), chronopotentiometry (CP) and electrochemical impedance spectroscopy (EIS) measurements. The measurement was performed with three-electrode equipment, which consists of Ag/AgCl as the reference electrode, Pt as the counter electrode and one glassy carbon electrode loaded with a sample on it as the working electrode. The prepared working electrode was analysed at different scan rates (10–100 mV s<sup>-1</sup>) within a potential window of  $-0.6$  V to  $0.2$  V (undoped, 2% Co-doped),  $0$  V to  $0.6$  V (4% Co) and  $-0.8$  V to  $0.6$  V (8% Co-doped MoS<sub>2</sub>) using a 1 M Na<sub>2</sub>SO<sub>4</sub> electrolyte. The comparative CV representation of undoped and 2% Co, 4% Co and 8% Co-doped MoS<sub>2</sub> at a scan rate of 10 mV s<sup>-1</sup> is provided in Fig. 12(a). It is observed from Fig. 12(a) that 8% Co-doped MoS<sub>2</sub> shows the highest CV area at 10 mV s<sup>-1</sup> scan rate which indicates better electrochemical performance compared to other MoS<sub>2</sub> moieties. Therefore, the CV plots of 8% Co-doped MoS<sub>2</sub> at different scan rates (10, 20, 40, 60, 80, and 100 mV s<sup>-1</sup>) are depicted in Fig. 12(b). The variation of specific capacitance (calculated from the CV profile) at different scan rates of undoped and 2% Co, 4% Co and 8% Co-doped MoS<sub>2</sub> is depicted in Fig. 12(c) and the corresponding numerical values are listed in Table S1 (ESI<sup>†</sup>). The greater capacitive behaviour of 8% Co-doped MoS<sub>2</sub> is attributed to the following factors: (1) the presence of a more metallic 1T phase resulting in high electrical conductivity and low internal resistance; (2) 1T phase being more electrochemically active in the edge planes;<sup>90</sup> and (3) increased defect levels,<sup>91</sup> validated from XPS and steady-state UV-vis absorption spectra and BET surface area (for undoped and 8% Co-doped MoS<sub>2</sub> the BET surface area is 33.84 m<sup>2</sup> g<sup>-1</sup> and 43.47 m<sup>2</sup> g<sup>-1</sup> respectively), facilitating charge transport and adsorption of transported ions within 8% Co-doped MoS<sub>2</sub> leading to rapid redox reactions. The area under the CV curve shows a symmetric rectangular-like shape revealing the better choice for energy storage application as an ideal supercapacitor.<sup>92</sup> The specific capacitance of the symmetrical supercapacitor was calculated from the CV profile following eqn (3):

$$C_{sp} = \int I(V)dV/vm\Delta V \quad (3)$$

where  $\int I(V)dV$  is the area under the CV curve,  $m$  is the mass of

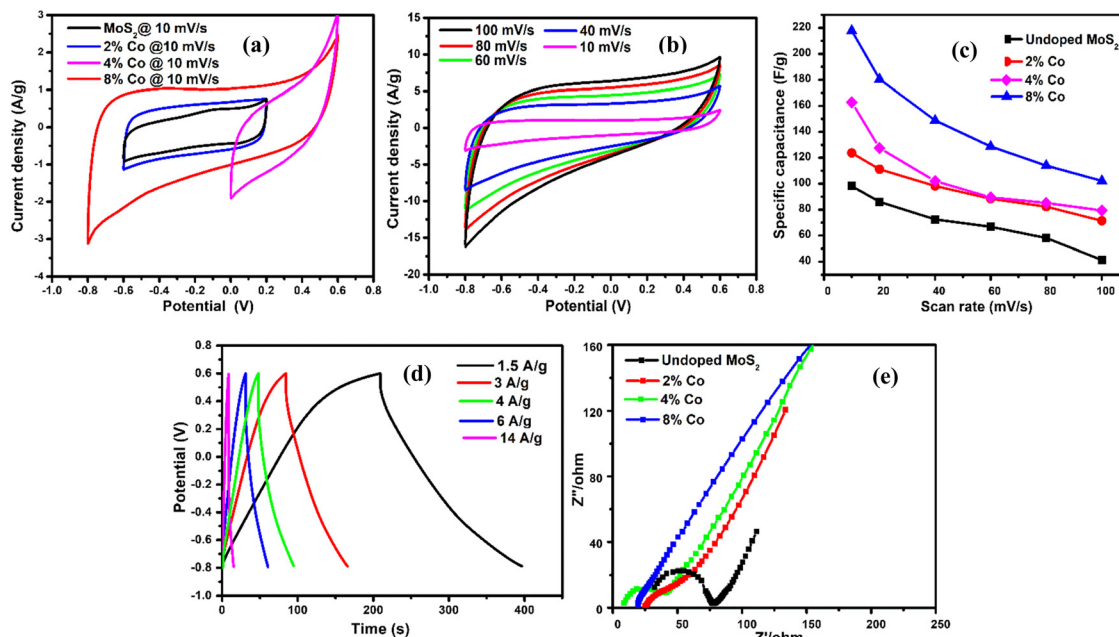

Fig. 12 (a) Comparative CV curves of undoped and 2% Co, 4% Co and 8% Co doped MoS<sub>2</sub> NFs, (b) CV scans of 8% Co doped MoS<sub>2</sub> at different scan rates, (c) plot of specific capacitance at different scan rates for undoped and 2% Co, 4% Co and 8% Co doped MoS<sub>2</sub>, (d) GCD plot of 8% Co-doped MoS<sub>2</sub> at different current densities, and (e) Nyquist plots of undoped and 2% Co, 4% Co and 8% Co doped MoS<sub>2</sub> electrodes.

the electrode materials,  $\nu$  is the scan rate, and  $\Delta V$  is the potential window taken. 8% Co-doped MoS<sub>2</sub> shows the highest specific capacitance of 217.9 F g<sup>-1</sup> at a voltage scan rate of 10 mV s<sup>-1</sup> which is approximately 1.7, 1.5 and 1.3 times greater than that of undoped (98.1 F g<sup>-1</sup>), 2% Co, and 4% Co-MoS<sub>2</sub> electrode (123.7 F g<sup>-1</sup>) materials, respectively. It has been observed that upon increasing the scan rate, the capacitive value decreases. Usually, at a higher scan rate, sufficient ion diffusion cannot take place within a constant time, and therefore, the capacitance value decreases.<sup>92,93</sup> Similarly, the galvanostatic charge–discharge (GCD) technique was carried out to further evaluate the capacitance behaviour of as-synthesized materials at different current densities (Fig. 12(d) and Fig. S4(b, d and f), ESI†). The GCD curve of 8% Co-doped MoS<sub>2</sub> shows the symmetric charging and discharging curve which reveals the good capacitive behaviour of the 8% Co-doped sample. The specific capacitance of the hybrid material was derived from the GCD curve following eqn (4):

$$C_{sp} = I \times \Delta t / m \Delta V \quad (4)$$

where  $I$  is the current (mA),  $\Delta t$  is the discharge time (s),  $m$  is the active electrode material (mg) and  $\Delta V$  is the potential window (V). The specific capacitance values of undoped and 2% Co, 4% Co, and 8% Co doped MoS<sub>2</sub> electrodes with varying current densities obtained from the GCD plot are listed in Table S2 (ESI†). It has been observed that specific capacitance values obtained from CV and GCD measurements are nearly the same which indicates validation of our measurements and stability of the as-prepared electrode materials. To better understand the reason for the improved electrochemical performance of 8% Co-doped MoS<sub>2</sub>, electrochemical impedance spectroscopy (EIS)

of undoped and 2% Co, 4% Co and 8% Co-doped MoS<sub>2</sub> in the frequency range of 1 Hz–100 kHz was performed (Fig. 12(e)). The prepared MoS<sub>2</sub> nanostructures show the supercapacitor feature, *i.e.*, a semicircle at higher frequencies, which is related to the surface area and electrical conductivity, and a straight line in the lower frequency region. The intercept on the real axis is ascribed to the equivalent series resistance ( $R_s$ ), and the diameter of the semicircle corresponds to the charge transfer resistance ( $R_{ct}$ ) in the electrode/electrolyte system. The  $R_s$  values for undoped and 2% Co, 4% Co and 8% Co-doped MoS<sub>2</sub> are 31.1  $\Omega$ , 24.8  $\Omega$ , 8.7  $\Omega$  and 18.9  $\Omega$ , respectively. With the increase in cobalt doping the  $R_s$  value decreases from low-doping (2% Co) to high-doping concentration (8% Co-doped MoS<sub>2</sub>) which confirms that Co doping has enhanced the electrical conductivity of MoS<sub>2</sub> NFs. The 8% Co-doped MoS<sub>2</sub> electrode exhibits the smallest semicircle, indicating that the electrode has lower charge transfer resistance than the other two electrodes because the existing 1T phase and more available active sites decrease the charge transfer resistance. The 8% Co-doped MoS<sub>2</sub> electrode shows a nearly vertical shape because electrons could transfer fast as rapid ion diffusion occurs due to less resistance at the electrode–electrolyte interface. The low-frequency straight line shows the capacitive behaviour of MoS<sub>2</sub> nanomaterials (Fig. 12(e)). The highest slope of the straight line parallel to the imaginary axis is obtained for 8% Co-doped MoS<sub>2</sub>, suggesting that 8% Co-doped MoS<sub>2</sub> has optimal performance among the prepared MoS<sub>2</sub> nanostructures. Table 6 presents the comparative electrochemical performance of MoS<sub>2</sub> (pure or in composite form when used as a single electrode material), as published in previous works, with the results obtained from our highest Co-doped (8% Co) MoS<sub>2</sub> NFs, indicating improved

Table 6 Electrochemical performance of MoS<sub>2</sub> and its derived electrodes in supercapacitors

Nanostructured electrode material	Electrolyte	Specific capacitance (single electrode)	Ref.
MoS <sub>2</sub> nanosheets	1 M KCl	148 F g <sup>-1</sup> at 1 A g <sup>-1</sup>	94
MoS <sub>2</sub> /PEI-GO	2 M Na <sub>2</sub> SO <sub>4</sub>	153.9 F g <sup>-1</sup> at 1 A g <sup>-1</sup>	95

electrochemical behaviour of our material. Therefore, the doping-induced phase and defect engineering of MoS<sub>2</sub> NFs for enhanced electrochemical property in supercapacitors paves the way toward the production of more efficient electrode materials by designing Co-doped 1T phase and defect-rich MoS<sub>2</sub> ultrathin NF-based composites.

## 4. Conclusion

The well-matched 1T phase incorporation in 2H-phase MoS<sub>2</sub> NFs using Co as a dopant at different weight percentages (0%, 2%, 4%, 6%, 8%) has been successfully carried out *via* a facile one-step hydrothermal technique. The evolution of the 1T phase, defects and vacancies and introduction of zigzag edges with Co doping have been verified using Raman, TEM and XPS measurement techniques. The robust ferromagnetism with Co doping was shown to have originated from ferromagnetic exchange interaction of Mo<sup>4+</sup> and Co<sup>2+</sup> with sulfur vacancies *via* the BMP model and magnetic moment contributed from zigzag edges. The asymmetry nature of the DOS and spin splitting near the Fermi level of Co-doped MoS<sub>2</sub> NFs contributed by d states of Mo and Co atoms and p states of neighbouring S atoms confirms that substitutional doping of the Co atom at the Mo site can effectively induce a spin-polarized state corresponding to ferromagnetism. The prominent feature of half-metallicity and formation of the defect level within the MoS<sub>2</sub> band gap has been evidenced from DOS results. In addition, various types of transport mechanisms existing in the different temperature regime have been explained and fitted well in the temperature variation resistivity curves. Moreover, Co-doping in MoS<sub>2</sub> shows better electrochemical performances due to the presence of more electrochemically active metallic 1T sites, edge defects, increased BET surface area and enhanced interlayer separation due to intercalated Co<sup>2+</sup>/Co<sup>3+</sup> ions. This work demonstrates that Co-doped ferromagnetic 1T-MoS<sub>2</sub> NFs are promising for constructing Co-doped 1T-MoS<sub>2</sub>-based heterojunctions for application in spintronic and detection-based devices as well as energy storage devices in the future.

## Conflicts of interest

The authors declare no conflict of interest.

## Acknowledgements
