# Emission colours of bistable photochromic compounds: Ce-doped alkaline (Rb, K, Na)–indium fluorides†

Manuel Gaudon,<sup>\*a</sup> Ines Andron,<sup>a</sup> Alain Demourgues,<sup>a</sup> Vincent Rodriguez,<sup>b</sup> Alexandre Fargues,<sup>a</sup> Etienne Durand,<sup>a</sup> Anthony Chiron,<sup>a</sup> Christine Frayret<sup>cd</sup> and Véronique Jubera<sup>a</sup>

The structural and spectroscopic properties of three  $\text{Ce}^{3+}$ -doped  $\text{A}_3\text{InF}_6$  compounds (with  $\text{A}^+ = \text{Rb}^+, \text{K}^+, \text{Na}^+$ ) are investigated. Containing indium, they all exhibit  $2\text{Ce}^{3+} + \text{In}^{3+} \rightleftharpoons \text{In}^+ + 2\text{Ce}^{4+}$  redox processes induced by UV irradiation between  $\text{Ce}^{3+}$  and  $\text{In}^{3+}$  cations. The photochromo-luminescent behaviour and associated kinetics, with the  $\text{Ce}^{3+}$  and  $\text{In}^+$  ion emission quenching through the redox equation, respectively, are investigated. Our studies highlight that different mechanisms (surface vs. bulk) need be considered to explain the decrease in the blue ( $\text{Ce}^{3+}$ ) and orange ( $\text{In}^+$ ) emission curves. Moreover, the comparison of  $\text{Ce}^{3+}$ -doped  $\text{Rb}_2\text{KInF}_6$ ,  $\text{K}_2\text{NaInF}_6$  elpasolites and  $\text{K}_3\text{InF}_6$  cryolite spectral distributions shows that changing the nature of the alkali cation makes colour tuning possible. The shift of the  $\text{Ce}^{3+}$  and  $\text{In}^+$  colour emissions between the three as-prepared compounds is mainly due to the variation in the ionic-covalent nature of the chemical bonds around the active cation sites. The final calculated optical difference between the two bistable states varies from 0.31 to 0.48 depending on the alkali subnetwork.

## 1. Introduction

As photochromism can be defined as the ability of a compound to change its colouration under UV or visible irradiation [· · ·], the photochromoluminescence property is herein defined as the ability of the studied inorganic fluorides to reversibly change their emissive colouration resulting from UV irradiation. Hence, in photochromoluminescent materials, the A colour emission state is shifted to the B colour emissive state from irradiation at a  $\lambda_A$  wavelength (forth-irradiation), whereas reversibly, the B state can return to the A state from irradiation at a  $\lambda_B$  wavelength (back-irradiation). Such compounds can be developed in view of various applications, such as information storage,<sup>1–3</sup> UV sensors,<sup>4</sup> and security inks.<sup>5</sup>

The studied compounds are inorganic indium-based fluorides, with a double perovskite-type structure, constituted mainly on alkali-fluorine ionic bonds with the general formula  $A_2BKInF_6$  (A and B being alkaline elements).<sup>6</sup> Compounds were doped with trivalent cerium in substitution of trivalent indium, with a substitution concentration of 2 mol%. Both cerium and indium ions are present at the source of the potential modulation in the emission of the Ce-doped fluorides. Indeed, in such inorganic fluorides: RE-doped  $A_2BKInF_6$  series (RE: rare earth element), a redox process can be produced between cerium and indium cations, as demonstrated by Chaminade *et al.*<sup>7</sup> or more recently developed by Cornu *et al.*<sup>8,9</sup> It was shown in the last former article that the UV irradiation of  $Ce^{3+}$ -doped  $Rb_2KInF_6$  elpasolite-type compounds induces a reversible redox process.

Under UV irradiation at 315 nm, the progressive disappearance of two  $\text{Ce}^{3+}$  ions in favour of the appearance of one  $\text{In}^+$  cation is associated with the  $\text{Ce}^{3+}$  blue emission quenching and the increase in the orange  $\text{In}^+$  emission (forth-irradiation). A reversible phenomenon is observed under material irradiation at 255 nm (back-irradiation). A nice on-off effect of the  $\text{Ce}^{3+}/\text{In}^+$  cation emission is obtained; the cycling of this redox process has been checked over 5 cycles under UV irradiation; and the stability of both  $\text{Ce}^{3+}-\text{In}^{3+}$  (A state) and  $\text{Ce}^{4+}-\text{In}^+$  (B state) states was confirmed over 10 years.<sup>9</sup>

In this paper, attempts to observe a redox phenomenon similar to that in Ce-doped  $\text{Rb}_2\text{KInF}_6$  compounds have been

performed on the structurally close compounds: Ce-doped  $K_2NaInF_6$  elpasolite and Ce-doped  $K_3InF_6$  cryolite. One target is to tune the colour contrast between the two states (forth- and back-irradiation) in this series. The studied halide compounds are all related to the perovskite structure. The latter are generally studied for their wide range of physical properties, such as ferroelectricity, dielectricity, pyroelectricity and piezoelectricity.<sup>10</sup> The crystallographic structure of the three as-prepared compounds (Ce-doped  $Rb_2KInF_6$  was again prepared as a reference) was studied by X-ray diffraction and Raman spectroscopy in the first part. In the second part, the luminescence properties of the cerium or indium luminescent centres in these three compounds are compared and interpreted based mainly on the Stokes shift consideration.<sup>11</sup> The kinetic mechanism of  $Ce^{3+}$  luminescence quenching (forth redox) and  $In^+$  luminescence (back redox) quenching is deeply investigated.

## 2. Experimental

The elpasolite/cryolite compounds were prepared from the solid-state route in sealed tubes.

$\alpha$ - $InF_3$  was issued from direct fluorination using diluted  $F_2$  (10%, Ar filled) gas treatment at  $T = 450$  °C during 6 hours of  $InF_3 \cdot xH_2O$ , hydrated fluorides, which were prepared from a coprecipitation process.

The reagents  $RbF$ ,  $KF$ ,  $NaF$ ,  $CeF_3$  fluorides (commercial compounds, Aldrich) and  $InF_3$  used for the synthesis were hygroscopic, so they were previously treated at 110 °C for 3 hours under vacuum to remove all traces of water and then placed in a glove box (BAG). The reagents were then weighed in stoichiometric proportions and ground in an agate mortar. They were introduced into a clamped argon atmosphere glove box and sealed platinum tube to prevent any air entry. The tube was placed in a muffle furnace and heat-treated at 700 °C for 12 hours.

Powder X-ray diffraction patterns were collected on a Philips X'Pert MPD X-ray diffractometer with a Bragg–Brentano geometry using  $Cu K\alpha_{1,2}$  radiation ( $10^\circ < 2\theta < 130^\circ$ , step 0.02° and counting time of 30 seconds). The diffractograms were refined using the Rietveld refinement method with the conventional reliability factors for refinement quality assessment. The Fullprof program package was used. Unit-cell parameters, zero-shift, peak profile parameters, atomic positions and isotropic displacement factors were refined; however, occupancies were fixed to the target composition.

Raman spectra were recorded at room temperature on a Xplora confocal Raman microscope from Horiba Scientific (objective 50×, NA = 0.50) using a CW 532 nm laser excitation. The laser power was less than 15 mW for all samples. The spectrometer includes a grating with 2400 grooves per mm and an air-cooled CCD camera for detection. Unpolarized Raman spectra were measured over the frequency range 150–750  $cm^{-1}$  with a spectral resolution better than 3  $cm^{-1}$ . The spectral range below 150  $cm^{-1}$  has been deliberately rejected because the longpass edge filter for the collection of the Raman Stokes

signal strongly disturbs the profile and the intensities of the peaks possibly present in this range.

The photoluminescent properties were analysed using a Fluorolog 3 Horiba spectrofluorimeter connected by a 450 W continuous Xenon source. Raw data were corrected for the experimental parameters: variation of the incident flux, monochromator transmission and photomultiplier sensitivity.

## 3. Results and discussion

### 3.1 Structural investigation

Perovskite designates any  $ABX_3$  structural material, formed on the basis of a three-dimensional network of corner-sharing  $BX_6$  octahedra in all three spatial directions and with large A cations occupying all cuboctahedral cavities, delimited by the eight  $BX_6$  octahedra (Fig. 1).<sup>12</sup> The studied halogenated perovskites have the generic formula  $A_2BB'F_6$  with a strict alternation of the B ( $Na^+$  or  $K^+$ ) and  $B'$  ( $In^{3+}$ ) cations that causes the doubling of the lattice parameter (ordered double perovskites). The  $Rb_2KInF_6$  (labelled  $Rb_2K$ ) and  $K_2NaInF_6$  (labelled  $K_2Na$ ) compounds both crystallize in this so-called elpasolite structure. Finally, a special case of elpasolite is the  $A_3BX_6$  cryolite (named after the  $Na_3AlF_6$  archetypal mineral), in which the A atoms occupy half of the octahedra and all cuboctahedron sites, as for the  $K_3InF_6$  (labelled  $K_3$ ) compound.

The X-ray diffraction patterns of the three studied compounds are depicted in Fig. 2. The as-quoted  $Rb_2K$  and  $K_2Na$  compounds both crystallize in the  $Fm\bar{3}m$  space group, as already attested by the literature (ICSD files 00-048-1754 and 00-023-1361,

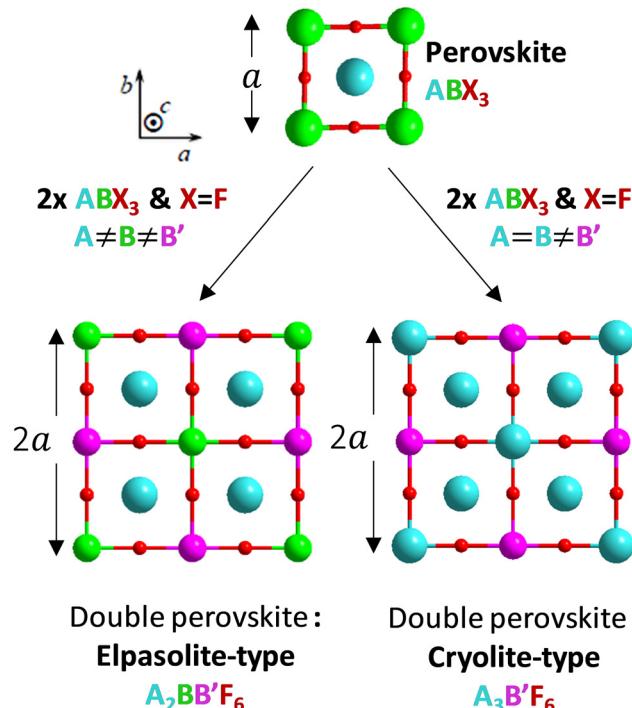

Fig. 1 Structural filiations linking the perovskite framework and the two studied double perovskite types: elpasolite-type and cryolite-type.

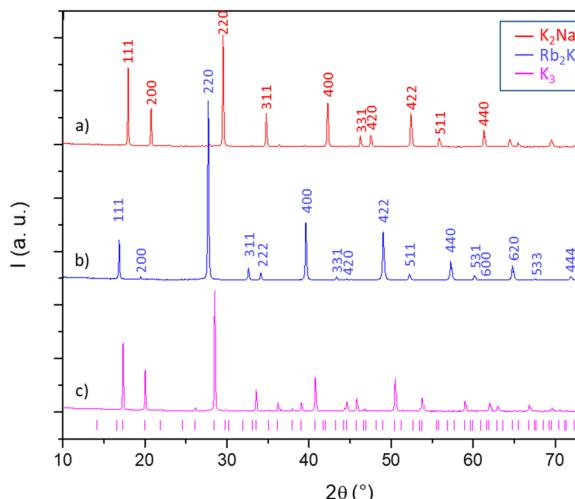

Fig. 2 X-Ray diffraction patterns of the three studied compounds: (a)  $\text{K}_2\text{Na}$ , (b)  $\text{Rb}_2\text{K}$  (both with  $\text{Fm}\bar{3}m$  space group) and (c)  $\text{K}_3$  (with intermediate peak indexation corresponding to  $\text{Fd}\bar{3}$  space-group for the latter).

respectively, for  $\text{Rb}_2\text{K}$  and  $\text{K}_2\text{Na}$ ). Moreover, the clear right-shift of the peak positions of the  $\text{K}_2\text{Na}$  phase with respect to the  $\text{Rb}_2\text{K}$  phase already shows that the unit-cell parameter of the first is the smallest. The  $\text{K}_3$  compound has a peak series that seems to coincide with the 01-072-1763 file ( $\text{Fd}\bar{3}$  space group), but the peak assignment is not fully satisfying and deserves deeper investigation.

In the  $\text{A}_2\text{BB}'\text{F}_6$  investigated compositions, the ionic radius into octahedral sites, either the B ions ( $1.38\text{ \AA}$ ,  $1.02\text{ \AA}$ , for  $\text{K}^+$  and  $\text{Na}^+$ , respectively) or the  $\text{B}'$  ions ( $0.8\text{ \AA}$  for  $\text{In}^{3+}$ ), are too high compared to the radii of A cations, which are located in cubooctahedral sites ( $1.72\text{ \AA}$  and  $1.64\text{ \AA}$  for  $\text{Rb}^+$  and  $\text{K}^+$ , respectively). Both the compound frameworks are subjected to internal stresses associated with a Goldschmidt tolerance factor, less than 1, causing the tilting of the octahedra chains to satisfy the valence of the whole cation set.<sup>13</sup> As previously shown in our former study devoted to  $\text{Rb}_2\text{K}$  compound,<sup>8,9</sup> considering a  $\text{Fm}\bar{3}m$  cubic system for the first two compounds ( $\text{K}_2\text{Na}$ ,  $\text{Rb}_2\text{K}$ ), the octahedra rotation results in a positioning of the fluorine ions in the 96j Wyckoff

position, with an equiprobable random occupancy of a quarter compared to the 24e position located on the In-B-In axes. The 96j fluorine position is distinguished from the 24e position by off-centering the In-B-In axes by a distance that is characterized by the fluorine z coordinate.

The  $\text{K}_3$  compound has a Goldschmidt factor significantly lower than 1 ( $t = 0.868$ ), and therefore, a lower symmetry than the  $\text{Fm}\bar{3}m$  cubic cell is expected.<sup>14</sup> From Glazer theory and the fixed symmetry relations between space groups, we assumed that the  $\text{K}_3$  phase could crystallize in a cell with an  $\text{I}4/m$  space group. Furthermore, this space group corresponds to the low-temperature polymorph of  $\text{Rb}_2\text{K}$ .<sup>15</sup> Refinements were performed maintaining a “doubled”  $c$  parameter with respect to the  $\text{Fm}\bar{3}m$  elpasolite unit-cell. However, the refinement leads to low reliability factors. Thus, a full resolution of the  $\text{K}_3$  crystalline framework is proposed with the  $\text{I}4/m$  space group. There are four positions for indium atoms and three positions for potassium atoms. The twelve-coordinated potassium atoms are located in two different 16i positions. Finally, there are ten positions for fluorine atoms. The indium and potassium octahedra constituting the  $\text{I}4/m$  double-cell of the  $\text{K}_3$  compound are depicted in Fig. 3, and each distinct octahedron (peculiar Wyckoff position) is represented by a different edge colour.

Table 1 summarizes the refined parameters and reliability factors of the structural hypotheses carried out for fluorine ions at position 24e or 96j on  $\text{Rb}_2\text{K}$  and  $\text{K}_2\text{Na}$ , considering the just previously defined  $\text{I}4/m$  double-cell for  $\text{K}_3$  (detailed atomic positions for this latter compound are reported in Table S1a, ESI†).

Obviously, the unit-cell volume per unit formula ( $Z$ ) is directly related to the alkaline ionic size of the compounds; thus, the equivalent unit-cell volume ( $Z = 4$ ) decreases from  $\text{Rb}_2\text{K}$  ( $V = 751.6\text{ \AA}^3$ ,  $Z = 4$ ), then  $\text{K}_3$  ( $V/4 = 692.47\text{ \AA}^3$ ,  $Z = 16$ ), and finally to  $\text{K}_2\text{Na}$  ( $V = 623.95\text{ \AA}^3$ ,  $Z = 4$ ).

For the first two compounds ( $\text{Rb}_2\text{K}$  and  $\text{K}_2\text{Na}$ ), the positioning of fluorine in the 96j position instead of the 24e position makes it possible to significantly reduce the reliability factor values for the two systems. We also observe a decrease in the  $B_{\text{iso}}$  isotropic displacement factors associated with fluorine ions. The fluorine

atom is closer to the position *x* = 0.25 (midpoint between the B and the B' cation) for the K<sub>2</sub>Na phase than for Rb<sub>2</sub>K.

For the K<sub>3</sub> sample, a very complex framework based on multiple octahedral sites was evidenced. There are indeed 3 kinds of octahedron sequences along the *c* axis and 3 successive layers of atoms in the (*ab*) plane (Fig. 3b). Along the *c* axis, the potassium and indium octahedra generally tilt in the opposite direction from each other, as also observed for the neighbouring octahedra within each layer.

Raman spectroscopy studies of the InF<sub>6</sub> entities were undertaken to complete the X-ray diffraction studies. This optical spectroscopy is particularly sensitive to bond vibrations and allows the instantaneous environment of each ion to be probed, including dynamic distortions at short time scales down to a few tens of femtoseconds (fs). As a reminder, both the Rb<sub>2</sub>K and K<sub>2</sub>Na phases exhibit a single Wyckoff position for indium and potassium ions. The InF<sub>6</sub> octahedral sites are perfectly regular.<sup>16</sup> In contrast, according to previous X-ray diffraction

**Fig. 4** Refinement of the  $\nu_5$  (F<sub>2g</sub>) vibration band attributed to each of the three studied compounds considering a single Gaussian peak or a 3-Gaussian peaks for the K<sub>3</sub> compound.

studies, for the  $K_3$  compound, the different octahedral sites show strong disparities in their geometry. In the three samples, the  $InF_6$  octahedral sites show 3 active Raman modes:  $\nu_1 (A_{1g})$ ,  $\nu_2 (E_g)$  and  $\nu_5 (F_{2g})$ . The doubly degenerated antisymmetric valence vibration  $\nu_2 (E_g)$  has a very low intensity at approximately  $380\text{ cm}^{-1}$ . Therefore, we have concentrated our analysis on the two other vibration modes: they correspond to the three degenerate  $\nu_5 (F_{2g})$  shear modes and the nondegenerate  $\nu_1 (A_{1g})$  breathing mode. Whether for the  $\nu_5 (F_{2g})$  (Fig. 4) or  $\nu_1 (A_{1g})$  (Fig. 5) vibration mode, the same observations leading to the same conclusions can be formulated. For these two vibration modes, the Raman intensity profiles of the compounds  $K_2Na$  and  $Rb_2K$  are perfectly refined by considering that the vibration band comes from a single Gaussian contribution. However, the two vibration signals of the  $K_3$  compound fit better by considering the band resulting from the convolution of at least three Gaussian contributions (the  $\chi^2$  value is drastically decreased from 7.064 to 0.639, while 3 Gaussian contributions are taken into account for the fitting). This Raman analysis therefore clearly reflects the great disparity of  $In$  sites and  $In-F$  distances in cryolite-type structures.

The parameters extracted from the refinement of the  $\nu_5 (F_{2g})$  and  $\nu_1 (A_{1g})$  bands for the three studied compounds are listed in Table 2. Two additional observations can be made, considering that the frequency of vibration mode is higher than this one: (i) the respiration mode is strongly constrained by the presence of sodium  $Na^+$  instead of  $K^+$  on site B (position at  $522\text{ cm}^{-1}$  for  $K_2Na$ , approximately  $502-509\text{ cm}^{-1}$  for  $Rb_2K$  and  $K_3$ ); (ii) the shear mode is strongly relaxed by the presence of  $Rb^+$

Table 2 Parameters extracted from the refinement of the  $\nu_5 (F_{2g})$  and  $\nu_1 (A_{1g})$  bands

Refined parameters	$K_2Na$	$Rb_2K$	$K_3$	$K_3$	
	1-Gaussian envelope		3-Gaussian envelope		
$\nu_5 (F_{2g})$	$d(In-F)_{moy} (\text{\AA})$	2.12(1)	2.14(1)	2.13(1)	2.13(1)
	Position ( $\text{cm}^{-1}$ )	233	218	230	218 230
	Width ( $\text{cm}^{-1}$ )	14	16	27	26 15 33
$\nu_1 (A_{1g})$	Intensity (a.u.)	1.2	0.9	1.1	0.7 1.1 0.6
	Position ( $\text{cm}^{-1}$ )	522	509	502	495 502
	Width ( $\text{cm}^{-1}$ )	19	16	27	13 16 21
	Intensity (a.u.)	1.2	0.9	1.1	1.3 0.7 0.9

ions instead of  $K^+$  on site A ( $218\text{ cm}^{-1}$  for  $Rb_2K$  instead of  $230-233\text{ cm}^{-1}$  for  $K_3$  and  $K_2Na$ ).

### 3.2 Luminescence properties: photochromoluminescence.

Doped with 2% (molar substitution at the indium site) cerium ions,  $Rb_2K$ ,  $K_2Na$  elpasolites and  $K_3$  cryolite present  $4f \rightarrow 5d$  electronic transitions under UV irradiation. Fig. 6 shows the corresponding excitation and emission graphs normalized at the maximum. Table 3 lists the Stokes shift values calculated as the wavenumber difference ( $\text{cm}^{-1}$ ) between the maximal intensity of the lowest  $5d(T_{2g})$  excitation level and the corresponding  $4f^2(F_{5/2})$  arrival level. The emission band is clearly constituted from the overlapping of two Gaussian contributions, indexed to the  $5d(T_{2g}) \rightarrow 4f^2(F_{5/2})$  and  $5d(T_{2g}) \rightarrow 4f^2(F_{7/2})$  transitions. The deconvolution of the  $K_3$  emission is reported as an illustration (Fig. 6c). Energy differences of  $2897\text{ cm}^{-1}$ ,  $2347\text{ cm}^{-1}$  and

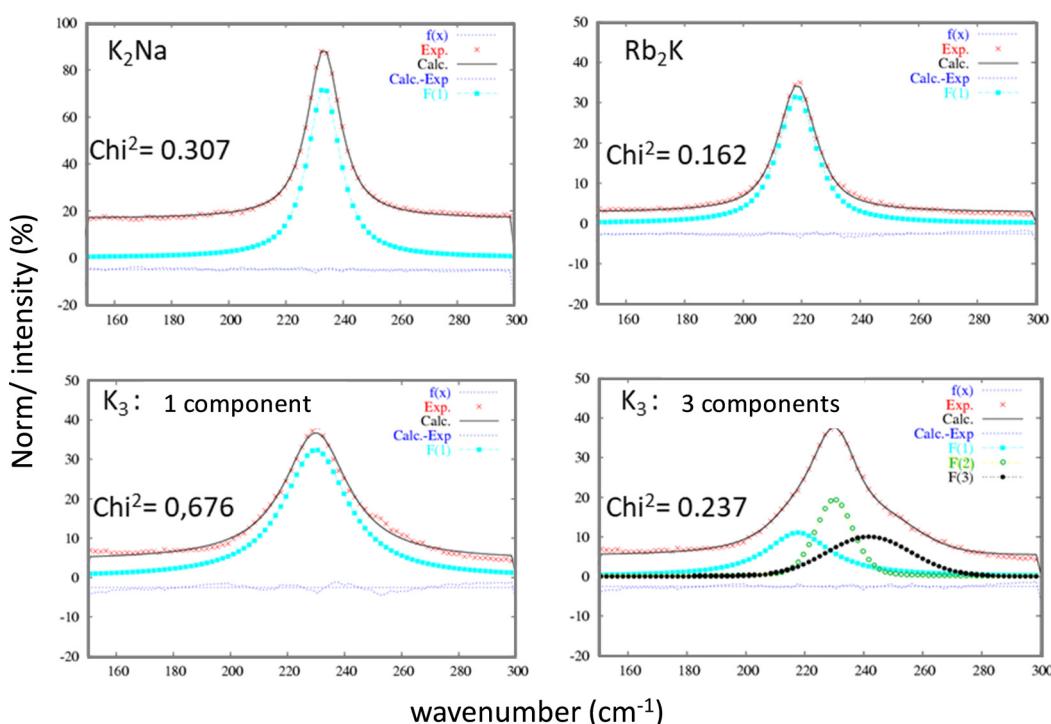

Fig. 5 Refinement of the  $\nu_1 (A_{1g})$  vibration band attributed to each of the three studied compounds considering a single Gaussian peak or a 3-Gaussian peak for the  $K_3$  compound.

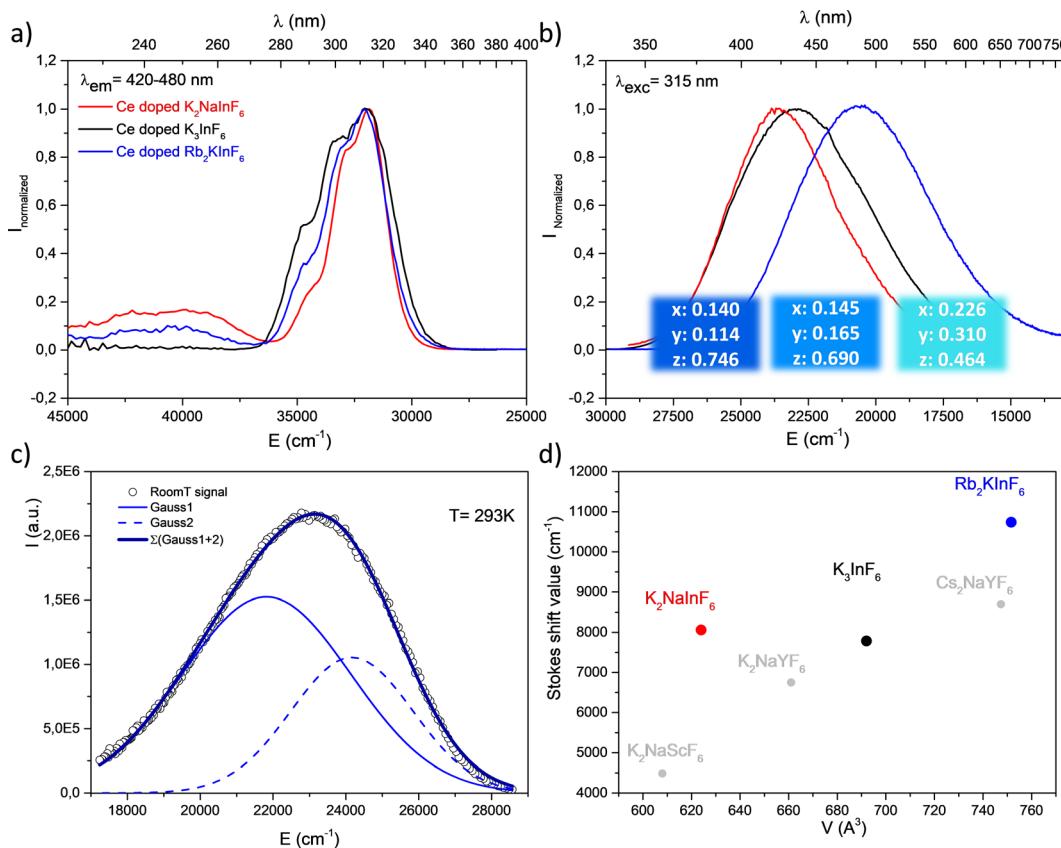

Fig. 6 Excitation spectra (a), emission spectra and corresponding colour coordinates (b), deconvolution of the emission spectra into two  $5d(T_{2g}) \rightarrow ^2F_{7/2}$  and  $5d(T_{2g}) \rightarrow ^2F_{5/2}$  bands at room temperature of  $K_3$  (c) and Stokes shift of  $Ce^{3+}$  doped-fluoride compounds (d).

2424  $cm^{-1}$  for  $Rb_2K$ ,  $K_2Na$  and  $K_3$ , respectively, are observed, in agreement with the expected value resulting from the splitting of the two  $Ce^{3+}$  4f levels by spin orbit coupling.<sup>17</sup> Regardless of the nature of the host lattice, the maximum of the excitation band is located at approximately 313 nm, which indicates a very weak difference in the crystal field effect on the 5d orbital splitting. However, the global emission is significantly shifted to the highest energy *versus* the decrease in the alkali size (as a reminder,  $r_{Rb}[6/12] = 1.52/1.72 \text{ \AA}$ ;  $r_K[6/12] = 1.38/1.64 \text{ \AA}$ ;  $r_{Na}[6/12] = 1.02/1.39 \text{ \AA}$ ). Thus, the  $Rb_2K$  and  $K_2Na$  emission bands peak at 485 nm and 423 nm, respectively. The  $K_3$  emission is maximum at 435 nm. The corresponding trichromatic  $x$ ,  $y$ ,  $z$  coordinates associated with luminescence colouration are indicated in Fig. 6b (colour panels are also proposed due to the conversion of  $xyz$  parameters into the RGB system).

Stokes shift values ( $\Delta_{SS}$ ) follow the order  $\Delta_{SS} Rb_2K > \Delta_{SS} K_2Na > \Delta_{SS} K_3$ . The standard deviation of the In-F distances at the  $Ce^{3+}$  site is equal to 0.01  $\text{\AA}$  (Table 2); this parameter cannot

explain such an evolution.  $\Delta_{SS}$  reflects both the variation of the equivalent unit cell volumes ( $Rb_2K > K_3 > K_2Na$ ) and the breathing of the  $InF_6$  polyhedra. As discussed previously, a larger volume results in an increased disorder of the fluorine anions (see Table 1). In particular, considering that the softness of the structure increases with alkali size, we suggest that the capability of a larger  $Ce^{3+}$  coordination polyhedron to be distorted, leading to its energetic and spatial reorganization. Thus, the cryolite structure appears as a more rigid host lattice. Such a tendency seems to be confirmed by experimental data reported in the literature for similar structural matrices (Fig. 6d). Low-temperature measurements were performed on the  $K_3$  compound (an equivalent study has been reported for the  $Rb_2K$  elpasolite).<sup>8</sup> A weak thermal quenching of 12% (integrated area), a decrease in the full width at half maximum, and a UV shift are observed from a drop in the temperature down to 8 K. The results are illustrated in Fig. S1 (ESI†).

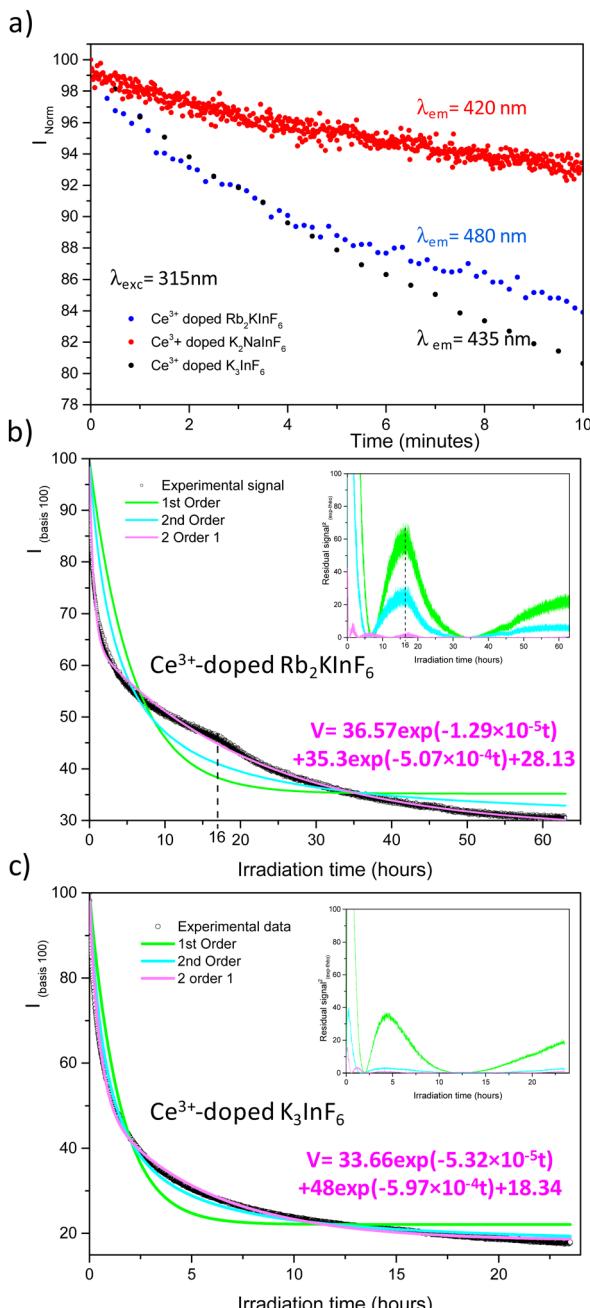

Fig. 7 Kinetic curves of Ce-doped  $\text{Rb}_2\text{K}$  and  $\text{K}_2\text{Na}$  elpasolites  $\text{K}_3$  cryolite (a); fit of a long-time acquisition of the kinetic curves of  $\text{Rb}_2\text{K}$  and  $\text{K}_3$  compounds. The square value of the residual difference between the calculated and experimental values is reported in inset (b and c). The fitting equations based on the (iii) model are indicated in pink.

As published previously, the emission of  $\text{Ce}^{3+}$ -doped  $\text{Rb}_2\text{KInF}_6$  elpasolite is not stable under UV excitation. An electron transfer occurs between the rare earth and indium cations, leading to a redox process (fourth reaction) between the two elements. It is thus possible to record the kinetics of  $\text{Ce}^{3+}$  ion oxidation by following the decrease in the corresponding emission curve. As illustrated below (Fig. 7a), the redox process has also been detected on the  $\text{K}_2\text{Na}$  and  $\text{K}_3$

compounds. After 10 minutes, losses in intensity of approximately 15%, 6% and 20% are observed for the  $\text{Rb}_2\text{K}$ ,  $\text{K}_2\text{Na}$  and  $\text{K}_3$  compounds, respectively. A deeper characterization is proposed for both the  $\text{Rb}_2\text{K}$  elpasolite and  $\text{K}_3$  cryolite. The kinetic curves of the  $\text{Ce}^{3+}$  ions were recorded under excitation at 315 nm and a maximum emission fixed at 485 nm and 435 nm for  $\text{Rb}_2\text{K}$  and  $\text{K}_3$ , respectively. On one hand, the oxidation velocity of  $\text{Ce}^{3+}$  cations and their disappearance have been considered equal to the global emission. Considering this hypothesis for the low doping rate, the emission intensity is proportional to the concentration of luminescent cations and can be expressed as  $V = -d[\text{Ce}^{3+}]/dt$  avec  $[\text{Ce}^{3+}]$  with  $[\text{Ce}^{3+}]$ , the concentration and  $t$ , the time. On the other hand, several kinetic models following the general rule  $V = k[\text{Ce}^{3+}]^\alpha$  with  $\alpha$ , the order of the reaction and  $k$ , the velocity constant, have been run by changing the  $\alpha$  value.

The results of the fits are illustrated in Fig. 7b and c, and the corresponding parameters are listed in Table S2 (ESI†). The  $R^2$  reliability factor was calculated as follows.<sup>18,19</sup>

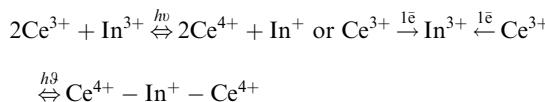

$$R^2 = 1 - \sqrt{\sum (x_{\text{signal}} - x_{\text{theo}})^2 / x_{\text{theo}}^2} \times 100,$$

where  $x_{\text{signal}}$  is the experimental value and  $x_{\text{theo}}$  is the simulated value.

Different hypotheses were considered. (i model) is a single first-order kinetic model corresponding to the disappearance of a single cerium luminescent centre such as  $-d[\text{Ce}^{3+}]/dt = k_1[\text{Ce}^{3+}]^1$ , leading to  $[\text{Ce}^{3+}]_t = [\text{Ce}^{3+}]_0 \exp(-kt)$  expressed as  $(100 - A)\exp(-k_1 t) + A$  on a 100 basis to take into account the  $A$  nonreacting cerium fraction.  $A$  is the threshold of the minimum intensity reached over a long time, and  $k_1$  is the constant velocity ( $\text{s}^{-1}$ ) of cerium III photooxidation. The results are shaped as green curves in Fig. 7b and c. (ii model) The reaction is considered a second-order mechanism, always relying on a single redox centre.  $V$  is calculated as follows:  $-d[\text{Ce}^{3+}]/dt = k_2[\text{Ce}^{3+}]^2$ , equal to  $(100 - A)/(1 + 2(100 - A)) \times k_2 t + A$ , where  $k_2$  is the two-order velocity constant ( $\text{s}^{-1}$ ) (blue curves). Finally, the accumulation of two simultaneous 1st order kinetic laws (iii model) (pink curves) is such as  $-d[\text{Ce}^{3+}]/dt = k_1[\text{Ce}^{3+}]^1 + k_2[\text{Ce}^{3+}]^2$  leading to a disappearance kinetic such as  $(100 - A - B)\exp(-k_1 t) + B \exp(-k_2 t) + A$ , with  $k_1$  and  $k_2$  used for the slow and fast kinetic constants, respectively. The two first law models are not fully satisfactory, and significant residual signals are obtained at the beginning of the irradiation and at 16 hours and 4 hours for  $\text{Rb}_2\text{K}$  and  $\text{K}_3$ , respectively. However, the (iii model) leads to a very low  $R^2$  value, and it is reasonable to conclude that two different  $\text{Ce}^{3+}$  sites with two different kinetics are involved. The total fitted parameter values are reported in Table S2 (ESI†).

The most surprising finding is that the main part of the cerium is actively embedded in the redox process since the  $A$  nonreacting fraction is approximately 20–30% (28.13 and 18.34 are the values extracted from the fit on  $\text{Rb}_2\text{K}$  and  $\text{K}_3$ , respectively). Indeed, we have shown in our previous work in  $\text{Rb}_2\text{K}$  compound that the redox is clearly originating from an overlapping of the cerium and indium external atomic orbitals,

*i.e.*, from cations in the first neighbouring positions. The redox process involves two  $\text{Ce}^{3+}$  ions for one  $\text{In}^+$  cation, as illustrated below:

The probability of being involved in a redox process for  $\text{Ce}^{3+}$  ions, *i.e.*, to not be “isolated” from other  $\text{Ce}^{3+}$  ions is  $P = 1 - (1 - p)^n$ , where  $p$  is the substitution rate by  $\text{Ce}^{3+}$  at the indium site, and  $n$  is the total amount of potential locations to find cerium cations that can coparticipate in the redox reaction (active redox coordination sphere number). The  $n$  value is equal to 56 because, to be isolated from redox potentiality, each  $\text{Ce}^{3+}$  ion must be placed farther from a next-to-next neighbouring position from a second  $\text{Ce}^{3+}$  ion (56 next-to-next neighbours).<sup>20</sup> The probability of finding a second active cerium ion around the one considered in the active sphere is  $1 - 0.98^{56} \approx 68\%$  for  $p = 2\%$ , in relatively good agreement with the  $A$  value (nonreactive cerium fraction). This first calculation indicates that the redox mechanism is effective, while two cerium cations belong to the first neighbouring sphere of a single indium site (with 12 neighbours). Furthermore, electron transfer between two cerium III must also be considered helpful for this process. Additionally, it can be imagined that  $\text{Ce}^{3+}-\text{Ce}^{3+}-\text{In}^{3+}$  chains within a “cascade” double electron injection from the two cerium ions towards the indium site, occur more quickly than the case that two independent cerium ions have to inject one electron each into a “central” indium site. Then,  $B$  eliminates the cerium rate, which is the proportion of ions concerned by the rapid kinetic law ( $k_2$  constant) and can correspond to cerium ions involved in this “cascade” transfer. Considering a doping with exactly 2% of cerium on indium site with perfectly homogeneous distribution, the  $\text{iii}$  model, implemented with consideration of a quick ( $\text{Ce}-\text{Ce}-\text{In}$  triplets) and slow ( $\text{Ce}-\text{In}-\text{Ce}$  triplets) redox centre mechanisms, proportion of nonreacting cerium ions ( $A$  fraction)/reacting with fast kinetic ( $B$  fraction)/

reacting with slow kinetic ( $100 - A - B$  fraction) will be:  $1 - (1 - 0.98^{56}) = 32\% / 1 - (0.98^{12} \times (1 - 0.98^{56})) = 46.6\% / 100 - 46.6 - 32 = 21.4\%$ , respectively. These results are in good agreement with the experimental values.

After far UV irradiation, the luminescence of monovalent indium cations was detected for the three studied compounds. It consists of  $5s^2 \leftrightarrow 5s^1 5p^1$  transitions. Concerning the  $\text{In}^+$  cation, spin-orbit coupling results in the global splitting of the p orbitals into  ${}^3\text{P}_0$ ,  ${}^3\text{P}_1$ ,  ${}^3\text{P}_2$  and  ${}^1\text{P}_1$  levels, with  ${}^1\text{S}_0$  being the ground state. The absorption bands are labelled A ( ${}^1\text{S}_0-{}^3\text{P}_{0,1}$ ), B ( ${}^1\text{S}_0-{}^3\text{P}_2$ ), and C ( ${}^1\text{S}_0-{}^1\text{P}_1$ ).<sup>21</sup> In an octahedral environment, the emission results from the de-excitation of the  ${}^3\text{P}_1$  level, which is split into a  ${}^3\text{A}_{1u}$  ( $A_T$  high energy component) and a  ${}^3\text{A}_{1u}$  ( $A_x$  low energy component). The first transition is usually quenched at room temperature. In addition, the Jahn-Teller effect is predominant among the spin-orbit couplings, and the spectral distribution in absorption and emission is strongly affected. Fig. 8 shows the excitation and emission spectra of the three fluoride compounds.<sup>22-25</sup>

As indicated above, the redox process induced under UV irradiation stabilized indium in the monovalent oxidation state. In the three fluorides, a large orange-red emission due to the  $A_x$  ( ${}^3\text{P}_0 \rightarrow {}^1\text{A}_1$  ( ${}^1\text{S}_0$ )) transition is observed, and the corresponding excitation bands peak at approximately 240 nm. For the  $\text{Rb}_2\text{K}$  and  $\text{K}_3$  compounds, measurements were performed at 8 K to confirm the origin of these transitions through the expected appearance of the  $A_T$  component. The spectral characteristics are listed in Table 4.

Both excitation and emission bands are redshifted in parallel to the decrease in the alkali radii. This reflects the Nephelauxetic effect first described by C. K. Jørgensen in 1962.<sup>26</sup> The interelectronic repulsion of a transition metal is weaker when integrated in a complex than for the free ion because of the overlap of the ligand–metal orbitals and the expansion of the electronic cloud over a wider area. The electronic repulsion is reduced, leading to decreased energy levels.<sup>27,28</sup> This effect is driven by the covalence and polarizability of the chemical bonding. The excitation energy decreases with increasing bond covalence.

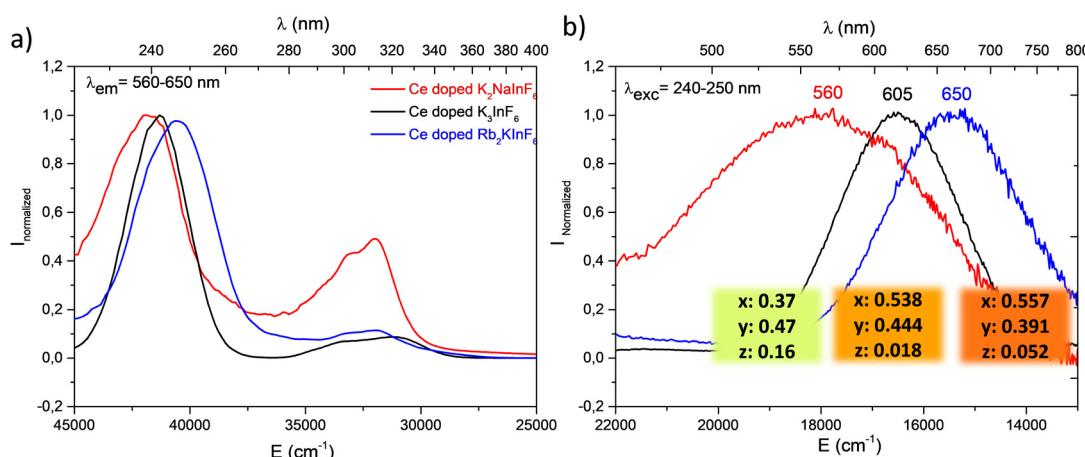

Fig. 8 Excitation (a) and emission spectra (b) after 10 minutes of irradiation at 315 nm of  $\text{Ce}^{3+}$  doped fluoride compounds. Measurements were performed at room temperature.

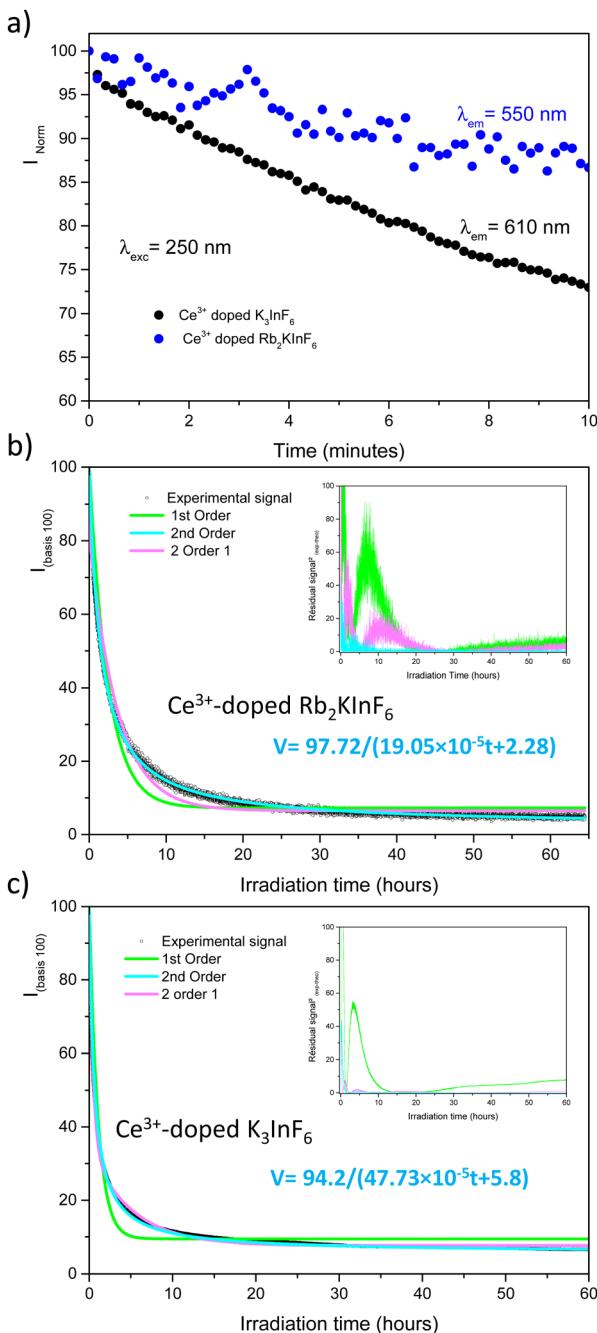

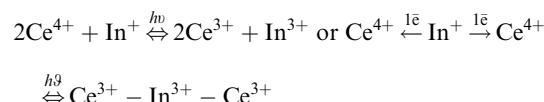

Fig. 9 Kinetic curves of  $\text{Rb}_2\text{K}$  elpasolite and  $\text{K}_3$  cryolite (a) after irradiation at 315 nm; fit of a long time acquisition of the kinetic curves. The square value of the residual difference between the calculated and experimental values is reported in inset (b and c). The fitting equations based on the ii model are indicated in blue.

Antagonist chemical bonding needs to be considered to better understand the observed shifts in excitation and emission. In all the studied  $\text{A}_2\text{BInF}_6$  ( $\text{A} = \text{B}$  for  $\text{K}_3\text{InF}_6$  cryolite) compounds, indium cations are surrounded by fluorine anions. The stronger the A-F bond ionicity ( $\text{A} = \text{Rb, K, Na}$ ) is (Fig. S2, ESI<sup>†</sup>), the higher the covalence of the In-F bond, and the lower the energetic levels at the origin of the indium luminescence. Under excitation, the order of  $E_{\text{ex}}(\text{Rb}_2\text{K}) = 40\ 485 \text{ cm}^{-1} < E_{\text{ex}}(\text{K}_3) = 41\ 322 \text{ cm}^{-1} < E_{\text{ex}}(\text{K}_2\text{Na}) = 42\ 017 \text{ cm}^{-1}$  is observed. Consequently, the corresponding emission bands appear to shift in the same manner. RGB colour emission is illustrated as previously.

The reversibility of the redox process (back redox reaction) was checked for both compounds. Fig. 9 illustrates the kinetic curves of  $\text{In}^+$  luminescence under 250/245 nm excitation for  $\text{Rb}_2\text{K}$  and  $\text{K}_3$ . After 10 minutes of irradiation at room temperature, 50% of the  $\text{Rb}_2\text{K}$  signal ( $A_x$  component peaking at 650 nm) is lost, whereas this value is equal to approximately 30% for the  $\text{K}_3$  compound ( $A_x$  component peaking at 610 nm). The decrease in  $\text{In}^+$  is associated with a recovery of  $\text{Ce}^{3+}$  ions, as mentioned previously.<sup>8,9</sup>

The three previously described kinetic models have been applied similarly to the  $\text{In}^+$  ion decreasing curves. The different fitted parameters are listed in Table S3 (ESI<sup>†</sup>); the residual signals are reported in the inset of Fig. 9.

Nearly all the  $\text{In}^+$  luminescent ions that were formed during the fourth redox process are involved in the back-redox reaction (98% and 94% for  $\text{Rb}_2\text{K}$  and  $\text{K}_3$ , respectively). The fits show that the best result is obtained for the 2nd order kinetic law (lowest residual signal and highest value of  $R^2$ ), in agreement with the fact that the indium ions have to release two electrons through two different neighbouring ceriums (one per cerium cation) to be reoxidized.

The constant  $k_1$  for the  $\text{K}_3$  compound is twice the value of  $\text{Rb}_2\text{K}$ . A total of 170 hours of irradiation are necessary to reach 10% of the initial signal for  $\text{Rb}_2\text{K}$ , whereas 12 hours are sufficient to quench 90% of the  $\text{K}_3$  emission. This can be interpreted as the smaller the alkali cations are, the more rigid the host lattice is thus, the rigidity of the crystallographic network could accelerate the electron transfer.

Finally, the UV irradiation of  $\text{Ce}^{3+}$ -doped  $\text{Rb}_2\text{KInF}_6$ ,  $\text{K}_2\text{NaInF}_6$  elpasolites and  $\text{K}_3\text{InF}_6$  cryolite makes possible a reversible switch of the luminescence from blue to yellow-orange-red from a reversible redox process between cerium

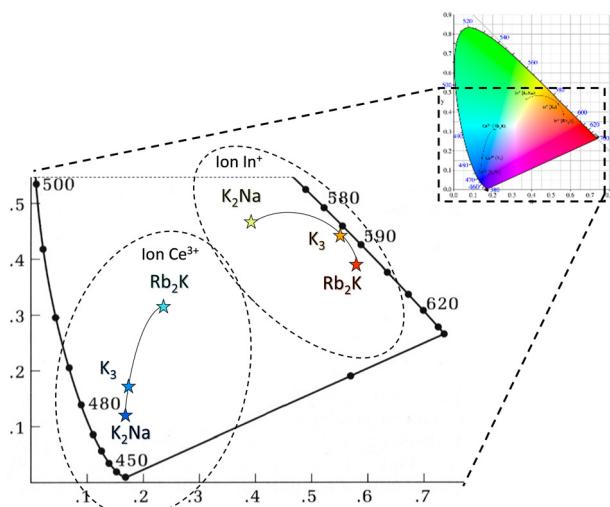

Fig. 10 CIE xy trichromatic diagram based on Ce<sup>3+</sup> and In<sup>+</sup> in Ce<sup>3+</sup>-doped Rb<sub>2</sub>KInF<sub>6</sub>, K<sub>2</sub>NaInF<sub>6</sub> elpasolites and K<sub>3</sub>InF<sub>6</sub> cryolite.

and indium ions due to atomic orbital overlapping. Due to different polarizabilities, the use of various alkali cations makes it possible to tune the redox kinetics and these emissive colours, as illustrated in Fig. 10.

From the chromatic  $x$  and  $y$  parameters between the Ce<sup>3+</sup> and In<sup>+</sup> spectral distributions, the maximum of the calculated optical contrast ( $OC = \sqrt{(x_{Ce^{3+}} - x_{In^{+}})^2 + (y_{Ce^{3+}} - y_{In^{+}})^2}$ ) is obtained with the cryolite compound and is equal to 0.482. OC values of 0.314 and 0.424 are calculated for the Rb<sub>2</sub>K and K<sub>2</sub>Na compounds, respectively.

## 4. Conclusion

From solid-state synthesis, three Ce<sup>3+</sup>-doped fluorides, Ce-doped Rb<sub>2</sub>KInF<sub>6</sub> and K<sub>2</sub>NaInF<sub>6</sub> elpasolite-type and Ce-doped K<sub>3</sub>InF<sub>6</sub> cryolite-type, have been prepared. In addition to the refinement of the crystallographic elpasolite structures as already well described in the literature, coupling X-ray diffraction and Raman spectroscopy, a new space group with full atomic positioning was herein proposed for the cryolite-type compound.

The reversible photochromoluminescent properties of Ce<sup>3+</sup>-doped Rb<sub>2</sub>KInF<sub>6</sub>, K<sub>2</sub>NaInF<sub>6</sub> elpasolite and K<sub>3</sub>InF<sub>6</sub> cryolite have been demonstrated. Supported by the neighbouring probability of the involved cations, photoluminescence is confirmed to come from the redox process between neighbouring cerium and indium ions due to orbital overlap. Before far UV irradiation (Ce<sup>3+</sup>/In<sup>3+</sup> state), Ce<sup>3+</sup> emission bands are shifted to lower energy with increasing alkali size. After the forth-redox reaction (Ce<sup>4+</sup>/In<sup>+</sup> state), the In<sup>+</sup> luminescence is also tuned by the alkali size due to the Nephelauxetic effect. Hence, cyan to red (Rb<sub>2</sub>K) or blue to yellow (K<sub>3</sub>) photochromism can be achieved. A deep kinetic investigation was performed to better understand the successive decrease in Ce<sup>3+</sup> and In<sup>+</sup> emission during forth- and back-irradiation, respectively. The forth-redox is governed by

the accumulation of two 1st order laws, while for the back-redox, the In<sup>+</sup> disappearance kinetic curve follows a 2nd order law. The redox processes appear faster for the cryolite compound than for the Rb<sub>2</sub>K compound, suggesting that a more rigid host lattice accelerates electron transfer. Noticeable changes in the optical contrasts were obtained along the fluoride series.
