Cytotoxic sub-nanometer aqueous platinum clusters as potential antitumoral agents

We show here that platinum clusters can be generated in water by the sole action of simple, cheap and recyclable polymers, thus litres of the bioactive substance can be produced. These ligand-free clusters are excellent antitumoral agents against HeLa and A2870 cells, outperforming cisplatin and acting on cisplatin-resistant tumoral cells. The price of this new antitumoral agent is at least five times lower than current drugs. The synthetic approach can be extended to other bioactive metals such as rhodium and iridium.

A polarization-sensitive photothermoelectric photodetector based on mixed-dimensional SWCNT–MoS₂ heterostructures†

Pei-Yu Huang,^a Hong-Ji Chen,^a Jing-Kai Qin,^{id}*^a Liang Zhen^{ab}
and Cheng-Yan Xu^{id}*^{ab}

Mixed-dimensional van der Waals (vdW) integration has been demonstrated to be effective for the modulation of the physical properties of homogeneous materials. Herein, we reported the enhancement of photothermal conversion and decrease of thermal conductivity in metallic single-walled carbon nanotube (SWCNT) films with the integration of chemical vapor deposition-grown monolayer MoS₂ films. The induced temperature gradient in SWCNT–MoS₂ hybrid films drives carrier diffusion to generate photocurrent *via* the photothermoelectric (PTE) effect, and a self-powered photodetector working in the visible band range from 405 to 785 nm was demonstrated. The maximum responsivity of the device increases by 6 times compared to that of the SWCNT counterpart. More importantly, the mixed-dimensional device exhibits polarization-dependent photogeneration, showing a large anisotropy ratio of 1.55. This work paves a way for developing high-performance, polarization-sensitive photodetectors by mixed-dimensional integration.

Introduction

Photothermoelectric (PTE) photodetectors based on the Seebeck effect have attracted extensive attention due to advantages such as broadband spectral response,¹ room temperature operation,² self-power capability,³ *etc.* In principle, a typical PTE process relies on the photothermal conversion and thermo-electrical effect. Light illumination would induce a local temperature rise of the material, thus contributing to a temperature gradient across the sample. The excited carriers will diffuse directionally from the hot terminal to the cold terminal, resulting in an electric potential difference. The photovoltage V_{ph} originating from the PTE effect can be described as:

$$V_{\text{ph}} = \int S(x)\Delta T(x)dx \quad (1)$$

where $S(x)$ and $\Delta T(x)$ are the Seebeck coefficient and temperature difference, respectively. Therefore, besides a large Seebeck coefficient, high light absorption capacity and low thermal

conductivity are also essential to establish a large temperature gradient for high performance PTE photodetectors.⁴

Low-dimensional materials such as graphene,^{5,6} WSe₂,⁷ black phosphorus (B-P),⁸ and single-walled carbon nanotubes (SWCNTs)⁹ were proven to have a large PTE effect. Among them, SWCNTs exhibit broad optical absorption (~ 200 nm to 200 μm),¹⁰ high electron mobility ($\sim 10^5$ $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$),¹¹ and a relatively large Seebeck coefficient ($\sim +260$ $\mu\text{V K}^{-1}$),¹² and thus they are regarded as an ideal candidate for fabricating state-of-the-art PTE photodetectors. For example, Martel *et al.* investigated the PTE effect of suspended SWCNT films in a vacuum under highly localized illumination.¹³ They demonstrated that the freestanding SWCNT films exhibit a position-sensitive photo-responsivity of 0.3 V W^{-1} , which is independent of the SWCNT–metal contact barriers. However, the performance improvement of SWCNT-based PTE photodetectors still faces great challenges, since the intrinsic high thermal conductivity and low optical absorption of ultra-thin SWCNT films usually cause a small temperature gradient across the device channel.

The hybridization of two-dimensional (2D) functional materials is effective for the modulation of the physical properties of SWCNTs,^{14–18} offering new opportunities to design advanced devices with high performance and multi-functionality. Benefiting from the direct band gap and broadband light absorption in the visible region, monolayer MoS₂ shows great potential for hybridization to improve the performance of SWCNT-based photodetectors. In this work, we directly synthesized atomically thin MoS₂ monolayers on highly aligned SWCNT films, and demonstrated that the hybrid films

† Electronic supplementary information (ESI) available: Schematic growth diagram of SWCNT–MoS₂ heterostructures, SEM, XPS and Raman characterization measurements, and optoelectronic performance and photocurrent distribution measurements. See <https://doi.org/10.1039/d2na00609j>

can work as the channel material for constructing a high-performance PTE photodetector with polarization sensitivity. We systematically investigated the optoelectronic properties of the hybrid films *via* scanning photocurrent microscopy (SPCM). Owing to the enhancement of light absorption and the decrease in thermal conductivity, the responsivity of the self-powered PTE photodetector based on SWCNT–MoS₂ hybrid films increases by 6 times compared to that of the SWCNT counterpart. Attributed to the anisotropic optical absorption of the hybrid films, the device also demonstrated a strong polarization-sensitive photoresponse in the visible band, showing a large anisotropy ratio of 1.55 under 532 nm light illumination.

Experimental section

Preparation of aligned SWCNT films

We prepared highly aligned SWCNT films on a SiO₂/Si substrate using a self-assembly approach reported in previous work.¹⁹ Metallic SWCNTs with an average diameter of 1.4 nm were purchased from Sigma-Aldrich. Sodium deoxycholate (DOC, Aladdin) was used as a surfactant for SWCNT dispersion. About 1 mg of SWCNT bundles were initially dispersed in 1% (wt/vol) DOC aqueous solution by tip sonication for 30 min. The dispersed SWCNT suspension was then diluted below the critical micelle concentration (CMC), and the final concentration of DOC was about 0.05%. Before depositing films, the SiO₂/Si substrate was treated with O₂ plasma to improve the hydrophilicity of the surface, which was vertically immersed in the as-prepared SWCNT suspension for 24–48 h at 0.04 MPa pressure.

Growth of monolayer MoS₂ on SWCNT films

Before MoS₂ growth, a hydrogen annealing process was carried out to obtain a clean surface of SWCNT films. The as-fabricated SWCNT films were loaded into a tube furnace, and the temperature of the furnace was ramped to 650 °C within 10 min. The annealing process was kept for 10 min in Ar/H₂. MoS₂ monolayers were synthesized on SWCNT films *via* atmospheric pressure chemical vapor deposition (APCVD) using MoO₃ and S powders as precursors (ESI Fig. S1†). 250 mg of S powder was placed in the upper stream and heated to ~160 °C using a heating belt, while mixed powders of MoO₃ (~0.5 mg) and NaCl (~0.5 mg) were loaded into another quartz boat. The SiO₂/Si substrate coated with SWCNT films was placed 3–5 mm above the quartz boat. The growth temperature was set to be 830 °C, and 50 sccm Ar was used as the carrier gas.

Materials characterization

The morphology of SWCNT–MoS₂ hybrid films was obtained with an optical microscope (OM, Zeiss AxioScope 5), scanning electron microscope (SEM, Zeiss Quanta FEG 250 with 5 kV operation voltage) and atomic force microscope (AFM, Bruker Icon). The micro-Raman and micro-photoluminescence (PL) measurements were performed with a confocal microscope-based Raman spectrometer (Metatest corporation, Scan pro advance) under 532 nm. The binding energy of elements was

obtained using X-ray photoelectron spectroscopy (XPS) measurements (ESCALAB 250 Xi). Before the transmission electron microscopy (TEM) measurements, the hybrid films were transferred onto microgrid-supported Cu grids *via* a polyvinyl alcohol (PVA) assisted transfer technique. The HADDF-STEM image and SAED patterns were collected using an FEI Talos F200s transmission electron microscope with 200 kV operation voltage.

Device fabrication and measurements

The device based on SWCNT–MoS₂ hybrid films was fabricated *via* laser direct writing, followed by the deposition of Ti/Au (10/80 nm) electrodes. Optoelectronic measurements were carried out with the assistance of a Metatest ScanPro system (Metatest corporation, Scan pro advance). A focused 532 laser was generated by a digital modulator (Coherent, OBIS), and the spot size was set to be 0.5 μm for SPCM characterization. A Keithley 2612B was used to supply the source–drain bias voltage and collect data. All the measurements were performed at atmospheric pressure and room temperature.

Results and discussion

The morphology of pre-deposited SWCNT films is shown in ESI Fig. S2.† 20 μm-width SWCNT strips are regularly patterned with a spacing of 30 μm on a SiO₂/Si substrate. The SEM image reveals that most of the SWCNT bundles in an individual stripe are well aligned along the axial direction of SWCNTs. From the polarized Raman spectra, we found that the Raman intensity of the characteristic peak (G band) for SWCNTs reaches the highest value with the incident light parallel to the axial direction of SWCNTs, while it decreases to the minimum value with the light along the perpendicular direction, confirming the polarization-sensitive characteristics of SWCNT films (ESI Fig. S3†). Fig. 1a and ESI Fig. S4† display the optical images of the as-fabricated SWCNT–MoS₂ hybrid films. MoS₂ monolayers prefer to grow on the SWCNT films and aggregate into continuous films along the parallel direction of SWCNT strips. The hydrogen annealing process plays a key role in the epitaxial growth of MoS₂ monolayers on SWCNT films. Owing to the excessive nucleation sites arising from the residual surfactant and amorphous carbon, MoS₂ particles randomly distributed on the entire substrate are obtained without a hydrogen annealing process (ESI Fig. S5†). Typical SEM and AFM images of the SWCNT–MoS₂ hybrid structures are shown in Fig. 1b and c. The underlying SWCNT films exhibit an undulating morphology with nanopores in the range of several hundreds of nanometers. The height of the upper MoS₂ film is measured to be 0.78 nm, corresponding to the thickness of the monolayer. In the MoS₂ growth process, precursors tend to be confined in the gaps and pores of SWCNT networks. It would lead to the priority nucleation of MoS₂ on SWCNT films, thus resulting in the formation of MoS₂ monolayers with relatively rough surface and irregular edges (ESI Fig. S6†).

XPS spectrum of SWCNT–MoS₂ hybrid films is shown in ESI Fig. S7.† The peaks at 229.5 and 233 eV are ascribed to the Mo⁴⁺

Fig. 1 Morphology and structural characterization of SWCNT–MoS₂ hybrid films. (a) OM and (b) SEM images of SWCNT–MoS₂ hybrid films. (c) AFM tomography image and height profiles of SWCNT–MoS₂ hybrid films. (d) HADDF-TEM image of SWCNT–MoS₂ hybrid films. Inset image displays the SAED patterns of the red rectangle in (d). (e) Raman spectra and (f) PL spectra of pure MoS₂ and SWCNT–MoS₂ hybrid films.

3d_{5/2} and 3d_{3/2}, and the peaks at 163 and 164.1 eV belong to the S 2p_{3/2} and 2p_{1/2} core levels. Note that the peak at 284.9 eV, which represents the C–C bond of SWCNTs, slightly blueshifts by 0.3 eV after MoS₂ monolayer growth. This indicates that the increase of surface charge density occurs due to the electron injection from MoS₂ into SWCNTs.²⁰ TEM was carried out to identify the crystal quality of SWCNT–MoS₂ hybrid films (Fig. 1d). From the HADDF-TEM image, we can clearly observe the uniform growth of MoS₂ monolayers along the axial direction of the nanotube bundles. Selected-area electron diffraction (SAED) patterns show a set of hexagonally arranged spots, which are marked as MoS₂ with a (100) interplanar spacing of 2.8 Å.²¹

Raman spectroscopy and PL microscopy were also performed to investigate the lattice vibration and optical properties of SWCNT–MoS₂ hybrid films. The results are shown in Fig. 1e, f and ESI Fig. S8.† We can see that the peak position of the MoS₂ E_{2g} mode in hybrid films exhibits a relatively large redshift (~4 cm⁻¹) compared with the pure MoS₂ monolayer, which can be ascribed to the in-plane tensile strain induced during the growth process.²² Meanwhile, the strain-caused lattice distortion would widen the band gap of the MoS₂ monolayer,²³ resulting in the redshift of the PL peak by 16 meV. Attributed to the electron transfer from MoS₂ to SWCNTs as discussed above,²⁴ the A_{1g} peak of MoS₂ redshifts by 0.8 cm⁻¹, and the G mode of SWCNTs also blueshifts by 1 cm⁻¹.

With the mixed-dimensional SWCNT–MoS₂ hybrid films as the channel material, we designed a self-powered photodetector, in which the photocurrent is generated relying on the PET effect. Fig. 2a shows a schematic design of the PTE detector. The dual-channel device was fabricated along the stripe of films with Ti/Au (10/80 nm) as electrodes. The channel length and width are patterned to be 5 and 8 μm, respectively. As shown in

ESI Fig. S9,† the typical linear characteristic of the *I*_{ds}–*V*_{ds} curve under dark conditions indicates a good ohmic contact at the electrode–channel heterointerface. When a 532 nm laser irradiates the channel of the device, an obvious photocurrent was generated without external bias, showing a typical self-powered characteristic. The short-circuit current (*I*_{sc}) rises from 22 to 49 nA with the increase of light power from 0.26 to 0.59 mW, and the corresponding open-circuit voltage (*V*_{oc}) also increases from 0.9 to 2.1 mV (Fig. 2b). We further evaluated the device performance under laser illumination with different wavelengths (405, 532, and 785 nm). The wavelength-dependent short-circuit photocurrent is measured by utilizing a digital modulator to switch the different fiber laser ON/OFF ratios of 4 s. As shown in Fig. 2c, the device demonstrates considerable photogeneration with good stability at zero bias, and the magnitude of the photocurrent would increase linearly with illumination power (Fig. 2d and ESI Fig. S10†). The power law *I*_{ph} ∝ *P*_{in}^α is used to fit the power-dependent photocurrent, where *P*_{in} and α are the actual incident power and ideal factor, respectively. The ideal factors (α) are calculated to be 0.97, 0.97 and 0.98 for 405, 532 and 785 nm light illumination, respectively. The linear characteristics indicate the high efficiency photoelectric conversion of our devices in the visible band.

Two key metrics for the photodetector, photoresponsivity (*R*) and detectivity (*D**), were evaluated. They can be defined by the formulas:

$$R = I_{\text{ph}}/P_{\text{in}} \quad (2)$$

$$D^* = RS^{1/2}/(2qI_d)^{1/2} \quad (3)$$

where *I*_{ph}, *I*_d, *P*_{in}, and *S* represent the photocurrent, dark current, incident power density, and effective illumination area,

(b) I_{ds} – V_{ds} characteristic curves of the detector under darkness and light illumination. (c) Photoresponse of the device under different wavelength lasers with an identical power of 0.15 mW. (d) Power-dependent photocurrent and (e) photoresponsivity of the device under 405, 532, and 785 nm light illumination. (f) The response speed of the device under 532 nm light illumination.

respectively. Under 405 and 532 nm laser illumination, similar responsivity and detectivity were obtained, which were calculated to be $88.2 \mu\text{A W}^{-1}$ and 4.2×10^6 Jones, respectively (Fig. 2e). Note that the responsivity and detectivity of the device under 785 nm illumination dramatically decrease to $0.75 \mu\text{A W}^{-1}$ and 4.1×10^4 Jones. According to the absorption spectrum of SWCNT–MoS₂ hybrid films (ESI Fig. S11[†]), we can infer that the degradation of device performance should be attributed to its poor absorbance at 785 nm. Devices based on SWCNT films and MoS₂ monolayers are also fabricated for comparison (ESI Fig. S12[†]). The SWCNT–MoS₂ hybrid device reveals a much larger photocurrent than that of SWCNT PTE detector at zero bias, and the calculated responsivity increases considerably by 6 times. The response time of our device was also measured using an oscilloscope. As shown in Fig. 2f, a fast photoresponse is observed with a rising edge of 102 ms and descending edge of 84 ms within all examined wavelengths. The value is one order of magnitude smaller than that of previously reported PET photodetectors based on polymer–CNT nanocomposites.^{25–27} There is usually a conflict between the responsivity and response speed in SWCNT-based PTE detectors.⁴ A steep temperature gradient can improve the responsivity but lead to the deterioration of the response time due to the slow heat dissipation. A great balance between them can be achieved by integrating a MoS₂ monolayer into SWCNT films. Moreover, one can expect that the device performance can be further improved by comprehensively optimizing the suspension structure and length of the channel. Note that SWCNT–MoS₂ hybrid devices also demonstrate excellent stability under air conditions (ESI Fig. S13[†]). The photoresponse can be well maintained without any decrease even after exposure to air for 2 months.

To better understand the origin of photogeneration in SWCNT–MoS₂ heterostructures, we performed scanning photocurrent microscopy (SPCM) measurements at room temperature to probe the spatial distribution of the photocurrent. The left panel in Fig. 3a shows the optical image of the sample for SPCM measurements. The Raman mapping images collected from the channel area clearly reveal the intact triangular MoS₂ monolayers and non-uniform distribution of SWCNTs (right panels, Fig. 3a). When the laser spot focuses on the different sides of the heterojunction, opposite photocurrent signals appear, and the shape of the SPCM map can be well maintained with the increase of laser power from 0.29 to 0.72 mW (Fig. 3b and ESI Fig. S14[†]). The profiles of current intensity along the channel are plotted in Fig. 3c. With the rise of the laser power, one can see that the photocurrent gradually increases in each heterogeneous region without any deviation. The current extracted from the peak position linearly increases from 3.7 to 10.8 nA, and the reverse current at the opposite side also linearly changes from 2.2 to 5.7 nA (Fig. 3d). The results imply that the PTE effect plays a critical role in the photogeneration in SWCNT–MoS₂ devices.^{13,28–30}

As shown in Fig. 3e, for the photodetector operating in the PTE model, hot carriers are generated under local laser irradiation, followed by scattering with optical phonons, which would result in the localized temperature rise of SWCNT–MoS₂ hybrid films. The temperature gradient would cause a voltage difference between hot and cold regions, thus leading to the photocurrent generation. Therefore, a large photocurrent can be expected with a steep temperature gradient between two electrodes. The opposite photogeneration can be attributed to the inversion of the temperature gradient at different positions.^{13,31} We observed a good linear I_{ds} – V_{ds} characteristic and large V_{oc}

variances in the SWCNT–MoS₂ PET photodetector. This is in sharp contrast to the photovoltaic photodetector, which works relying on the built-in electric field *via* the Schottky contact or p–n junction and usually exhibits asymmetric I_{ds} – V_{ds} characteristics.^{32–35}

Compared to the device based on pure SWCNT films, the active area for photogeneration extends considerably to the middle region of the channel in the SWCNT–MoS₂ PTE photodetector (ESI Fig. S15[†]), which indicates that a half thermal diffusion length is enough to generate a distinct photocurrent. It can be well explained by the high temperature rise in the illumination area and the low thermal conductivity of SWCNT–MoS₂ hybrid films. On one hand, light absorption in the visible band is significantly enhanced by integrating MoS₂ monolayers into SWCNT films (ESI Fig. S11[†]). Excited electron–hole pairs in MoS₂ monolayers would relax to the edge of energy bands before recombination, and the facilitated photo-thermal conversion would result in an effective temperature rise after light illumination.³⁶ On the other hand, a mass concentration of defects, including S vacancies in MoS₂, lattice distortion at the heterointerface, and nanopores in SWCNT networks, exist in SWCNT–MoS₂ hybrid films. Therefore, a strong phonon scattering effect and inhibited heat flow along the channel can be expected.^{37–39} As a result, a pronounced PTE effect is demonstrated in the photodetector based on SWCNTs–MoS₂ hybrid films.

The polarization sensitivity provides an additional dimension of information for developing new applications of photodetectors such as polarized light imaging⁴⁰ and photoswitching.⁴¹ Benefitting from the anisotropic optical

absorption in SWCNT–MoS₂ hybrid films, the PTE photodetector also demonstrates polarization-dependent photocurrent generation. As shown in Fig. 4a, linearly polarized light is obtained by introducing a polarizer into the optical system, and the polarization angle can be modulated with a half-wave plate rotating from 0° (parallel to the channel) to 360°. The polarization-resolved absorption spectra of SWCNTs–MoS₂ hybrid films are given in Fig. 4b. The inset of Fig. 4b provides the OM image of the sample for measurements. We can see that the maximum light absorbance is obtained with the incident light parallel to the axial direction of the strips, and the minimum value is achieved along the perpendicular direction. The polarization-dependent optical absorbance of the hybrid films was plotted into polar coordinates for clarity (ESI Fig. S16[†]), which can be fitted using the function:

$$I_{\text{abs}} = a \cos 2\theta + b \sin 2\theta \quad (4)$$

where I_{abs} , and θ refer to the absorbance and polarization angle, respectively. The dichroic ratios are calculated to be 1.76, 1.67 and 1.45 for 405, 532 and 785 nm light, respectively, indicating the excellent anisotropic absorption of MoS₂–SWCNT hybrid films in the visible band.

Fig. 4c presents the polarization-resolved photocurrent mapping images under 532 nm linear polarized light illumination. The photocurrent of the device would decrease gradually with the polarization angle switching from 0° to 90°, and it would rise back to the original value at a polarization angle of 180°. These results are consistent with the polarization-resolved absorption spectra. The detailed polarization-dependent

Fig. 4 Polarization-resolved photodetector based on SWCNT–MoS₂ heterostructures. (a) Schematic diagram of the polarization-dependent absorption measurement. (b) Polarization-sensitive absorption spectrum of SWCNT–MoS₂ hybrid films. Scale bar: 10 μ m. (c) Spatial distribution of photocurrent under excitation by 0°, 90°, and 180° linearly polarized 532 nm lasers. Scale bar: 2 μ m. (d) Linear polarized light dependence of photocurrent under 532 nm illumination. (e) Polar coordinates of the polarization-sensitive photoresponse under 532 nm laser illumination.

photocurrent of the SWCNT–MoS₂ hybrid device under 532 nm laser illumination is plotted in Fig. 4d. The photocurrent fluctuates periodically with the variation of the polarization angle from 0° to 360° and a maximum value of 16.7 nA is achieved at 0° and 180°. The data were then extracted and fitted using the same function (4). As shown in Fig. 4e, the plotted polar figure exhibits a symmetric pattern with two petals. The anisotropy ratio, defined as the ratio between the maximum and minimum value of photocurrent, is calculated to be 1.55 under 532 nm illumination. In addition, 405 and 785 nm linearly polarized lasers are also utilized to investigate the wavelength-dependent polarization response of the device, and anisotropy ratios of 1.36 and 1.55 were obtained, respectively (ESI Fig. S17†). Compared with state-of-the-art PTE photodetectors, the device based on SWCNT–MoS₂ hybrid films demonstrates outstanding photoresponsivity and sensitivity to polarized light in the visible band, indicating its great potential for polarized light detection and polarization imaging without an external power source (ESI Table S1†).

Conclusions

In summary, we demonstrated the growth of MoS₂ monolayers on aligned SWCNT films through a simple CVD method. The hybrid films reveal an enhanced PTE effect and can work as the channel material for the fabrication of self-powered photodetectors. Under 532 nm illumination, the responsivity of the PTE photodetector based on SWCNT–MoS₂ hybrid films increases by 6 times compared with that of the SWCNT counterpart. In addition, the device exhibits a polarization-dependent photocurrent with a maximum anisotropy ratio of 1.55. This work suggests that the combination of 2D materials with 1D

materials has great potential for developing high-performance, polarization-sensitive optoelectronic devices.

Author contributions
