Synthesis, characterisation, and feasibility studies on the use of vanadium tellurate(vi) as a cathode material for aqueous rechargeable Zn-ion batteries†

Mangayarkarasi Nagarathinam, [©] ^a Cindy Soares, ^a Yue Chen, [©] ^b Valerie R. Seymour, [©] ^a Vlastimil Mazanek, ^c Mark A. Isaacs, [©] ^d Zdenek Sofer, [©] ^c Oleg Kolosov, [©] ^b John M. Griffin [©] ^a and Nuria Tapia-Ruiz [©] *

Aqueous rechargeable zinc-ion batteries (AZIBs) have drawn enormous attention in stationary applications due to their high safety and low cost. However, the search for new positive electrode materials with satisfactory electrochemical performance for practical applications remains a challenge. In this work, we report a comprehensive study on the use of the vanadium tellurate $(NH_4)_4\{(VO_2)_2[Te_2O_8(OH)_2]\}\cdot 2H_2O$, which is tested for the first time as a cathode material in AZIBs.

1. Introduction

Rechargeable aqueous zinc-ion batteries (AZIBs) are a promising alternative to lead-acid batteries in grid energy storage systems.¹⁻⁴ This is owing to the unique properties of Zn, which include a two-electron redox reaction, high theoretical gravimetric capacity (820 mA h g^{-1}), low redox potential (-0.76 V vs. standard hydrogen electrode (SHE)), low cost and abundance.^{5,6} Furthermore, AZIBs are risk-free and easier to scale up than the classic alkali-ion batteries, due to their non-toxicity, the use of a highly stable Zn metal anode, and non-flammable and nonvolatile aqueous electrolytes.7-10 Nevertheless, the success of this technology remains a challenge, as AZIBs require high demanding conditions, such as multivalent electrode materials with large interlayer spacing, and robust architectures to withstand the huge stress imparted upon reversible solvated Zn²⁺ ion intercalation.^{7,9} To date, significant efforts have been made to develop new manganese and vanadium-based cathode materials, where the latter have demonstrated impressively high capacities (~300 mA h g⁻¹), 9,11-15 superior rate performance and prolonged cycle life, albeit with low operation voltages. In the pursuit of finding alternative vanadium-based electrode systems with improved electrochemical properties in

2.1 Synthesis of VTe

 V_2O_5 (0.270 g, 1.5 mmol) and H_6TeO_6 (0.690 g, 3.0 mmol) were added to 10 ml of H_2O and stirred in a beaker until a homogeneous mixture was achieved. Then, 0.42 ml of 35% NH_4OH solution was added dropwise with constant stirring to this solution. The yellow-orange reaction mixture was heated at 80 °C for 2–3 min until a clear solution was observed. Then, the reaction mixture was stirred at room temperature for 24 h and the solution was filtered to obtain a yellow precipitate. The

AZIBs, we have investigated the use of (NH₄)₄(VO₂)₂-Te₂O₈(OH)₂·2H₂O as an electrode material, here abbreviated as VTe, which was first synthesised hydrothermally at 150 °C for 3 days by Hyejin et al. more than a decade ago.16 VTe consists of 1D infinite anionic {[VO₂]₂[Te₂O₈(OH)₂]}⁴⁻ chains separated by NH₄ cations and H₂O molecules, which act as strong pillars to keep structural integrity (Fig. 1a). Electrode materials with polyanionic groups such as phosphates, silicates and sulfates have been reported to have higher electrochemical potential and improved thermal stability than their corresponding oxide counterparts.17,18 Thus, we will investigate the inductive and resonance effect of the [Te₂O₈(OH)₂]⁻⁶ polyanionic moiety in the redox potential of the vanadium oxide system and explore the redox activity of the Te ions upon Zn2+ ion insertion/ extraction. This is the first example of a vanadium tellurate(vi) compound synthesised at room temperature and tested as a cathode in AZIBs, only preceded by studies on the high-voltage K2Ni2TeO6 cathode used in potassium-ion batteries,19 and Na₂M₂TeO₆ compounds (M = Ni, Co, Zn, Mg), which showed high ionic conductivities (4-11 S m⁻¹) at 300 °C.^{20,21}

yellow precipitate was washed with water and then dried at $60\,^{\circ}$ C under vacuum (0.850 g, 82% yield). All the chemicals were used as received from Sigma Aldrich without further purification. All the solvents used were of reagent grade.

2.2 Characterisation

Powder X-ray diffraction (PXRD) data were collected at ambient temperature using a Rigaku Smartlab X-ray diffractometer with a 9 kW Cu source generator (λ K $_{\alpha1}=1.54051$ Å) equipped with a high-resolution Vertical θ/θ 4-Circle Goniometer and a D/teX-ULTRA 250 high-speed position sensitive detector system. The crystal structure obtained by PXRD data were refined by the Rietveld refinement method using the TOPAS R2-1 software program. 22

Fourier transform infrared (FTIR) spectra were collected in the 400–4000 cm⁻¹ range with a resolution of 8 cm⁻¹ using a Shimadzu IRTracer-100 FTIR spectrophotometer. Spectra were collected as the sum of 36 scans. Samples were prepared by mixing the VTe powders with KBr (Sigma Aldrich, 99%) using an agate mortar and pestle and then pressing the mixture into pellets at 5 tonnes per cm².

Elemental analysis was carried out on a Vario MICRO Cube instrument in CHNS analysis mode with a program designed for measuring 2 mg samples. For the measurement, samples were weighed directly into Sn boats using a high-precision balance. Oxygen was injected into the sample for 70 s and He was used as a carrier gas. The system was zeroed by running blank samples and then it was subsequently calibrated using a sulfanilamide $(C_6H_8N_2O_2S)$ standard. Elemental analysis data for $H_{22}N_4O_{16}Te_2V_2$ (in %): H 3.31; N 8.05. (Theoretical (in %): H 3.21, N 8.11)

Thermogravimetric analyses (TGA) were carried out using a Thermys Analyzer (Setaram) with a DTA protected sensor. The sample was placed in an alumina crucible and heated from room temperature to 700 $^{\circ}$ C in an argon atmosphere at a heating rate of 10 $^{\circ}$ C min⁻¹.

The microstructure of the samples was analysed using field emission scanning electron microscopy (FESEM), where the images were acquired using a JEOL JSM-7800F operating at 10.0 kV. Elemental analysis was performed at 12.0 kV using an X-ray Energy Dispersive Spectrometer (EDS) (X-Max50, large area 50 mm² Silicon Drift Detector (SDD) from Oxford Instruments). Samples were placed onto carbon tabs (G3348N, Agar Scientific) attached to the metal holder and coated with a thin layer of gold using a Quorum Q150RES sputter coater (Quorum Technologies Ltd) to increase their conductivity.

Transmission electron microscopy (TEM) images and selected area electron diffraction (SAED) patterns were obtained using an EFTEM 2200 FS microscope (JEOL). A 200 keV acceleration voltage was used for TEM data collection. Sample preparation was attained by drop-casting the suspension (1 mg ml $^{-1}$ in water) on a TEM grid (Cu; 200 mesh; formvar/carbon) and then drying it at 60 °C for 12 h.

¹H and ¹⁵N solid-state NMR spectra were obtained at 16.4 T on a Bruker Avance III spectrometer operating at Larmor frequencies of 700.1 and 71.0 MHz, respectively. For ¹H experiments, powdered samples were dried at 100 °C under vacuum for 24 h and packed into 2.5 mm rotors and spun at 30 kHz. For ¹⁵N experiments, powdered samples were packed into 4 mm rotors and spun at 12.5 kHz. 1H spectra were acquired using a DEPTH pulse sequence to remove the background signal, with a recycle interval of 10 s. 15N spectra were acquired using cross polarisation from ¹H. ¹²⁵Te solid-state NMR spectra were obtained at 9.4 T on a Bruker Avance III 400 MHz spectrometer operating at a Larmor frequency of 126.2 MHz. Powdered samples were packed into 4 mm rotors and spun at 14 kHz. ¹²⁵Te spectra were acquired using a single 90° pulse with a repeat interval of 360 s. Spectra were referenced via secondary solid references of alanine (NH₃ $\delta_{iso} = 8.5$ ppm), glycine (NH₃ $\delta_{\rm iso} = -347.4$ ppm), and Te(OH)₆ (higher frequency peak $\delta_{\rm iso} =$ 692.2 ppm) for ¹H, ¹⁵N and ¹²⁵Te, respectively.

 1 H chemical shifts were calculated using density functional theory (DFT). A calculation was carried out on the (NH₄)₄{(-VO₂)₂[Te₂O₈(OH)₂]}·2H₂O crystal structure (ICSD 416841) using the CASTEP code. The structure was fully geometry optimised before calculation of the NMR parameters, using the GIPAW formalism²³ as implemented within CASTEP.^{24,25} Chemical shieldings were referenced *via* a separate calculation on L-

alanine (reference shielding = 30.5 ppm). Calculated 1 H chemical shifts are shown in Table S1.† Chemical shifts for crystallographically-distinct protons within H_2O molecules and NH_4^+ ions are averaged under the assumption of fast dynamic exchange between these positions.

2.3 Electrochemical tests

To fabricate the working electrodes, active material, super P carbon black and binder (Kynar 2801) in the weight ratio of 70:20:10 were thoroughly mixed with an agate mortar and pestle. The powdered mixture was then added to a vial and a few ml of N-methyl-2-pyrrolidone (NMP) were added to the mixture to make an electrode slurry. The slurry was stirred for 8 h at room temperature. 1.5 cm diameter electrodes with a thickness of 20 μ m were prepared by casting the slurry onto Ti foil (used as a current collector) with a doctor-blade, and punching the electrode-coated foil with a heavy-duty manual puncher. The mass loading of the active material was typically 2–3 mg cm⁻².

The electrochemical properties of VTe were evaluated using CR2032 stainless steel coin cells. Zn metal (180 μm thickness) was used as the counter and the reference electrode, glass microfiber filter (GB-100R, Whatman) as the separator, and a 3 M ZnSO₄·7H₂O aqueous solution as the electrolyte. Coin cells were aged at room temperature for 6 h before data collection took place. Galvanostatic charge/discharge cycling (GC) at different current rates and voltage windows were carried out using a Neware battery cycler (current range: 1–10 mA). Cyclic voltammetry (CV) data were collected at room temperature using an Iviumstat instrument (Ivium, Alvatek). Data were collected using a scan rate of 0.2 mV s $^{-1}$ in the voltage window of 0.4–1.4 V vs. Zn $^{2+}$ /Zn.

For the preparation of the concentration cells, VTe half-cells were discharged to 0.2 V to insert $\rm Zn^{2+}$ ions in the VTe electrode. The electrodes were removed in an open atmosphere from the discharged cells, paired immediately with a fresh VTe electrode and assembled in a CR2032 coin cell using a glass microfiber filter as the separator and an aqueous 3 M ZnSO₄ solution as the electrolyte. The mass of the electrodes of the two cells was kept similar and the specific capacity is calculated using the pristine VTe electrode. Galvanostatic charge/discharge cycling of the concentration cells at a constant current of 10 mA g⁻¹ in the voltage range of -1.7-1.5 V was carried out at room temperature using an Iviumstat instrument (Ivium, Alvatek). The concentration cell has an open-circuit voltage of -0.411 V and it is initially charged to 1.5 V and then discharged to -1.7 V continuously.

2.4 Ex situ X-ray photoelectron spectroscopy

X-ray photoelectron spectroscopy (XPS) data on ex situ samples were acquired using a Kratos Axis SUPRA fitted with monochromated Al k α (1486.69 eV) X-rays operating at 15 mA emission and 12 kV HT (180 W) and a spot size/analysis area of 700 \times 300 μ m. The instrument was calibrated to gold metal Au 4f (83.95 eV) and dispersion adjusted to give a binding energy of 932.6 eV for the Cu 2p_{3/2} line of metallic copper. Ag 3d_{5/2} line

FWHM at 10 eV pass energy was 0.544 eV. Source resolution for monochromatic Al K α X-rays was \sim 0.3 eV. The instrumental resolution was determined to be 0.29 eV at 10 eV pass energy, using the Fermi edge of the valence band for metallic silver. Resolution with the charge compensation system was determined to be <1.33 eV FWHM on PTFE. High-resolution spectra were obtained using a pass energy of 20 eV, step size of 0.1 eV and sweep time of 60 s, resulting in a line width of 0.696 eV for Au $4f_{7/2}$. Survey spectra were obtained using a pass energy of 160 eV. Charge neutralisation was achieved using an electron flood gun with filament current = 0.38 A, charge balance = 2 V, and filament bias = 4.2 V. Successful neutralisation was adjudged by analysing the C 1s region, wherein a sharp peak with no lower binding energy structure was obtained. Spectra have been charge corrected to the main line of the carbon 1s spectrum (adventitious carbon) set to 284.8 eV. All data was recorded at a base pressure of below 9×10^{-9} Torr and room temperature of 294 K. Data were analysed using CasaXPS v2.3.19PR1.0. Peaks were fit with a Shirley background before component analysis.26 The samples were transferred from the glovebox using a custom vacuum sealed transfer arm.

2.5 Quartz crystal microbalance experiments

Quartz crystal microbalance (QCM) experiments were performed on an eQCM 10M quartz crystal microbalance (GAMRY). Electrodes were prepared by coating an Au-coated quartz crystal (QCM5140CrAu120-050-Q, 5 MHz, 14 mm sensor diameter, 12 mm front/5 mm back electrode diameter) with a mixture of the VTe powder (active material), super P carbon black (conductive agent), and Kynar 2801 (binder) in a weight ratio of 58:17:25. Then, the electrode was heated at $60\,^{\circ}\text{C}$ for 24 h. The thickness of the composite electrode was $ca.\ 20\ \mu\text{m}$. Operando EQCM was conducted during cyclic voltammetry tests. The mass change of the VTe-coated QCM electrode, Δm , was calculated from the change in resonance frequency (Δf), using the Sauerbrey eqn (1):

$$\Delta m = -\left(\frac{A\sqrt{\rho_{\rm q}\mu_{\rm q}}}{2{f_0}^2}\right)\Delta f \tag{1}$$

where f_0 is the resonance frequency of the QCM electrode before the electrochemical tests, A is the ratio of the top electrode area to the QCM effective sensing area, ρ_q is the density of quartz (2.648 g cm⁻³), and μ_q is the shear modulus of quartz (2.947 × 10^{11} g cm⁻¹ s⁻²).²⁷

The number of moles of electrons that participate in the charge transfer (N), can be calculated by applying Faraday's law (eqn (2)):

$$N = \frac{n\Delta m}{M_{\rm w}} = \frac{\Delta C}{F} \tag{2}$$

where ΔC is the charge passed corresponding to the Δm mass change during electrolysis, $M_{\rm w}$ is the molecular weight, F is Faraday's constant, 96 485 C mol⁻¹ and n is the valence number of Zn.

Eqn (2) can be then written as:

$$\left| \frac{\Delta m}{\Delta C} \right| = \frac{M_{\rm w}}{Fn} \tag{3}$$

By plotting the Δm vs. ΔC , the molecular weight of the exchanged ion can be calculated from the slope value according to the eqn (3).

2.6 Post-mortem studies

For post-mortem studies, electrodes were electrochemically cycled at different states of charge and then coin cells were disassembled and the electrodes washed with deionised water a few times under a steady flow of nitrogen gas. Electrodes were transferred immediately to a glovebox antechamber which was first flushed with Ar gas 5 times and then dried under vacuum at room temperature. For XPS measurements, electrodes were packed in the glovebox under Ar atmosphere. Electrodes were in contact with air during PXRD, FTIR and, FESEM data collection.

Results and discussion

 $(\mathrm{NH_4})_4\{(\mathrm{VO_2})_2[\mathrm{Te_2O_8}(\mathrm{OH})_2]\}\cdot 2\mathrm{H_2O}$ (VTe), was obtained using a modified synthetic procedure from the literature (see Experimental section). Fairbourd analysis on the XRD data showed that the structure crystallises in a monoclinic $P2_1/n$ space group with a=7.37(1) Å, b=17.12(2) Å and c=7.37(1) Å, $\beta=118.70(3)^\circ$, in agreement with the literature (Fig. 1b). The structure of VTe consists of 1D infinite anionic $\{[\mathrm{VO_2}]_2[-\mathrm{Te_2O_8}(\mathrm{OH})_2]\}^{4-}$ chains along the c direction with edge-shared VO₆ and $\mathrm{TeO_5}(\mathrm{OH})$ octahedral units that form $\mathrm{V_2O_{10}}$ and $\mathrm{Te_2O_8}(\mathrm{OH})_2$ dimers. These chains are connected by an extended hydrogen network of N-H···O and O-H···O bonds (originated by the presence of $\mathrm{NH_4}^+$ cations and $\mathrm{H_2O}$ molecules in the structure), and O-H···O hydrogen bonds from the OH group of the $\mathrm{TeO_5}(\mathrm{OH})$ dimers (Fig. 1a). No impurities were observed in the diffraction data.

The large interlayer spacing of 8.6 Å in VTe allows a rapid migration of Zn²⁺ ions along the ac plane. The intralayer spacing compares well to other ammonium vanadate systems with excellent electrochemical performance due to their large ion diffusion channels, such as $NH_4V_4O_{10}$ and $(NH_4)_{0.5}V_2O_5$. ^{28,29} Elemental analysis confirmed the percentage of nitrogen and hydrogen as in the proposed molecular formula for VTe (see Experimental section), while EDX analysis confirmed that the V: Te and V: N elemental ratio is nearly equal to 1:1 and 1:2, respectively (Fig. S1†). Thermogravimetric analysis data showed a mass loss of 23.4% between R.T. and 410 °C, which agrees with the removal of all the H₂O and NH₃ molecules in the compound (Fig. S2†). SEM/TEM images in Fig. 1c and d showed that the VTe sample consists of 200-500 nm platelets. The TEM image in Fig. 1d showed that the platelets have smooth edges, and its corresponding ring-like SAED pattern (Fig. S3†) revealed the polycrystalline nature of the sample. The ¹H MAS NMR spectrum of VTe showed three main resonances at 10, 7 and 5 ppm. Based on their relative intensities and chemical shifts, these were attributed to OH groups, pillared NH₄⁺ ions and H₂O molecules, respectively (Fig. 1e). DFT calculations on the

published crystal structure¹⁶ support this assignment (Fig. 1e). The OH resonance was slightly broader than the $\mathrm{NH_4}^+$ and $\mathrm{H_2O}$ resonances owing to stronger dipolar interactions, which reduced its apparent intensity in the experimental spectrum.

The ^{15}N MAS NMR spectrum for the pristine material showed a single peak at -357 ppm, which contrasts with the two crystallographic NH₄⁺ environments in the crystal structure (Fig. S4†). DFT calculations predicted a small chemical shift difference of 6 ppm between the two N sites, which is less than the \sim 8 ppm linewidth in the experimental spectrum. This explains the inability to distinguish between these two sites. The 125 Te MAS NMR spectrum showed two distinct resonances of similar intensity at 765 and 740 ppm (Fig. S5†). This is inconsistent with the published crystal structure, which shows a single Te site. An explanation for this might be a small break in the symmetry of VTe due to the loss of H₂O molecules.

Electrochemical studies were conducted to assess the performance of VTe as a cathode material in AZIBs. CV data showed a multistep Zn²⁺ ion insertion/extraction process, where the first scan showed cathodic peaks at 1.04 and 0.59 V and anodic peaks at 0.75, 1.06 and 1.23 V, which correspond to reversible reactions involving V⁵⁺/V⁴⁺ and V⁴⁺/V³⁺ redox couples (Fig. 2a). These peaks were assigned by direct comparison to other vanadate systems. 28,30 Peaks at 1.06 and 1.23 V might be attributed to the extraction of Zn2+ ions from energetically different crystallographic sites during V⁴⁺/V⁵⁺ oxidation.³¹ GC data in the 0.4-1.4 V voltage window showed three discharge plateaus at ca. 0.90 V, 0.57 V and 0.49 V, totalling a capacity of 287 mA h g^{-1} (Fig. 2b, and magnified view in Fig. S6†). Upon charge, the capacity was not be fully retrieved (232 mA h g^{-1}), due to the irreversible nature of the lowest voltage plateau, leading to an initial coulombic efficiency (CE) of ca. 80%. A

Fig. 2 (a) CV data of VTe in the $0.4-1.4~V~vs.~Zn^{2+}/Zn$ voltage window, using a $0.2~mV~s^{-1}$ scan rate. (b) GC data of VTe in Zn half-cells in the $0.4-1.4~V~vs.~Zn^{2+}/Zn$ voltage window, using a current density of $10~mA~g^{-1}$. (c) GC data of concentration (VTe \parallel 3 M ZnSO $_4$ aq. \parallel Zn $_x$ VTe) cells in the -1.7-1.5~V~v voltage window at a current density of $10~mA~g^{-1}$ for the 1^{st} , 2^{nd} , 5^{th} , 10^{th} , 15^{th} , and 20^{th} cycles; and (d) specific capacity vs.~cycle number plot with coulombic efficiencies for concentration (VTe \parallel 3 M ZnSO $_4$ aq. \parallel Zn $_x$ VTe) cells over 20 cycles.

Paper

progressive capacity decay occurred with increasing cycle number, leading to a discharge capacity of 141 mA h g⁻¹ in the 20th cycle (Fig. S7†). FESEM images of the VTe electroded revealed particle agglomeration after the 20th cycle, which could be one of the reasons for poor cycling performance (Fig. S8†). GC tests were run using different voltage windows to optimise the long-term cycling stability of VTe without any further improvement on the cycling stability (Fig. S9†). Furthermore, rate capability studies in the 0.4-1.2 V voltage window using 10-340 mA g⁻¹ current rates are shown in Fig. S10.† Although the performance of VTe was not remarkable at high rates, several approaches previously used with other Zn cathodes might be followed to improve Zn²⁺ insertion/ extraction kinetics, e.g., further structure tuning and mixing VTe with conducting carbon-based materials.32,33 This work, however, falls outside the remit of the work presented in this

Electrochemical tests using concentration (VTe||3 M ZnSO₄ aq.||Zn_xVTe) cells (Fig. 2c) were run to disregard parasitic reactions arising from the use of Zn as a counter electrode, e.g., uncontrolled dendrite formation and Zn passivation, which could be the cause for the capacity decay observed in Zn halfcells.34 Load curves showed well-defined, long, and reversible voltage plateaus at ca. 0.5 and -0.5 V upon charge and discharge, respectively. The charge capacity increased from 219 to 258 mA h g⁻¹ from the first to the second cycle, while the discharge capacity remained the same (271 mA h g⁻¹). A reversible discharge capacity of 251 mA h g⁻¹ was observed after 20 cycles, which corresponds to an excellent capacity retention of 91% (Fig. 2d). These results contrast with the poorer capacity retention observed for VTe in the Zn half-cell after 20 cycles (i.e., 61%) (Fig. S7†). Therefore, these data suggest that potential success in the implementation of VTe in AZIBs will most likely require, at least, further optimisation of the Zn anode. Despite the good capacity retention, a large voltage hysteresis was observed between the charge and discharge plateau (Fig. 2c). We attribute this large voltage hysteresis to high energetics/ structural re-ordering occurring in the material, and slow kinetics during Zn²⁺ ion (de)insertion.³⁵ This may be reduced by optimising the electrolyte solution, tailoring the crystal size, morphology, and carbon coating of the material, among others.36,37

Zn 2p XPS spectrum of the electrode after 6 h under rest conditions (OCV) confirmed the presence of Zn2+ ions by showing two asymmetric peaks with binding energies of 1021.5 and 1044.6 eV, assigned to Zn 2p_{3/2} and Zn 2p_{1/2} core levels, respectively (Fig. 3a). Furthermore, the N1s XPS spectrum of the OCV sample showed a decrease in the intensity of the N1s peak (centred at 401.77 eV in the pristine electrode and indicative of the presence of NH₄⁺ ions), which confirmed that almost all the $\mathrm{NH_4}^+$ ions acting as pillars between the $\{[\mathrm{VO_2}]_2[\mathrm{Te_2O_8}(\mathrm{OH})_2]\}^{4-}$ chains are removed at this stage (Fig. S11†). Nevertheless, it needs to be noted that XPS is a surface analysis technique and that some NH₄⁺ ions could have been trapped in the bulk structure. Therefore, these data demonstrate that VTe is not completely stable in contact with the 3 M ZnSO₄ aqueous mild electrolyte solution, and that some pre-intercalation of Zn²⁺

Fig. 3 (a) Normalised Zn-2p XPS spectra, (b) V-2p XPS spectra, and (c) Te-3d XPS spectra of VTe at different states of charge. Electrode refers to the pristine electrode and OCV, 1Dch and 1Ch refer to the electrodes extracted from the cell after resting for 6 h, 1^{st} full discharge and charge cycles, respectively. (d) EQCM and corresponding CV data of VTe-coated electrode vs. Zn²⁺/Zn at 0.1 mV s⁻¹ in 3 M ZnSO₄ electrolyte solution.

ions takes place before applying current. Charge neutrality is then achieved by the reduction of V⁵⁺ ions to V⁴⁺, as observed in the V-2p XPS spectrum (Fig. 3b), where two peaks with maxima at 517.4 and 516.3 eV that correspond to the coexistence of V⁵⁺ and V4+ oxidation states were observed.

By contrast, the V-2p XPS spectrum of the pristine electrode showed a single V 2p_{3/2} peak with a binding energy of 517.5 eV and a broader V 2p_{1/2} spin-orbit pair at higher binding energy, i.e., 524.9 eV, which are typical for V5+ ions in oxides. 6,38,39

Preliminary operando EQCM studies were conducted to identify active charge carriers during Zn2+ ion intercalation (Fig. 3d, S12 and Table S2†). During the initial stages of discharge (Region I), the mass change per charge transfer (Δm / ΔC) matched with the theoretical value of ca. 1.1 Zn²⁺ (347.89 µg C⁻¹), implying that Zn²⁺ ions were inserted in their nonhydrated form. These data agrees with the cathodic peak observed in the CV data for the reduction of V5+ ions to V4+ (Fig. 2a). Region 2, which coincides with the second cathodic peak related to the further reduction of V⁴⁺ ions to V³⁺, corresponds to a total charge value of 309 μ g C⁻¹, equivalent to the insertion of 0.9 Zn²⁺ ions. During charge, the reverse process occurs, showing extraction of only one Zn^{2+} based on the $\Delta m/\Delta C$ value measured (292 μg C⁻¹), in agreement with the Zn 2p XPS spectrum, which shows that there are remaining Zn2+ ions upon charge (Fig. 3a) and that all V3+ ions have been oxidised to V^{4+} and V^{5+} ions (Fig. 3b).

N1s XPS spectra of the fully discharged and charged electrodes showed that the removal of NH₄⁺ ions was irreversible upon Zn²⁺ intercalation (Fig. S11†). Similar behaviour was reported in (NH₄)₂V₆O₁₆·0.9H₂O, where it was noted that Zn²⁺ insertion irreversibly displaced the NH₄⁺ ions from the structure.40 FTIR data agreed with the XPS data, showing a broad peak at about 3153 cm⁻¹ corresponding to the N-H asymmetric stretching mode of the NH₄⁺ ions, which is no longer present in the fully discharged and charged states (Fig. S13†).40 Upon discharge to 0.4 V, the Zn 2p peaks present in the Zn-2p XPS spectrum of the OCV sample shifted to lower binding energies (Fig. 3a). This is explained with a more covalent environment than that in the OCV state. Concomitant to the insertion of Zn²⁺ ions into VTe, we observed a reduction of the V5+/V4+ redox couple to V⁵⁺/V⁴⁺/V³⁺, which explains the broadening and shift toward lower binding energies of the V 2p_{3/2} and V 2p_{1/2} peaks in the V-2p XPS spectrum (Fig. 3b). 6,38,39 Furthermore, EDX data showed a qualitative increase in Zn2+ ions in the discharged state compared to the charged state (Table S3†). The extra discharge capacity observed in the galvanostatic data might be accounted for the irreversible formation of insulating byproducts such as zinc hydroxide sulfate (ZHS) salts at the electrode surface due to electrolyte decomposition. 41,42 IR spectrum of the discharged sample showed strong peaks at 1055 and 1116 cm⁻¹, typically attributed to the S-O stretching bands of SO₄²⁻ moieties in the sample (Fig. S13†).⁴³

After charging to 1.4 V, we observed that the Zn $2p_{3/2}$ and Zn $2p_{1/2}$ peaks did not fully disappear in the XPS spectrum due to incomplete removal of Zn^{2+} ions (Fig. 3a), confirming the low first coulombic efficiency observed in the galvanostatic data (Fig. 2b). The Zn 2p peaks showed lower binding energy to those observed in the discharged state, which suggests weaker interactions between Zn^{2+} ions and the electrode host.⁶ Zn^{2+} ion extraction was followed by re-oxidation of the majority of the V^{4+} and V^{3+} ions to V^{5+} (Fig. 2b), further confirming the reversible reactions involving the V^{5+}/V^{4+} and V^{4+}/V^{3+} redox couples observed in the CV data shown in Fig. 2a.

Te-3d XPS spectra of VTe at the pristine state showed two peaks at 576.9 and 587 eV corresponding to the Te-3d_{5/2} and Te 3d_{3/2} core levels, respectively, and characteristic of the binding energy of Te⁶⁺ ions (Fig. 3c).⁴⁴⁻⁴⁶ At the OCV state, we observed a shift of the two peaks to lower binding energy, which we attribute to the presence of different Te environments in the electrode in contact with the electrolyte. For instance, Te⁶⁺ ions in Te(OH)6 and TeO3 have binding energies of 576.7 and 577.3 eV.45,47 Upon full discharge, these peaks further shifted to lower binding energies, i.e., 576 and 586.4 eV and two additional peaks with maxima at 577.7 and 588.2 eV appeared, which might be attributed to a change in the valence state of Te⁶⁺ to Te⁴⁺. Nevertheless, given the different forms in which Te⁶⁺ can be present, detailed research is required to unambiguously assigned those peaks to Te⁴⁺. On the other hand, at the fully charged state, the peaks associated with the Te-3d_{5/2} and Te3d_{3/2} showed almost identical binding energies to those observed at the OCV state, suggesting a reversible process.

Ex situ XRD studies were performed on VTe electrodes at different charge states to understand the structural changes

taking place during the first cycle (Fig. S14†). XRD data, showed structural changes occurring in the material during the first discharge process, guided by the presence of new main diffraction peaks at 11.9°, 32.3° and 35.6° 2θ (marked with a star symbol). Attempts to model the structure of the fully reduced phase were carried out using Expo2014 software.^{49,50} The best possible solution found yielded a phase with a monoclinic crystal structure and lattice parameters a=9.67 Å, b=7.44 Å and c=4.66 Å; α , $\gamma=90^\circ$ and $\beta=92.3^\circ$. No traces of crystalline impurities were observed in the XRD data despite the presence of IR peaks originating from ${\rm SO_4}^{2-}$ ions. Therefore, it is likely that these sulfate-containing compounds are amorphous (Fig. S13†).

XRD data of the charged electrode showed a clear loss of crystallinity in the material, as reflected by the peak broadening observed in the diffraction pattern. Nevertheless, some of the diffraction peaks observed in the discharged product were still present, showing that the structure is kept after charge. A detailed diffraction study of the effects of Zn²⁺ insertion/extraction in this material is still required. Based on the above-mentioned experimental results, we propose that the following reactions occur during OCV (eqn (4)), and first discharge (eqn (5)) and charge processes (eqn (6)):

Cathode at the OCV state:

$$(NH_4)_4\{(VO_2)_2[Te_2O_8(OH)_2]\} \cdot 2H_2O + xZn^{2+} \rightarrow (NH_4)_{4-z}Zn_x\{(VO_2)_2[Te_2O_8(OH)_2]\} \cdot nH_2O + zNH_4^+$$
(4)

Cathode during the first discharge:

$$(NH_4)_{4-z}Zn_x\{(VO_2)_2[Te_2O_8(OH)_2]\} \cdot nH_2O + (4-x+y)Zn^{2+} \rightarrow Zn_4(VO_2)_2Te_2O_{8+z}(OH)_{2-z} \cdot nH_2O + (4-z)NH_4^+$$
 (5)

Cathode during the first charge:

$$Zn_4(VO_2)_2Te_2O_{8+z}(OH)_{2-z} \cdot nH_2O \rightarrow Zn_{4-x}(VO_2)_2Te_2O_8(OH)_2 \cdot nH_2O$$
 (6)

4. Conclusions

In conclusion, we tested (NH₄)₄{(VO₂)₂[Te₂O₈(OH)₂]}·2H₂O as a cathode material in AZIBs. Reversible Zn²⁺ ion intercalation in the material is attainable due to the presence of redox centres and large spacing between the 1D $\{[VO_2]_2[Te_2O_8(OH)_2]\}^{4-}$ chains. To the best of our knowledge, this is the first-ever reported vanadium tellurate(vi) tested as a positive electrode in AZIBs. The material shows a remarkable discharge capacity of ca. 283 mA h g^{-1} in the 0.4–1.4 V vs. Zn^{2+}/Zn voltage range, using a current density of 10 mA g⁻¹. Furthermore, in concentration cells, VTe shows excellent cycling stability, retaining about 91% of its initial discharge capacity after 20 cycles. Despite the promising results, improvements to the present work are under progress and include various strategies, such as the optimisation of suitable electrolyte formulations, where the V⁵⁺ state remains stable and prevents the pre-insertion of Zn2+ ions, and cycling with a modified Zn anode in a half-cell. Nevertheless, we

believe that these results provide great opportunities for the exploration of this material and family-related compounds as energy storage materials for AZIBs.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

NTR is indebted to the Royal Society (RG170150), Faraday Institution (FIRG018), Energy Lancaster and Lancaster University for financial support. We are grateful to Dr Sara Baldock for assistance with SEM data collection and Dr Nathan Halcovitch for his help with elemental analysis. XPS data collection was performed at the EPSRC National Facility for XPS ("HarwellXPS"), operated by Cardiff University and UCL, under Contract No. PR16195. ZS would like to thank the Czech Science Foundation (GACR No. 20-16124J) for financial support.
