# Probing the role of surface activated oxygen species of CeO<sub>2</sub> nanocatalyst during the redox cycle in CO oxidation†

Ruishi Zhang,<sup>‡a</sup> Xiaoyuan Liu,<sup>‡b</sup> Hai Liang,<sup>a</sup> Xijun Yang,<sup>a</sup> Jing Li,<sup>cd</sup> Wenfeng Ye,<sup>de</sup> Xiaomin Wang<sup>\*a</sup> and Baodan Liu<sup>ib\*cd</sup>

The oxygen species of CeO<sub>2</sub> nanocatalysts plays a key role in the CO oxidation. In this work, nanocrystalline CeO<sub>2</sub> with infrared spectroscopy detectable surface superoxide (O<sub>2</sub><sup>−</sup>) species at room temperature is fabricated and CO oxidation is used as a probe reaction for the exploration of the characteristics of surface O<sub>2</sub><sup>−</sup> species on the CeO<sub>2</sub> surface. We discover that the surface O<sub>2</sub><sup>−</sup> species have ignorable influences on the overall reaction rate of CO oxidation on pure ceria by comparing P-CeO<sub>2</sub> (CeO<sub>2</sub> prepared by precipitation method) with HT-CeO<sub>2</sub> (CeO<sub>2</sub> prepared by hydrothermal method). It is concluded that the reaction between CO molecules and surface O<sub>2</sub><sup>−</sup> species is the first and the fast step in the whole redox cycle, while the release of surface lattice oxygen is the second and the rate determining step of the catalysts. This work gives an intuitionistic exploration on the redox properties of pure nanocrystalline CeO<sub>2</sub> with surface O<sub>2</sub><sup>−</sup> species and reveals the influences of these species in the whole redox circle of CO oxidation.

## Introduction

Ceria is one of the most attractive materials in the catalysis industry (three-way catalysts, CO oxidation, *etc.*) due to its excellent oxygen storage/release capacity (OSC/ORC).<sup>1,2</sup> As a typical reducible oxide, pure ceria is n-type catalyst which usually shows weaker CO oxidation capability than those p-type oxides (Co<sub>3</sub>O<sub>4</sub>, CuO, NiO, *etc.*).<sup>3–5</sup> However, the considerable amount of oxygen vacancies on the surface lead to diverse absorption features of non-stoichiometrical ceria.<sup>6</sup> Thus, the non-stoichiometrical ceria loaded with noble metal nanoparticles is usually applied in varieties of selective catalytic reactions.<sup>7,8</sup>

Over the past few decades, the preparation of nanocrystalline ceria with tunable catalytic properties greatly boosts the usage

of it in catalytic chemistry.<sup>9–12</sup> Nanocrystalline ceria owns huge surface area and much higher degree of non-stoichiometry features than bulk one.<sup>13</sup> These merits favor the formation of surface defects and lead to a significant enhancement of OSC/ORC of nanocrystalline ceria. For example, Avelino *et al.* reported Au loaded nanocrystalline CeO<sub>2</sub> shows two orders of magnitude reaction rate than Au loaded bulk ceria.<sup>14</sup> Very recently, researchers discovered the existence of activated oxygen (O<sub>x</sub><sup>y</sup> (2 ≤ x ≤ 3, −2 ≤ y ≤ 0)) on the surface of nanocrystalline ceria at room temperature (RT), which is usually regarded as catalytically active component.<sup>15</sup> Previous works have demonstrated the oxygen release under low temperatures (~400 °C) using H<sub>2</sub>-TPR measurement and attributed it to the existence of superoxide ions (O<sub>2</sub><sup>−</sup>) verified by electron paramagnetic resonance (EPR) spectral methods.<sup>16–19</sup> Since then, extensive experimental efforts in combination with computer studies are applied to examine the existence of activated oxygen and this phenomenon is mostly regarded as an exclusive character of CeO<sub>2</sub> nanocrystals.<sup>20,21</sup> However, H<sub>2</sub>-TPR test could only reflect the reducibility of nanocrystalline CeO<sub>2</sub>, while the role of ceria in catalytic converters is actually more complex than that of a simple oxygen capacitor. Therefore, a complete catalytic reaction including both reduction and oxidation at the same time on the surface of the catalysts should be designed, and the influence of “activated oxygen” on the CO oxidation of nanocrystalline CeO<sub>2</sub> should be systemically investigated.

In this regard, we fabricated two types of ultra-small ceria nanoparticles: CeO<sub>2</sub> polyhedron with O<sub>2</sub><sup>−</sup> species at room temperature prepared by precipitation method (P-CeO<sub>2</sub>) and

CO oxidation reaction was performed at atmospheric pressure in a tubular quartz reactor. For each test, 80 mg of catalysts was diluted through the addition of 500 mg quartz sand, after then, silica wool was put in both end of the catalysts. The feed gas was kept at a lean CO condition (ratio of partial pressure:  $p(\text{CO}) = 0.998\%$ ,  $p(\text{O}_2) = 20.04\%$ ) using He as the balance gas. The total gas flow rate was maintained at 10 sccm using mass flowmeters (HORIBA METRON S49 32/MT). An online gas chromatograph (FULI INSTRUMENTS GC9790Plus) equipped with automatic six-way valve in combination with thermal conductivity detector (TCD) was used to analyze the feeding gas.

## Results and discussion

Fig. 1 shows the structure information of all three types of  $\text{CeO}_2$  nanostructures used in this work. It can be seen that all the  $\text{CeO}_2$  nanocatalysts are well crystallized and show cubic structure. There is no any impurity peak in XRD pattern, indicating the good phase purity of as-synthesized HT- $\text{CeO}_2$  and P- $\text{CeO}_2$ , as well as commercial C- $\text{CeO}_2$ . From Fig. 1b we can find the peak position and the full width at half maximum (FWHM) of cubic P- $\text{CeO}_2$  and HT- $\text{CeO}_2$  nanoparticles show high consistency in crystallographic symmetry and phase purity. Fig. 1c shows the particle size distribution of HT- $\text{CeO}_2$  nanocubes and we can also calculate the average particle radius of 5.13 nm of HT- $\text{CeO}_2$  through a simple statistical analysis. From Fig. 1b, we can also notice that the purchased C- $\text{CeO}_2$  shows much sharper peaks and the peak position shifts slightly towards the high angle direction. All these differences indicate that P- $\text{CeO}_2$  and HT- $\text{CeO}_2$  show obvious lattice expansion due to the size effect, as observed in Fig. 1d.<sup>22</sup>

The morphologies and exposed facets of P-CeO<sub>2</sub>, HT-CeO<sub>2</sub> and C-CeO<sub>2</sub> are also elaborately investigated using SEM and TEM techniques since the catalytic properties of CeO<sub>2</sub> nanocrystals are strongly dependent on the surface active sites.<sup>23,24</sup> For HT-CeO<sub>2</sub> before annealing treatment, a uniform

Figure 1 consists of three panels (a, b, d) illustrating the structural and morphological characteristics of the synthesized  $\text{CeO}_2$  samples.

**(a) XRD patterns:** The plot shows the intensity (a.u.) versus  $2\text{-Theta}$  ( $^\circ$ ) for three samples: HT- $\text{CeO}_2$  (top, red), P- $\text{CeO}_2$  (middle, orange), and C- $\text{CeO}_2$  (bottom, black). The patterns show characteristic peaks for  $\text{CeO}_2$  (JCPDS No. 03-065-0104), with the (111), (200), (220), (311), (400), (311), and (421) planes indexed. The C- $\text{CeO}_2$  pattern shows sharper peaks compared to the HT- and P- $\text{CeO}_2$  samples, indicating higher crystallinity.

**(b) Magnified XRD patterns:** The plot shows the intensity (a.u.) versus  $2\text{-Theta}$  ( $^\circ$ ) for the (111) and (200) peaks of HT- $\text{CeO}_2$  (red), P- $\text{CeO}_2$  (orange), and C- $\text{CeO}_2$  (black). The C- $\text{CeO}_2$  peaks are significantly sharper and more intense than those of the HT- and P- $\text{CeO}_2$  samples, further confirming its higher crystallinity.

**(d) Size distribution:** The plot shows the percentage (%) versus size (nm) for the three samples. The size distribution is bimodal for all samples, with peaks around 2-3 nm and 4-5 nm. The C- $\text{CeO}_2$  sample shows a higher percentage of larger particles (4-5 nm) compared to the HT- and P- $\text{CeO}_2$  samples.

**(e) Lattice spacing ( $d_{(111)}$ ) versus size:** The plot shows the lattice spacing  $d_{(111)}$  (nm) versus size (nm) for the three samples. The lattice spacing decreases as the particle size increases, following a linear trend. The C- $\text{CeO}_2$  sample has the largest size and the smallest lattice spacing, while the HT- and P- $\text{CeO}_2$  samples have smaller sizes and larger lattice spacings.

**Fig. 1** (a and b) XRD patterns of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub>, C-CeO<sub>2</sub>; (c) the particle size distribution of HT-CeO<sub>2</sub> nanocubes; the calculated average particle size is 5.13 nm; (d) the plot of (111) interplanar spacing of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub> as a dependence of particle size.

Fig. 2 TEM bright field images, HRTEM images and their corresponding FFT patterns of (a–c) HT-CeO<sub>2</sub> nanocube before annealing; (d–f) HT-CeO<sub>2</sub> after 400 °C annealing; and (g–i) P-CeO<sub>2</sub>.

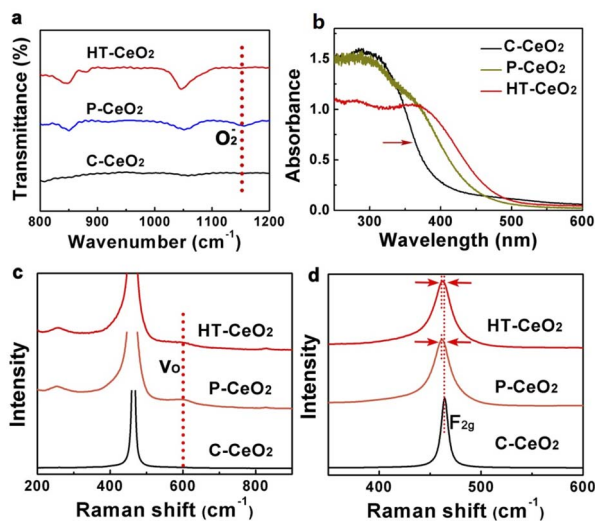

distribution of ultra-small cubic nanoparticles can be observed from the TEM bright-field image (Fig. 2a). The HT-CeO<sub>2</sub> exhibits an obvious single crystal nature and the interplanar distance of HT-CeO<sub>2</sub> from the direct measurement in HRTEM image (Fig. 2b) matches well with *d*-spacing of (002) plane in cubic CeO<sub>2</sub> (JCPDS no. 34-0394; *a* = *b* = *c* = 5.41 Å) and in good combination with the result obtained from the fast Fourier transform (FFT) pattern taken along [−100] zone axis (Fig. 2c). In addition, the main exposed facets of CeO<sub>2</sub> nanocube can be confirmed to be (001) crystalline planes. After 400 °C annealing in air, the crystal grain size becomes larger (10.9 nm, Fig. 2d) and the proportion of (111) exposed facets increases (Fig. S1†). Further annealing the CeO<sub>2</sub> nanocubes at 650 °C in Ar can cause fierce crystal growth and particle agglomeration. Moreover, the (111) facets evolve into the main exposed facets of HT-CeO<sub>2</sub> (Fig. S2†). Similarly, the P-CeO<sub>2</sub> also shows a polyhedral morphology with (002) and (111) exposed facets (Fig. 2g, h and S3†). Both annealed HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> are well crystallized, as confirmed by the clear lattice images and their corresponding FFT patterns (Fig. 2f and i).

For comparative study, the morphology of commercially purchased CeO<sub>2</sub> (C-CeO<sub>2</sub>) is also presented (Fig. S4†). The similarity of size and shape between P-CeO<sub>2</sub> and HT-CeO<sub>2</sub>

allows us to make a comparative investigation on the O<sub>2</sub><sup>−</sup> species. The ultra-small HT-CeO<sub>2</sub> shows no 400 °C peak in IR spectrum at RT (Fig. 3a). It is understood that the surface of HT-CeO<sub>2</sub> is fully covered with oleic acid during the hydrothermal reaction, and the oleic acid layer is finally converted into surface carbonates after subsequent annealing, which can be confirmed by IR measurement (Fig. S5†).<sup>25</sup> Contrast to HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> shows a characteristic IR peak at around 1150 cm<sup>−1</sup>, which originates from O<sub>2</sub><sup>−</sup> species.<sup>26</sup> It is known that the surface carbonates are spectators in a certain CO oxidation process and the possibilities of side reaction involving surface carbonates can be eliminated.<sup>25</sup> The Brunauer–Emmett–Teller (BET) surface area value of P-CeO<sub>2</sub> and HT-CeO<sub>2</sub> is also similar (Table 1), which is much larger than that of C-CeO<sub>2</sub>. From the isothermal adsorption–desorption curves shown in Fig. S6,† we can see that all the three CeO<sub>2</sub> nanocatalysts show a typical type IV curve, but the N<sub>2</sub> adsorption behaviour in the three catalysts is different. At low pressure, the C-CeO<sub>2</sub> shows the weakest N<sub>2</sub> adsorption, while the HT-CeO<sub>2</sub> exhibits the best; at medium and high pressure, the C-CeO<sub>2</sub> and P-CeO<sub>2</sub> show more obvious hysteresis compared with HT-CeO<sub>2</sub>. Then we can conclude the proportion of micropores of HT-CeO<sub>2</sub> is higher than that of P-CeO<sub>2</sub> while the P-CeO<sub>2</sub> sample owns a higher amount of

**Fig. 3** (a) FT-IR spectra of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub>, the peak at 1150 cm<sup>-1</sup> of P-CeO<sub>2</sub> indicates the existence of superoxide; (b) diffuse reflectance UV-Vis spectroscopy of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub>; (c and d) normalized Raman spectra of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub>, the Raman shift at 600 cm<sup>-1</sup> corresponds to the oxygen vacancy and the red shift of F<sub>2g</sub> peaks of P-CeO<sub>2</sub> and C-CeO<sub>2</sub> indicates the lattice relaxation caused by size effect.

**Table 1** Average size, *d*-spacing of (111) lattice plane and BET surface areas of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub>

Sample	Size (nm)	<i>d</i> <sub>(111)</sub> (Å)	<i>S</i> <sub>BET</sub> (m <sup>2</sup> g <sup>-1</sup> )
HT-CeO <sub>2</sub>	10.8	3.142	100.19
P-CeO <sub>2</sub>	11.9	3.140	81.67
C-CeO <sub>2</sub>	>1000	3.123	5.93

mesopores. In addition, from Table 1 we can see that the particle size of P-CeO<sub>2</sub> and HT-CeO<sub>2</sub> is maintained at approximately the same value (11.8 nm for P-CeO<sub>2</sub> and 10.9 nm for HT-CeO<sub>2</sub>), which is calculated through the FWHM of (111) peak in XRD patterns using Scherrer equation (Fig. 1a).

Ceria is best-known for its excellent OSC/ORC and the oxygen species including oxygen vacancy, lattice oxygen and absorbed oxygen show significant influence on the catalytic performance.<sup>27,28</sup> For nanosized ceria, there are also a considerable amount of oxygen vacancies spontaneously generated on the surface and in body at room temperature except for superoxide adsorption. Oxygen vacancy is an intrinsic defect which has a strong influence on the optical property of nanocrystalline ceria. UV-Vis spectroscopy is used to qualitatively detect these defects in CeO<sub>2</sub> samples (Fig. 3b). It can be seen that the C-CeO<sub>2</sub> shows an optical absorption edge near 380 nm (3.26 eV), which can be understood as the electron hopping from O 2p orbit to Ce 4f orbit.<sup>29,30</sup> Both HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> samples exhibit an obvious red-shift and broadened absorption edge against C-CeO<sub>2</sub>, which is somehow contradicted to the blue-shift result obtained by other groups.<sup>19</sup> Considering the ultra-small size (~10 nm) of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub>, the effect of exciton-LO-phonon coupling can be employed to explain the red-shift of

UV-Vis absorption edge. Exciton-LO-phonon coupling is induced by the large number of defects in ceria and can influence the carrier effective mass and carrier scattering by the lattice.<sup>31</sup> According to the theory of Kazunori *et al.*<sup>32</sup> and the experimental results of other groups, this exciton-LO-phonon effect enhances with the increase of quantum-dot radius and can lead to the broadening and the red-shift of adsorption edge.<sup>9,31</sup> When the CeO<sub>2</sub> size is smaller (*i.e.* 4.6 nm), the quantum confinement effect will play the key role to induce the blue-shift.<sup>19</sup> To further convince our results, Raman spectroscopy is also used to ascertain the existence of oxygen vacancies (Fig. 3c and d). We can see the existence of oxygen vacancy peaks (600 cm<sup>-1</sup>) and the slight red-shift of F<sub>2g</sub> peaks of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> compared with C-CeO<sub>2</sub>, which originates from the lattice expansion induced by oxygen vacancies.<sup>33,34</sup> The degree of lattice expansion in the three types of CeO<sub>2</sub> can be quantitatively evaluated through the XRD data in the sequence of:

$$d(\text{HT-CeO}_2) > d(\text{P-CeO}_2) > d(\text{C-CeO}_2)$$

To further determine and quantitatively measure the surface species of ceria, XPS experiment is carried out (Fig. 4a–c). There are two C 1s peaks detected in HT-CeO<sub>2</sub> and P-CeO<sub>2</sub>, which can be classified as C pollution (284.6 eV, C–C, C–H bonds) and O–C=O species (288.6 eV). The peak of O–C=O species in P-CeO<sub>2</sub> further verifies the existence of surface carbonates. Considering the absence of carbon reagent during P-CeO<sub>2</sub> preparation, the surface carbonates are probably formed through the participation of CO<sub>2</sub> from atmosphere during annealing. Further annealing treatment in Ar at 650 °C can fully remove these surface carbonates (Fig. S7†). However, the particle size becomes larger due to the aggregation and the quantum size effect vanishes subject to the high temperature annealing. Even so, the carbonate peaks of P-CeO<sub>2</sub> are weaker than that of HT-CeO<sub>2</sub> (Fig. 4a). The smaller carbonate coverage

**Fig. 4** (a–c) C 1s, O 1s and Ce 3d XPS peaks of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub>.

gives way to the exposure of super oxide species of P-CeO<sub>2</sub> sample. To further analyse the chemical valence of Ce ion, the Ce XPS peak is split into Ce<sup>3+</sup> and Ce<sup>4+</sup> based on their featured binding energy position and the details of XPS curve fitting can be found in ESI.† It can be seen that both Ce<sup>3+</sup> and Ce<sup>4+</sup> species are detected in all samples, and the peaks located at 899.1, 881.1, 903.2 and 885.0 eV (Table S1†) correspond to the v<sup>0</sup>, u<sup>0</sup>, v' and u' shake-down final states of Ce<sup>3+</sup>, while the other six peaks centered at 882.4, 901.0, 888.5, 907.3, 898.1 and 916.5 eV can be classified as the v, u, v'', u'' and v''', u''' shake-down final states of Ce<sup>4+</sup> (Fig. 4c).<sup>35,36</sup> The Ce<sup>3+</sup> species are originated from the simultaneously formed oxygen vacancies, which means that one oxygen vacancy will create two Ce<sup>3+</sup> sites and result in the non-stoichiometry of ceria. The quantitative proportion of surface Ce<sup>3+</sup> (Ce<sup>3+</sup>/Ce percentage) can be calculated to 7.97% for C-CeO<sub>2</sub>, 28.43% for P-CeO<sub>2</sub> and 28.15% for HT-CeO<sub>2</sub>, respectively.<sup>36</sup> Three O 2s peaks located at around 529.4, 531.6 and 532.8 eV are also detected in all samples (Fig. 4b). The O 1s peak located at around 529.4 eV corresponds to lattice oxygen for all samples. The 531.6 eV peak can be indexed to the oxygen vacancy for HT-CeO<sub>2</sub> and C-CeO<sub>2</sub>. It has been reported that the position of oxygen vacancy peak and super oxygen peak are identical.<sup>37</sup> Considering the existence of O<sub>2</sub><sup>-</sup> on P-CeO<sub>2</sub> surface, the peak at 531.6 eV of P-CeO<sub>2</sub> should be classified as the combination of surface O<sub>2</sub><sup>-</sup> and oxygen vacancy. The peak at around 532.8 eV is usually regarded as surface hydroxy.<sup>19,38</sup> While for P-CeO<sub>2</sub> and HT-CeO<sub>2</sub> in this work, this peak should originate from the combination of surface hydroxy and surface carbonate. Correspondingly, the proportions of surface oxygen vacancies are 10.18% for C-CeO<sub>2</sub> and 26.75% for HT-CeO<sub>2</sub>, respectively. It should be noted that the value 23.72% is the combination of oxygen vacancies and O<sub>2</sub><sup>-</sup> species for P-CeO<sub>2</sub>. Based on XPS results, we can find the remarkable enhancement of Ce<sup>3+</sup> and oxygen vacancies on the surface of nanoceria due to the lower oxygen vacancy formation energy at the low coordinated sites and the smaller bond strength of nanoceria. The result is also in good agreement with the studies of other groups.<sup>19,37,39</sup>

Finally, we evaluated the CO oxidation properties of three CeO<sub>2</sub> samples under lean CO conditions (excessive oxygen). The light-off curves of HT-CeO<sub>2</sub> show the best CO oxidation ability ( $T_{50}$ : 273 °C, Table S2†) without performance decay during 12 h period at 287 °C (Fig. 5). The P-CeO<sub>2</sub> sample shows a little bit higher conversion temperature at  $T_{50}$  and the slower reaction rate than that of HT-CeO<sub>2</sub>. The catalytic performance of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> samples are both much higher than C-CeO<sub>2</sub> because of the larger surface area of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> and more exposed active sites. Additionally, the HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> contain larger proportions of low coordinated Ce ions and larger amount of surface oxygen vacancies than C-CeO<sub>2</sub>, which can remarkably reduce the vacancy formation energy.<sup>22,40,41</sup> As a result, the CO oxidation temperature of nanoceria could be distinctly reduced compared with that of commercial C-CeO<sub>2</sub>. We also calculate the activation energy ( $E_a$ ) of all three samples according to the Arrhenius plots and find that the HT-CeO<sub>2</sub> shows the lowest  $E_a$  of 48.6 kJ, followed by P-CeO<sub>2</sub> (55.4 kJ). It should be noted that the calculation is based on the premise

Fig. 5 (a) Light-off curves of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub>; (b) reaction rates of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub>; (c) Arrhenius plots of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub>; (d) catalytic stability experiment of HT-CeO<sub>2</sub> in a period of 12 hours; (e) reaction rates of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> based on surface areas. Reaction conditions: catalyst, 80 mg;  $p(\text{CO})$ : 0.998%;  $p(\text{O}_2)$ : 20%; gas flow rate: 10 mL min<sup>-1</sup>.

that the concentrations of adsorbed reacting species on CeO<sub>2</sub> nanocatalysts is constant in the investigated temperature range. Taking into account the strong surface effect during CO oxidation on HT-CeO<sub>2</sub> and P-CeO<sub>2</sub>, we can also calculate the reaction rates based on surface area (Fig. 5e) and the obtained values of HT-CeO<sub>2</sub> and P-CeO<sub>2</sub> exhibit high degree of consistence. It seems that the surface O<sub>2</sub><sup>-</sup> species have no influence on the overall CO oxidation rate of P-CeO<sub>2</sub>. IR test (Fig. S8†) is further implemented on P-CeO<sub>2</sub> after CO oxidation and a noticeable difference is found that the O<sub>2</sub><sup>-</sup> peak has been vanished. It should be noted that the O<sub>2</sub><sup>-</sup> species can also form at the surface of ceria at relatively high temperature. Soria *et al.*<sup>17</sup> reported that the O<sub>2</sub><sup>-</sup> forms under the temperature higher than 300 °C, but disappears at room temperature. Therefore, it can be asserted that the O<sub>2</sub><sup>-</sup> species on P-CeO<sub>2</sub> (11.8 nm) is not so stable at room temperature.

Herein a probable reaction route is proposed for the explanation of CO oxidation on nanoceria with O<sub>2</sub><sup>-</sup> species (Fig. 6). According to the molecular orbital theory, the bond energy of O<sub>2</sub><sup>-</sup> is weaker than O<sub>2</sub> because the bond order of O<sub>2</sub><sup>-</sup> (1.5) is smaller than O<sub>2</sub> (2.0). For this reason, the O<sub>2</sub><sup>-</sup> species on P-CeO<sub>2</sub> will firstly react with CO under relatively lower temperature and leave a lattice oxygen, which can be considered as the fast reaction step in the whole redox cycle. The remaining lattice oxygen then reacts with CO and creates an oxygen vacancy on the surface. In this step, the desorption of CO<sub>2</sub> requires the

Fig. 6 Schematic diagram describing the reaction route of O<sub>2</sub><sup>-</sup> contained P-CeO<sub>2</sub> in the whole redox cycle during CO oxidation.

bond-breaking of Ce–O. According to previous work, the energy barrier for CO<sub>2</sub> desorption in this step is around 2.17 eV, while the energy barrier involves O–O bond-breaking is about 0.84 eV.<sup>7</sup> The formation rate of oxygen vacancy tends to be very low especially at low temperature due to the high oxygen vacancy formation energy. Hence, the second reaction should be the rate determining step. Finally, the oxygen molecules are chemisorbed on oxygen vacancies to form new O<sub>2</sub><sup>-</sup> species at elevated temperatures.

## Conclusions

In summary, the CO oxidation as a probe reaction for evaluating catalytic performance of HT-CeO<sub>2</sub>, P-CeO<sub>2</sub> and C-CeO<sub>2</sub> has been designed and carried out. It has been found that there is no apparent catalytic performance improvement in O<sub>2</sub><sup>-</sup> contained P-CeO<sub>2</sub>. The CO oxidation rate should be directly governed by the second step including the Ce–O bond-breaking along with oxygen vacancy formation. Finally, it should be noted that in our experiment, although the synthesized P-CeO<sub>2</sub> powders owns O<sub>2</sub><sup>-</sup> species under room temperature, these superoxide ion species are unstable and show low fraction of coverage on the surface of the 11.8 nm P-CeO<sub>2</sub>. It is expected that CeO<sub>2</sub> nanoparticles (no larger than 10 nm) with ultra clean surface and superior thermal stability at 400 °C will be ideal candidate for further investigation of the surface O<sub>x</sub><sup>y</sup> (2 ≤ x ≤ 3, -2 ≤ y ≤ 0) species in CO oxidation. It is believed that this study can expand the understanding of the influences of surface O<sub>2</sub><sup>-</sup> species on the catalytic properties of nanocrystalline ceria in a whole redox cycle and will put forward references for the catalytic study in the system of metal/CeO<sub>2</sub>, and so forth.
