Defect engineering in semiconductor-based SERS

Ge Song,[ab] Shan Cong [iD][acd] and Zhigang Zhao [iD] *[abc]

Semiconductor-based surface enhanced Raman spectroscopy (SERS) platforms take advantage of the multifaceted tunability of semiconductor materials to realize specialized sensing demands in a wide range of applications. However, until quite recently, semiconductor-based SERS materials have generally exhibited low activity compared to conventional noble metal substrates, with enhancement factors (EF) typically reaching 10^3, confining the study of semiconductor-based SERS to purely academic settings. In recent years, defect engineering has been proposed to effectively improve the SERS activity of semiconductor materials. Defective semiconductors can now achieve noble-metal-comparable SERS enhancement and exceedingly low, nano-molar detection concentrations towards certain molecules. The reason for such success is that defect engineering effectively harnesses the complex enhancement mechanisms behind the SERS phenomenon by purposefully tailoring many physicochemical parameters of semiconductors. In this perspective, we introduce the main defect engineering approaches used in SERS-activation, and discuss in depth the electromagnetic and chemical enhancement mechanisms (EM and CM, respectively) that are influenced by these defect engineering methods. We also introduce the applications that have been reported for defective semiconductor-based SERS platforms. With this perspective we aim to meet the imperative demand for a summary on the recent developments of SERS material design based on defect engineering of semiconductors, and highlight the attractive research and application prospects for semiconductor-based SERS.

1. Introduction

SERS is an analytical tool used for obtaining fingerprint chemical information of a given surface *via* Raman spectroscopy. The non-destructive, ultrasensitive and generally rapid features afforded by the technique have attracted wide interest in the fields of materials, catalysis, biology and medicine. Conventionally, noble metal materials such as Au and Ag nanoparticles have been widely applied in SERS research. Noble metal nanoparticles, which exhibit inherently prominent localized surface plasmonic resonance (LSPR) activity, are often

Ge Song obtained her BSc in Chemistry from China Agricultural University and an MSc in Chemistry from Bristol University. She is now a PhD student at the University of Science and Technology China. Her research interests are inorganic nanomaterials and their SERS activities.
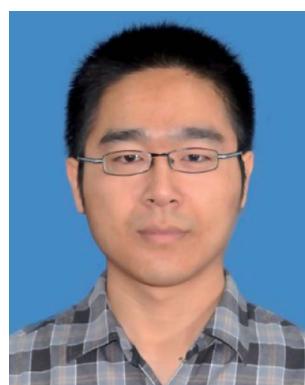

Shan Cong is a Professor at Suzhou Institute of Nanotech and Nanobionics, CAS, and a member of the Youth Innovation Promotion Association, CAS. He received his PhD from Zhejiang University in 2011. His research interests include the synthesis of low-dimensional nanocrystals and their applications in surface-enhanced Raman scattering (SERS) and photocatalysis.
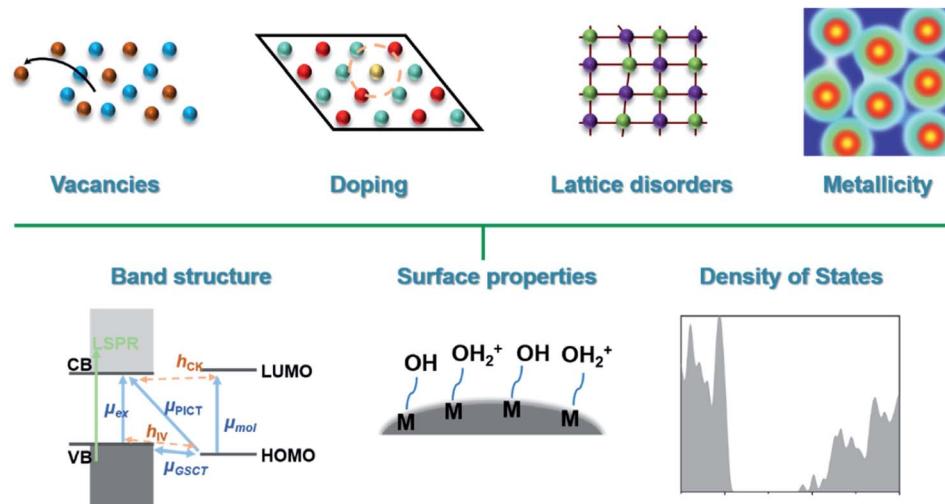

Scheme 1 Depiction of the main categories of defects in SERS–active semiconductors and material parameters that are influenced by defect engineering.

assembled into arrays to further induce strong EM enhancement, and have been used in the detection of probe molecules such as DNA structures, pesticide residues and small organic molecules.[1–6] However, noble metal-based substrates have also met challenges, such as high cost, difficulty of mass production, instability, and lack of selectivity.[7] As a relatively new branch of SERS research, semiconductors have been speculated as ideal SERS materials due to their multifaceted tunability, wide variety and easy accessibility.[8–24] It is speculated that semiconductor-based SERS substrates may complement noble metals by allowing for a wider selection of SERS-active materials, improved selectivity to probe molecules and reproducible mass production of SERS substrates. Based on the tuning of the band structure, selective interfacial interactions and signal enhancement can be produced towards specific probe molecules, while the tuning of surface properties and density of states (DOS) can result in more effective and reliable enhancement. These properties make semiconductors potentially valuable in the construction of specialized SERS platforms.

Zhigang Zhao is a Professor at Suzhou Institute of Nanotech and Nanobionics, Chinese Academy of Sciences. He received his PhD from Institute of Metal Research, Chinese Academy of Sciences in 2006, and did postdoctoral research at Dayton University (USA), Osaka University (Japan) and the National Institute of Advanced Industrial Science and Technology (AIST, Japan) from 2006 to 2011. His research interests include novel surface-enhanced Raman spectroscopy (SERS)-active materials and their applications.

However, due to the relative complexity of principles responsible for semiconductor-based SERS phenomena, the activation of SERS in semiconductors has for a long time been a great challenge. For this reason, strategies for designing highly SERS-active semiconductor substrates are urgently needed.

Defect engineering, which has long been well-established in the study of semiconductor materials, provides a series of ubiquitously effective strategies for activating and boosting the innate SERS activity of semiconductors. Defect engineering comprises a series of techniques that purposefully aim to break the periodic arrangement of atoms, and can be loosely divided into point defects and disorders of higher dimensions. Generally, they alter the band structure, surface properties and density of states of semiconductors, endowing semiconductors with enhanced light-trapping ability, surface interactions or charge-transport efficiency, which directly influence the SERS effect. Charge transfer (CT) processes, which are a dominant aspect of CM principles behind semiconductor-based SERS, directly benefit from the defect-induced physicochemical changes to semiconductors, thereby making defect engineering widely applicable and highly versatile for semiconductor-based SERS. As a result of recent research efforts, a myriad of SERS-active semiconductor substrates have emerged, which have creatively exploited defect engineering techniques, broadening the insight into defect engineering and mechanisms behind SERS. In addition to fundamental research interest, sensitive and selective SERS responses towards analyte species ranging from inorganic molecules to large molecular superstructures have been obtained, with presently reported EF reaching 10^8,[25] showing great promise for the practical application of semiconductor-based SERS.

This perspective targets the imperative need for a systematic summary of the rational design of defective semiconductors that have emerged over recent years, which encompass several major categories of materials including metal oxides, nitrides, transition metal dichalcogenides (TMDs) and carbon materials. Furthermore, the linkage of various defects to SERS activity is

discussed by identifying the three main material parameters that are affected by defect engineering, namely, the band structure, surface active sites and DOS (Scheme 1). The applications of such defective semiconductors as SERS platforms are also introduced, stretching across multiple disciplines such as trace sensing for food and environmental safety, biological sensing, reaction monitoring and CT characterization in chemical cells. The aim is to elucidate recent developments in the mechanistic principles of SERS, and defect engineering strategies available to researchers, in the hope that fellow researchers may be well-equipped in the search for SERS-activating strategies and deploying semiconductor-based SERS platforms in real-world applications.

2. Defect engineering strategies for SERS-active semiconductors

In this section the types of defects and their influences on the SERS activity of semiconductors are discussed. The classification of defects is usually based on the dimensionality of defects. Here, we examine the four types of defects most relevant to current research on the engineering of SERS-active semiconductors. However, it is worth noting that research into defect engineering extends far beyond these four categories, and there is yet much to be understood about the relationship between different defective structures and the chemical enhancement processes responsible for SERS activity. A summary of all materials discussed in this section is presented in Table 1.

2.1 Vacancies

Vacancies, the most well-studied type of defect in semiconductors, result from missing atoms in a crystal lattice. Although both metal and anionic vacancies can occur simultaneously in order to balance the charge within the lattice, nevertheless the types of vacancies are herein identified by their predominant occurrence, based on the final stoichiometry of the defective material as compared with that of its pristine counterpart.

Table 1 SERS-active semiconductors prepared with different defect strategies and reported SERS performance

| Defect types | Materials | Molecules | Reported SERS performance | | Ref. |
			EF	LOD	
Vacancies	$H_2/Ar\text{-}W_{18}O_{49}$	R6G	3.4×10^5	1×10^{-7} mol L^{-1}	26
	Cu_2O	4-MPY		5×10^{-10} mol L^{-1}	27
	WO_{3-x}	R6G	1.1×10^4	1×10^{-7} mol L^{-1}	31
	ZnO_{1-x}	R6G	1.1×10^4	1×10^{-7} mol L^{-1}	31
	WO_3	Au-4MBA	10.00		32
	Au/TiO_2	DNT		1×10^{-15} mol L^{-1}	33
	$Ag/Ag\text{--}TiO_2$	4-MBA	1.68×10^6		35
	WO_3	RhB	1.14×10^6	1×10^{-7} mol L^{-1}	36
	TiO_2	PABA		1×10^{-8} mol L^{-1}	37
	Cu_2O	SR3		0.3 mg kg^{-1}	40
	MoS_2	R6G	63.5		41
Dopants	$TiO_{2-x}N_y$	R6G		5×10^{-8} mol L^{-1}	31
	Black TiO_2	R6G	1.2×10^6	1×10^{-7} mol L^{-1}	42
	Cation-intercalated WO_3	R6G	8.86×10^4	1×10^{-6} mol L^{-1}	43
	$Co\text{--}MoO_{3-x}$	MB	1.01×10^5	1×10^{-7} mol L^{-1}	48
	N-doped graphene	RhB		5×10^{-11} mol L^{-1}	61
	N-doped graphite	CV	3.2×10^7	1×10^{-7} mol L^{-1}	62
	Ozone-treated graphene	RhB	2.5×10^4		57
	$MoS_{2-x}O_x$	R6G	1.4×10^5	1×10^{-7} mol L^{-1}	63
Lattice disorders	Amorphous TiO_2 nanosheets	4-MBA	1.86×10^6		64
	Amorphous ZnO nanocages	4-MBA	6.62×10^5		65
	Amorphous Rh_3S_6	4-NBT	3×10^4	1×10^{-7} mol L^{-1}	66
		R6G	1×10^5		
	H_xMoO_3 quantum dots	MB	9.5×10^5	1×10^{-9} mol L^{-1}	67
	$Ni(OH)_2$	MB	2.35×10^3	1×10^{-8} mol L^{-1}	68
	Ultrathin WO_3 nanosheets	MB		1×10^{-7} mol L^{-1}	69
	Cu_2O superstructures	R6G	8×10^5	6×10^{-9} mol L^{-1}	38
	Defective VO_2 nanosheets	R6G		1×10^{-7} mol L^{-1}	71
	$h\text{-}MoO_3$	MB	6.99×10^5	1×10^{-9} mol L^{-1}	72
Metallicity	MoO_2	R6G	3.75×10^6	1×10^{-7} mol L^{-1}	74
	MoO_{2-x}	R6G		1×10^{-8} mol L^{-1}	75
	$\delta\text{-}MoN$	R6G	8.16×10^6	1×10^{-10} mol L^{-1}	76
	$\gamma\text{-}Mo_2N$	2,4,5-TCP, 2,4-DCP		1×10^{-11} mol L^{-1}	77
	$\delta\text{-}MoN$	R6G	3.6×10^7	1×10^{-11} mol L^{-1}	78
	VO_2	R6G	6.7×10^7	1×10^{-10} mol L^{-1}	79
	TiN	R6G	$\sim 10^5$	1×10^{-7} mol L^{-1}	80
	Ti_3O_5	R6G		1×10^{-10} mol L^{-1}	81

Oxygen vacancies (OVs) are among the most prominently studied types of defects in SERS active materials, and oxygen-deficient metal oxides have been widely reported in recent years to exhibit SERS activity where their pristine forms are nearly inert. OVs are easily introduced into metal oxides by post-synthesis treatment means. Cong et al. for the first time reported achieving noble-metal-comparable SERS performance towards R6G by producing surface oxygen vacancies in $W_{18}O_{49}$ through H_2 or Ar atmosphere annealing (Fig. 1a).[26] It was proposed that the OVs play an irreplaceable role in magnifying the substrate–molecule surface interaction and promoting CT at the interface. Following this, thermal treatment has also been found effective in inducing OV-related SERS in other typical metal oxides. Yang et al.[27] proposed the fabrication of Cu_2O octahedrons with oxygen-vacancies by calcining Cu-MOFs in a reductive atmosphere, which facilitated stronger selective adsorption towards sulfhydryl groups, achieving an LOD of 5×10^{-10} M for 4-MPY. In addition to thermal treatment, irradiation-induced vacancies are also widely reported in materials engineering.[28–30] Zheng et al. proposed that by irradiating archetypical oxide thin films (WO_3, TiO_2 and ZnO) with an Ar^+ or N^+ ion beam, sensitive SERS activity comparable to that of noble metal substrates without hotspots can be generally induced, attributed to the OV-related electronic states that are created by ion irradiation (Fig. 1b).[31] Photoinduced surface OVs have been investigated by Maier and co-workers.[32–34] With prototypical metal oxides such as TiO_2, WO_3 and ZnO, they demonstrated a direct correlation between UV irradiation induced surface OVs and enhanced Raman signals towards surface functionalized Au-MBA (Fig. 1c). Zhou et al.[35] also showed the NIR irradiation tuning of the OV concentration in

TiO_2, which resulted in an irreversible accumulated increase in SERS activity towards 4-MBA. Electrical tuning of OVs was also achieved, by applying voltage to the WO_3 thin film, which induced the formation of OV chains within the crystal structure (Fig. 1d).[36] The approach demonstrated the in situ tuning of enhancement capability of the substrate, thereby allowing the substrate to be optimally adapted to different molecular concentrations. The thermal, irradiation and electrical approaches that have been developed offer facile means of not only inducing but also controlling the concentration of OVs in order to adapt to analysis requirements. However, OVs produced with such methods tend to be produced at or near the surface of the material, and could easily be healed by O_2 or H_2O molecules in air or aqueous solution. In comparison, tuning OVs during the synthetic procedure tends to provide more structural stability and variability. Yang et al.[37] proposed the controlled addition of PEG during a hydrothermal process to carefully tune the optical response and SERS of TiO_2 NPs. Consequently, the SERS response of small molecule PABA reached an LOD of 1×10^{-8} mol L^{-1}, while also maintaining stability for up to 180 days.

In addition to OVs, other types of vacancies have also been studied. Copper vacancies in cuprous oxide systems have been shown to enhance surface adsorption and SERS of R6G, CV, 4ATP and Sudan Red III.[38–40] S vacancies in MoS_2 were studied by Zuo et al.[41] Through femto-second pulse laser treatment, a significant number of micro/nanoscale defects and S vacancies were introduced, which were responsible for enhanced physical–chemical adsorption of molecules and consequent SERS activity, raising the EF towards R6G by 6-fold compared with that of pristine MoS_2.

2.2 Dopants

Extrinsic doping is another widely applied means of introducing defects into the material lattice. Depending on parameters such as the radius and charge of the dopant atom, the dopant could enter the host lattice by substituting the atoms of the host, or by intercalating into spaces between the lattice. Through controlling the type and concentration of the dopant, the intrinsic crystalline and electronic structure, and surface properties of the host material can be manipulated.

Cationic doping is very well established in SERS research. Small size cations such as H^+, Li^+, Na^+ and Al^{3+} are usually easily intercalated into the crystal lattice due to their small size. Yang et al.[42] reported the hydrogenation of black TiO_2 nanowires (Fig. 2a), which boosted SERS activity and photocatalytic self-cleaning ability of the substrate due to doping-induced formation of surface defects. Cong et al. reported electrochemical intercalation of IA–IIIA group cations into amorphous WO_3 thin films (Fig. 2b), which resulted in greatly enhanced detection of R6G.[43] This facile approach gives easy access to large-scale, uniform, reproducible and renewable fabrication of SERS-chips. Transition metal dopants are also a popular choice to create defects, which is especially helpful for enhancing optical properties of broad band semiconductors, as they contain ample d-orbitals that act as charge acceptors in photoinduced CT processes. Zhao and co-workers have conducted a series of research studies on the doping of metal oxides TiO_2 (ref. 44–46) and ZnO^{47} with transition metals, showing improved optical responses and SERS activity at the optimal doping concentration. Zheng et al.[48] showed that the doping of Co induced strong optical absorption in the vis-NIR region in MoO_{3-x}, resulting in synchronous SERS detection and photothermal conversion. More recently, research on rare earth metal doping has also presented interesting findings. Rare earth metals, which have highly variable valence states and electronic states, have been shown to endow the host semiconductor with useful luminescent, electromagnetic, conductive and electrochemical properties.[49,50] Yang et al.[51] reported Nd-doped ZnO, where the Nd dopant successfully enhanced the SERS detection for 4-MPY, and can be used to monitor the CT processes created due to Nd-related energy states. Due to their unique electronic structure, rare earth dopants have potential for enhancing CM-mediated SERS activity in semiconductors, which surpasses current reports.

Anionic doping with non-metallic impurities has been extensively studied, particularly in two-dimensional materials.[52–60] Nitrogen, a commonly used reductive dopant, can be easily introduced into the host structure by sample-treatment in a NH_3 or N_2 atmosphere. Feng et al.[61] showed significantly boosted SERS sensitivity in N-doped graphene, with an impressive detection level of 5×10^{-11} M for RhB (Fig. 2c). In another example, quantum-scale graphite doped with N^{62} exhibited enhancement towards 100 nM CV with the maximum EF reaching 3.2×10^7. Oxygen doping has also been investigated. Huh et al.[57] reported activated SERS in oxidized graphene, by treating graphene with UV/ozone irradiation, increasing the EF of pristine graphene from 10^3 to 10^4. Oxygen doping of TMD nanosheets was reported by Zheng et al.[63] by careful annealing of samples in an air atmosphere. At the appropriate concentration, oxygen incorporation induced strong SERS activity towards R6G in MoS_2, $MoSe_2$, WS_2, and WSe_2. To summarize, both cationic and anionic dopants are good candidates for tuning the electronic and surface properties of the host material, towards boosting its SERS performance. As shown in this section, cationic dopants appear to be preferable compared with anionic dopants due to the relatively facile experimental requirements for cationic doping and wider selection of cationic dopants (most transition and main group elements have been reported). In future investigations, we speculate that improved material engineering techniques will greatly aid the construction of doped semiconductors with greater variety and complexity, which will expand the selection of available SERS-active semiconductors.

2.3 Lattice disorders

In the above sections we have dealt with point-defect type materials, which constitute the main body of defect-related reports in semiconductor-based SERS. However, more complex defect types have also been considered. Lattice disorders, which can cover a variety of defects such as line defects, planar defects or bulk defects, have also received increased attention.

One notable form of lattice disorder is amorphous materials. In the case of amorphous structures, the entire lattice can be
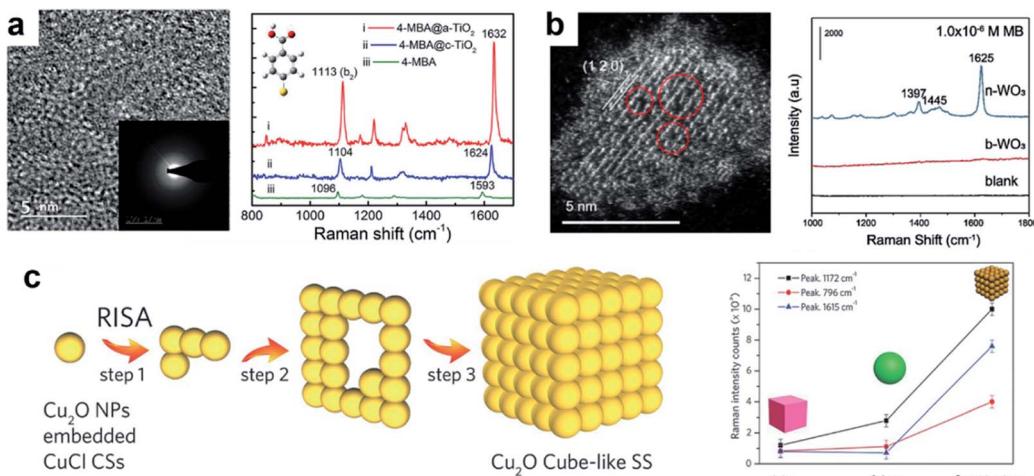

Fig. 3 Semiconductors with lattice disorders and their SERS performances. (a) The HRTEM micrographs of amorphous TiO_2 nanosheets and Raman spectra of 4-MBA on crystalline and amorphous TiO_2. viewed as highly disordered due to the absence of long-range ordering, which effectively provides plentiful defective sites for surface interactions. Some prototype amorphous semiconductor substrates have been studied, including amorphous TiO_2 (ref. 64) (Fig. 3a), ZnO,[65] Rh_3S_6,[66] H_xMoO_3 (ref. 67) and metal hydroxide $(M(OH)_x)$ nanostructures.[68] The promoted SERS activities in amorphous structures are predominantly due to enhanced surface adsorption and promoted interfacial CT, resulting from abundant surface defect sites.

Lattice disorders can also be spontaneously created by morphological tuning. Song *et al.* proposed that ultrathin metal oxide nanosheets spontaneously lose lattice oxygen due to their low dimensional structure, forming point defects and distortions in the lattice cell in order to maintain structural stability within the crystal (Fig. 3b).[69] As a result, the substrate–molecule interfacial CT can be promoted. The advantage of inducing defects in ultrathin nanosheets is that the crystalline form of the material can be retained, while ample localized surface defects serve as the main sites for highly efficient interfacial interactions. Consequently, the approach has been found to substantially promote the SERS behavior of WO_3, MoO_3 and MnO_2. Lattice fusion in special morphologies can also promote localized defects. In Cu_2O superstructures assembled from Cu_2O mesoporous spheres (MPS), Lin *et al.*[38] demonstrated the creation of a higher Cu vacancy content than that in Cu_2O cubes or single MPS, attributed to the lattice fusion between adjacent spheres (Fig. 3c). The detection limit for R6G on the Cu_2O superstructures consequently reached an ultralow level of 6×10^{-9} M. Similar morphology-driven lattice fusion leading to high SERS activity has also been observed in ZnO.[70]

Phase engineering is also useful for inducing defects in some semiconductors. Miao *et al.*[71] showed that three phases of VO_2 exhibited distinctly different levels of SERS activity, which was attributed to structure-originated differences in the tolerance

for defects. The monoclinic phase $VO_2(B)$ which consists of a layered structure was found to exhibit the highest SERS activity due to a higher tendency to accommodate oxygen vacancies. Patil *et al.*[72] developed a series of one-step hydrothermal procedures that produced MoO_3 crystals of different crystal phases, which simultaneously demonstrated the inherent optical response and SERS activity of defective $h-MoO_3$ and $\alpha-MoO_3$.

2.4 Metallic semiconductors

A special type of semiconductor must be mentioned here, namely metallic semiconductors which exhibit LSPR activity. Metallicity in semiconductors refers to their properties to transport electrons, which becomes prominent when the charge carrier density and density of states near the Fermi level increase.[73] Metallicity is of interest in SERS as CT-based enhancement and plasmonic resonance-based enhancement are directly influenced by the metallicity of the semiconductor. Defect engineering, which causes changes to the charge carrier density and electronic structure is therefore a convenient approach to increase metallicity in semiconductors. For most semiconductors, only weak LSPR activity is promoted by their increased defect-induced metallicity, nevertheless the LSPR contribution can be coupled with simultaneously enhanced CT contributions to synchronously improve SERS performance. Moreover, in some semiconductors, sufficient LSPR activity within Raman-appropriate frequencies can be produced. Typical examples of metallic semiconductors that are SERS-active due to high LSPR activity are Mo-based compounds. Strikingly, Xi and co-workers have notably reported several metallic Mo-based semiconductors which have been successfully used to detect several small organic molecules with reasonably low LOD, showing general applicability of metallic
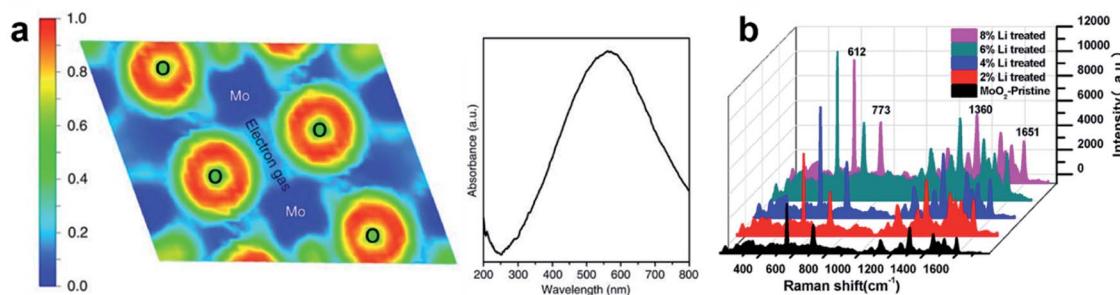

Fig. 4 Semiconductors with LSPR activity. (a) LSPR activity of MoO_2 nano-dumbbells. Reproduced with permission from ref. 74. Copyright 2017, Springer Nature. semiconductors as SERS sensors. Compared with semiconducting MoO_3, the more oxygen-deficient MoO_2 nano-dumbbells exhibit a high density of free electron gas that forms nonpolar Mo–Mo metallic bonds (Fig. 4a).[74] These characteristics promoted the surface plasmonic resonance at 532.8 nm laser excitation, contributing to high SERS activity. In addition to R6G, several polychlorinated phenol molecules were also detected at sub-micromolar concentrations. Moreover, the plasmonic activity of MoO_2 nanostructures can be further enhanced by introducing oxygen vacancies, as was shown by Cao *et al.*[75] who induced surface oxygen vacancy sites by reductive treatment with lithium (Fig. 4b). Similar to MoO_2, metallic Mo_2N and MoN nanostructures have also showed plasmonic activity.[76–78] In addition to molybdenum oxides and nitrides, Ti_3O_5, TiN and VO_2 with high EM activity have also been reported.[79–81] As LSPR is a non-selective enhancing effect, the conditions for LSPR-mediated SERS are not as stringent as CT-mediated effects, making LSPR semiconductors more adaptive towards different probe molecules.

3. Influences of defect engineering on semiconductors

The introduction of defects causes changes in several important parameters of semiconductor materials, which are directly related to their SERS activity. In this section, we introduce the three key parameters that can be regulated by defect engineering, namely the band structure, surface properties and DOS, as well as their respective relationships to SERS activity by referring to the fundamental theories of SERS.

3.1 Regulation of the band structure

The possibility for CT resonance to occur is the matching of the band structure in such a way that the energy discrepancy of the CT process is in close proximity to the laser energy. As many semiconductors generally do not exhibit strong surface plasmonic behavior, their SERS activity relies heavily upon CT resonances, which include intrinsic excitonic CT processes (μ_{ex}) and substrate–molecule CT processes (μ_{PICT}). Additionally, as vast numbers of semiconductors are wide-gap, requiring high energy (UV light) excitation, μ_{ex} is difficult to apply to SERS

applications which generally favor low energy excitation. For this reason, band structure tuning is particularly important for semiconductor-based SERS.

Bandgap shrinkage, sometimes observed in doped semiconductors due to the band gap renormalization effect, could reduce the excitation energy threshold for μ_{ex}.[63,82–84] For instance, in oxygen-incorporated MoS_2 nanosheets (Fig. 5a),[63] significant shifts of the CB and VB edges resulted in a narrowed bandgap that closely matched the energy of the incident laser (2.33 eV). Moreover, newly created direct excitonic pathways in the bandgap further increased the population of effective μ_{ex} resonance. Such a phenomenon has also been observed in other low dimensional TMDs.[85,86] In extension to TMDs, μ_{ex} resonance has also been achieved in trichalcogenide alloy $MnPS_xSe_{1-x}$ by controlling the concentration of Se towards similar effects of band gap tuning.[87]

In addition to the band gap, new energy states could be created due to various types of defects. Defect-induced disorders often cause the formation of surface state levels (E_{SS}),[88–90] which is useful for inducing electron transition from the VB with lower excitation energy. Doping will introduce new energy states *via* the impurity atom, in addition to E_{SS} levels, as is shown in the example of CT from E_{SS} and dopant-related states in Co-doped TiO_2 to 4-MBA[90] presented in Fig. 5b. The advantage of this strategy was also most effectively demonstrated by the doping of Nd in ZnO (Fig. 5c), in which several new absorption bands corresponding to the 4f, and 5d orbitals of Nd appeared in the visible light region.[51] As a result, the number of μ_{PICT} and μ_{ex} pathways is optimally increased, as was observed in the case of enhanced detection of 4-MPY.

The Fermi level (E_F) is also tunable by defect engineering. In graphene particularly, the Fermi level is an important tunable parameter that is greatly affected by the electronegativity of the dopant. Xu *et al.*[91] conducted a careful investigation of CT modulation in the SERS signal of CuPc on N- and O-doped graphene, illustrating that the CT between the Fermi level of graphene and LUMO of CuPc is greatly influenced by the dopant-dependent position deviation of E_F from the Dirac point (Fig. 5d). They also investigated a series of metal-phthalocyanine (M-Pc) molecules,[92] finding that in all cases the n-doped graphene (E_F up-shifted) performed worse than p-doped graphene (E_F down-shifted), which was attributed to the optimal

matching of E_F-LUMO energy discrepancy with the laser energy on p-doped graphene.

3.2 Regulation of active surface sites

In addition to the possibility of new CT pathways created by favorable energy matching, the actual establishment of effective CT channels depends crucially on the substrate–molecule surface interaction. Defect sites in semiconductors are often crucial to surface interactions. In the first place, for metal-based compounds undersaturated metal cations can serve as binding sites for the probe molecule. For instance, CO adsorption is found to be crucially facilitated by the bonding between CO and coordinately undersaturated Cu^+ sites in Cu_2O.[93] Different metal sites could have different affinities towards a given probe molecule. Hurst *et al.*[94] investigated the SERS effect of dopamine (characterized by the enediol ligand) functionalized on the surface of Fe_2O_3, TiO_2, CeO_2 and ZrO_2 nanoparticles, which showed varied number, shift and intensity of Raman scattering signals, evidencing the formation of different CT complexes and their different optical responses which are dependent on the chemical composition. The disruption of the periodic array by defects induces the formation of dangling bonds at the surface, which are unbonded orbitals localized at undercoordinated surface metal centers. These dangling bonds can be capitalized to create sites of strong substrate–molecule interactions and effective CT, as have been observed in highly defective structures. Amorphous materials have an advantage in this regard due to their lack of long-range ordering. The amorphous surfaces in ZnO nanocages,[65] for example, are richly populated by dangling bonds which causes thiols to form stronger Zn–S bonds that act as CT channels, as well as allowing for more effective electron transfer due to weaker electron constraint (Fig. 6a). Titanium oxide nanostructures have also been

a prototypical subject of study for surface tuning due to their well-known affinity towards multiple functional groups. It has been pointed out that dangling oxygen species (Ti–O) formed in small TiO_2 nanoparticles and their hydrogenated form can be highly active towards phenolic molecules such as dopamine, catechol and hydroquinone, both as binding sites and to facilitate CT.[95–97] Based on this, Lewis and Brønsted surface sites can be produced as a result of defect-tuning. Gong *et al.*[98] showed that with the substitution of SO_4^{2-} ions for O^{2-} in the TiO_2 lattice, Lewis acid sites are produced due to the bidentate coordination of SO_4^{2-} ligands to central Ti sites, while Brønsted acid sites are produced by the hydrogenated Ti–OH^+ surface sites, resulting in the enhancement of TiO_2–molecule CT interactions and subsequent SERS activity towards the molecule 4-MBA (Fig. 6b).

Van der Waals-type (vdW) nanosheets should also be discussed, as their SERS activity mainly originates from dipole–dipole interactions. Ling *et al.*[99] first reported that in polar vdW structures such as h-BN (containing polar B–N bonds) and MoS_2 (containing polar Mo–S bonds), increased probability of electron transition can be induced by local symmetry-perturbation upon interface dipole–dipole interactions with the probe molecule, which in turn contributes to SERS activity. Based on the nature of dipole–dipole interactions, the process can be enhanced by strengthening the polarity of chemical bonds in the vdW structures. With plasma treated MoS_2, Sun *et al.*[100] demonstrated the correlation between the amount of structural disorder and the formation of local dipoles which enhanced the overall SERS. Anbazhagan *et al.*[101] proposed that in lithium-exfoliated MoS_2, surface S and Mo vacancies are created that can promote dipole–dipole interactions with R6G, resulting in better substrate–molecule CT (Fig. 6c). The direction of substrate dipoles also affects dipole–dipole interactions greatly. Jia *et al.*[102] engineered a 2D Janus MoSSe structure which

generates out-of-plane dipoles due to the asymmetry of S–Mo–Se, enabling strong substrate–molecule interactions (Fig. 6d). Impressively, Janus MoSSe was successfully applied to the SERS detection of glucose, reaching a detection concentration of 1 mM and achieving an EF of 4×10^5. These results indicate that

although the dipole–dipole contribution is considered to account for a relatively small EF, the alteration of the bond polarity and structural symmetry in vdW nanosheets *via* defect engineering may very well lead to great improvement in their SERS performances.

3.3 Regulation of DOS

Upon establishing the probability and channel for CT occurrence, the efficiency of the CT process is the third key factor that influences SERS activity. Fermi's golden rule (eqn (1))[103,104] states that the electron transition probability rate (ω_{ab}) depends on the density of the final states (g_b), and the strength of the matrix element $|\langle b|M|a\rangle|^2$, namely the initial and final state ($|a\rangle$, $|b\rangle$) of the charge transition.

$$\omega_{ab} = \frac{2\pi}{\hbar}|\langle b|M|a\rangle|^2 g_b \tag{1}$$

As such it may be said that the DOS of the states relative to a given CT process is positively correlated with the efficiency of that CT process. Cong *et al.* demonstrated this defect-driven effect with metal-cation-doped WO$_3$ thin films.[43] Taking Al^{3+} ions as an example, it was found that the DOS near E_F of WO$_3$ is linearly correlated with the concentration of Al^{3+} and also positively affects the SERS signal of R6G (Fig. 7a). In addition to the increase in DOS, simultaneous accumulation of electrons in the W 5d orbitals also occurred which also served to increase the population of μ_{PICT}. Following this, the same phenomenon has been observed in other SERS systems. Song *et al.* found that the surface oxygen defects created in ultrathin WO$_3$ nanosheets also increased the DOS near E_F, which enhanced the SERS effect for MB (Fig. 7b).[69] The DOS increase related to defects has also been found in TMDs such as defective MoS$_2$ and WSe$_2$ (Fig. 7c).[41,63,105,106]

Lastly, it should be pointed out that an increased charge carrier density also leads to the surface plasmonic effect,[107] which has been observed in most defective materials mentioned in this perspective and can be simply characterized by the Urbach tail in the absorption spectra. Although the peak frequency of LSPR for most defective semiconductors falls beyond an applicable range as stated in 2.4, limiting the impact of the surface plasmonic effect to their overall SERS activity,

their contributions should still be taken into account. Moreover, EM contributions such as surface plasmon and Mie resonance effects can be coupled with CM-based contributors towards the highly activated multi-coupled SERS effect. Such an amalgamation has been successfully implicated in the system of Mo–Ta$_2$O$_5$–MV, proposed by Yang *et al.*, in which the coupling of μ_{PICT}, molecular resonance (μ_{mol}) and EM effects resulted in an overall EF of 2.2×10^7 and LOD of 9×10^{-9} M towards the probe MV (Fig. 7d).[25]

4. Applications of SERS-active defective semiconductors

The advantages of higher interfacial CT and molecule-selective interactions afforded by defective semiconductors make them uniquely suitable for specialized SERS sensing applications. The applications of semiconductor-based SERS platforms can be divided into two major categories. The first includes sensors for *ex situ* detection of chemical species, in other words sensors that are used in the conventional laboratory setting. Such sensors are usually of interest in analysis of food, environment, industrial products or biological samples. The second includes sensors for *in situ* analysis, usually for characterization of chemical reactions or CT processes in a device. In such cases the semiconductor may play multiple functions, such as acting as a catalyst and SERS sensor.

4.1 *Ex situ* sensing

Ex situ trace sensing platforms often involve samples with a complex chemical composition, and require quantitative detection of the target with minimal interference signal. In these scenarios the band structure and surface properties of semiconductors controlled by defect engineering can be especially useful. In environmental analysis, the detection of small ionic

species such as $Cr(VI)$ and PO_4^{3-} in water samples has been achieved with colloidal TiO_2 nanoparticles with rich surface hydroxyl groups.[108,109] Hydroxyl-group-rich TiO_2 colloids are also especially selective towards phenolic molecules, and have been proposed as SERS sensors for quantitative analysis of phenolic polymer inhibitors in olefins.[97] In food analysis, methods for the detection of prohibited substances are in high demand. Recently, a SERS-chip for detection of Sudan Red III in Chinese medicinal herbs was developed using defective Cu_2O nanostructures (Fig. 8a).[40] Biochemical sensing has also seen advances in recent years, with the range of detected bioactive species expanding rapidly, from biorelevant small molecules such as β-sitosterol and bilirubin to larger structures such as DNA.[110–112] Cancerous cells and biomarkers related to cancer are now detectable using a variety of semiconductor materials. VEGF, a biomarker for brain tumor, was detected using aptamer-functionalized WO_3.[113] Defective Ag_2O nanoparticles functionalized with folic acid have been constructed to selectively bind to cancer cells in blood, showing clear distinction in SERS spectra between liver cancer patients and healthy individuals (Fig. 8b).[114] *In vitro* mapping of cancer cells and their genomic DNA has been achieved with quantum sized semiconductors.[115–117] Quantum sized oxygen-deficient TiO_x particles were developed for detection of tumor biomarker EGFR (Fig. 8c),[117] exhibiting good cell adherence and low cytotoxicity. SERS analysis showed clear EGFR signals and a higher lipid content in breast cancer cells compared to non-cancerous fibroblast cells. The report also showed distinct SERS features for cervical cancer cell line HeLa. In addition to biosensing, therapeutic functions have also been achieved. Particularly, NIR-responsive semiconductors are extensively used in photothermal treatment (PTT) of cancerous cells, including hydrous RuO_2, WS_2, copper chalcogenides and Mo-based materials.[72,118–122] Photo-tuned MoO_2 quantum dots with varied optical responses in the NIR region are a good example of dual-functional SERS substrates,[122] with SERS activity towards bioactive molecules phenylalanine and amphotericin, and also showing good PTT performance towards cancer cell line HEP G2.

4.2 *In situ* sensing

The SERS technique has been especially favored in monitoring chemical reactions that take place in aqueous environments, as the interference of water signals can be minimized by Raman spectroscopy. The detection of intermediate or product species in a reaction does not usually require quantification, but requires high sensitivity and good surface adherence towards the target, which can be met by defective semiconductors that have tunable surfaces and high CT-induced SERS activity. Proof-of-concept studies of SERS in monitoring biochemical reactions have been proposed. Alessandri and Depero[123] demonstrated the use of all-oxide substrates in the monitoring of the glutathione (GSH) redox reaction with a core–shell structure of SiO_2 coated with amorphous TiO_2. Han *et al.*[124] demonstrated the SERS monitoring of the redox behavior of cytochrome b_5 (Cyt b_5), a hemoprotein, using TiO_2 as the substrate. In addition to probing biochemical reactions, SERS-active semiconductors

tend to also exhibit catalytic properties, which naturally intrigues research into establishing a SERS-based methodology to characterize catalytic processes at the molecular level. Zhang *et al.*[125] studied the photo-oxidation of silane to silanol on the CuO surface. The production of *OH species is identified *in situ*, which is attributed to the oxygen vacancies on the CuO surface which act as absorption and activation sites for H_2O_2. In another example, Wen *et al.* have studied the nanoenzyme properties of reduced $MnCo_2O_4$ with the aid of Au NPs to boost its SERS activity.[126] They also reported a SERS-kinetic model which monitored the oxidation of tetramethylbenzidine (TMB), based on reduced $MnCo_2O_4$ nanotubes, which had the double function of the SERS substrate and oxidase (Fig. 8d).[127] The highlight of the work is the access to *in situ* monitoring of the oxidization process based on quantitative SERS analysis of the oxidized TMB product (oxTMB) on the surface of oxygen-vacancy-rich $MnCo_2O_4$. It should be noted that while the CT-induced SERS performance of reduced $MnCo_2O_4$ nanotubes improved compared to that of pristine $MnCo_2O_4$, their oxidase-like catalytic activity slightly declined, which shows that the influence of defect engineering on SERS and catalytic activity differs.

In extension to the monitoring of isolated reactions, the demand for SERS characterization of more complex model systems and devices has also been on the rise.[128–132] It is well established that the CT effect can selectively influence the enhancement of specific molecules or specific vibrational modes, therefore the relative signal intensity of selected bands in the SERS spectrum can be used to reflect the degree of CT (ρ_{CT}) and the site of the reaction. This method has been extensively studied in solar-cell-like model systems. Wang *et al.*[128] reported the use of a combined Ag–TiO_2–FePc–MPY structure to demonstrate the manipulation of the CT direction based on band energy matching between components, which was reflected in the change of ρ_{CT} for selected SERS bands (Fig. 8e). This work is useful for guiding the design of solar-cell model structures and predicting the CT direction. In another instance, the CT-based change in SERS spectra has also been used to monitor the movement of surface adsorbed molecules[35](Fig. 8f). By monitoring the Raman frequency shift of 4-MBA adsorbed on a Ag/Ag-doped TiO_2 substrate under NIR irradiation, the reorientation of the molecule due to accumulated CT-induced electrostatic attraction can be observed. In organic photovoltaics, Luke *et al.*[132] reported the use of *in situ* Raman spectroscopy in monitoring the degradation process of organic photovoltaic devices, offering a practical methodology for understanding chemical reaction processes in devices.

5. Conclusion and outlook

In this perspective we have introduced defect engineering towards enhancing SERS activity in semiconductors, and discussed mechanisms behind the SERS activity of defective semiconductors. While the rapid development of novel semiconductor platforms can be credited in large part to defect engineering techniques, there is still much to be explored in the field. To begin with, defect engineering in SERS has mainly

© 2022 The Author(s). Published by the Royal Society of Chemistry

focused on point defects, while influences of more complex defects on the physicochemical parameters and SERS activities of semiconductors have not yet been fully investigated. For instance, research into SERS-activity as influenced by line defects, planar defects or volumetric defects has been limited. It could be argued that while introduction of vacancies and extrinsic dopants is facile and generally applicable to defect engineering strategies, the study of higher dimensional defective systems (lattice disorders and metallic semiconductors) may reveal novel SERS-promoting mechanisms and deepen our understanding of the fundamental relationship between defects and SERS activity. Second, the range of defective semiconductors that are under research has been largely limited to prototypical materials such as TiO_2, graphene and MoS_2. With the expanding range of novel semiconductors, the selection of materials for SERS applications has also grown to include materials such as MOFs, organic semiconductors and MXenes. New defect engineering techniques suited to each semiconductor category and new insights into the mechanisms behind SERS phenomenon will likely rise from these novel classes of materials. Third, refining the stability and reproducibility of defects in semiconductor-based SERS substrates will be an important issue. As SERS substrates are often expected to be deployed under complex working conditions, the production of SERS-active defective semiconductor materials which can maintain stability and signal reproducibility in complex systems will be of great significance.

The applications of semiconductor-based SERS were also discussed. Environmental analysis, food safety, biosensing and reaction monitoring in devices are all important branches of research with very different analysis requirements that may benefit from the development of novel SERS platforms. Current research interests suggest that SERS-sensing is increasingly moving towards *in situ* or point-of-care testing scenarios. However, present design of semiconductor-based platforms still requires variety to meet the specific demands of specialized detection. In this regard, the high tunability of semiconductor surfaces and chemical properties can be a great advantage for tailoring the SERS platform to suit the testing environment. Future research might focus on the selective adherence of substrates towards target species based on the tuning of surface properties of semiconductors, and regulating parameters of the optical response towards achieving highly sensitive SERS substrates. Moreover, deeper insight into defect engineering may help improve understanding of the design of multi-functional semiconductors which facilitate SERS along with other properties such as catalytic or photothermal activities.

The SERS phenomenon is complex in principle and still under investigation. The recent development of defect engineering in semiconductor-based SERS has greatly pushed the boundaries of the field, with the realization of increasingly high quality and sophisticated sensing platforms. We hope that this perspective provides fellow researchers with basic knowledge for designing semiconductor-based SERS substrates and that they might be inspired to perform deeper examinations of defect engineering and its uses in SERS research.

Author contributions

The manuscript was written through contribution from all the authors. G. S., S. C. and Z. G. Z. conceived the main outline of the manuscript. G. S. wrote the first draft of the manuscript. S. C. and Z. G. Z. discussed and helped revise the manuscript.
