

Exhaustive Post-Polymerization Modification

Showcasing research from Professor Le Li's laboratory, School of Chemistry, Sun Yat-sen University, Guangzhou, P. R. China.

Exhaustive Baeyer–Villiger oxidation: a tailor-made post-polymerization modification to access challenging poly(vinyl acetate) copolymers

The intrinsic differences between small molecules and polymers restricts the effective translation of existing small-molecule synthetic methodologies into efficient post-polymerization modifications. To address this, Professor Le Li's group introduce a novel approach, namely the Direct Optimization on Polymers (DOP) approach, to bridge the gap between small-molecule methodologies and polymer post-modification methods. To showcase the DOP approach, Professor Li and co-workers directly optimized Baeyer–Villiger (BV) oxidation on poly(methyl vinyl ketone) and its copolymers to enable an exhaustive BV post-polymerization modification which is particularly effective for preparing synthetically challenging poly(vinyl acetate) copolymers.

Exhaustive Baeyer–Villiger oxidation: a tailor-made post-polymerization modification to access challenging poly(vinyl acetate) copolymers†

Pengfei Ma,^{ab} Christopher M. Plummer,^c Wenjun Luo,^{ab} Jiyan Pang,^a Yongming Chen^{db} and Le Li^{*ab}

The discovery of exhaustive (nearly quantitative) post-polymerization modifications (PPM) relies heavily on the efficiency of their corresponding small-molecule protocols. However, the direct translation of existing small-molecule protocols into PPM methods has never been guaranteed due to the intrinsic differences between small-molecule substrates and polymers. Herein, we introduce the direct optimization on polymers (DOP) as a complementary approach to developing exhaustive PPM reactions. As proof of the DOP concept, we present an exhaustive Baeyer–Villiger (BV) post-modification which cannot be accessed by conventional approaches. This user-friendly methodology provides general access to synthetically challenging copolymers of vinyl acetate and more activated monomers (MAMs) including both statistical and narrow-dispersed block copolymers. Furthermore, a scalable one-pot copolymerization/exhaustive BV post-modification procedure was developed to produce such materials showing improved performance over regular PVAc.

Introduction

Complementary to conventional polymerization approaches, post-polymerization modification (PPM) represents another appealing strategy for polymer synthesis.¹ Polymer chemists continuously seek ideal PPM reactions where an exhaustive (nearly quantitative) functionalization can be achieved. The most common approach to access such transformations is the adaption of the corresponding small-molecule synthetic methodologies. The most notable examples include “click” reactions² and multicomponent reactions.^{1c,3} However, the translation of small-molecule protocols to polymers is not straightforward. Indeed, the development of an exhaustive PPM reaction is even more technically challenging than that of its small-molecule prototype in many cases (Scheme 1A and Fig. S1†). An exhaustive PPM reaction requires both a high degree of mechanistic fidelity and sufficient functionalization rates to prevent the production of defects,⁴ chain scission or cross-linking,^{1b,5} since

any side reaction will negatively alter the properties of the resultant polymers. Such stringent requirements greatly limit the reaction diversity⁶ of exhaustive PPM methods. An additional bottleneck for the development of PPM methods is the intrinsic difference between small-molecule substrates and polymers (e.g. reactivity, solubility, and packing/aggregation) which has been greatly overlooked (Scheme 1B). Indeed, the adaption of “mismatched” small-molecule protocols into PPMs was often fruitless. Therefore, we speculated that direct optimization on polymers (DOP) could constitute a new strategy and potentially accelerate the discovery of PPM reactions. In the DOP approach, polymer substrates will be used as model compounds for optimization, and the unique properties of polymers will be considered from the beginning of development.

To validate the effectiveness of the DOP approach, we aimed to develop an exhaustive Baeyer–Villiger (BV) post-modification of poly(methyl vinyl ketone) and its copolymers (Scheme 1C). Such a method can be applied to prepare challenging copolymers of vinyl acetate (VAc) and more activated monomers (MAMs),⁷ whose reactivities are mismatched in copolymerization.⁸ In our proposal, commercially available methyl vinyl ketone (MVK) would be used as a “masked-VAc” monomer since MVK readily copolymerizes with other MAMs⁸ and is also compatible with multiple reversible deactivation radical polymerization (RDRP) techniques.⁹

We were aware that significant challenges might occur during the development. Although small-molecule BV oxidation¹⁰ protocols were rich in literature, multiple side-reaction

pathways such as aldol reaction/condensation,¹¹ undesired oxidation¹² and radical cleavage¹³ were known to be associated with BV oxidation. Such side reactions could introduce defects into the polymer backbone and negatively affect the molar mass and dispersity (\bar{D}) of the polymers. In addition, uncertainty regarding the regioselectivity of the proposed BV post-modification must be considered since such selectivity for

a polymer substrate has never been established. Apparently, the development of an exhaustive oxidative PPM reaction remains a challenging task. However, recent accomplishments¹⁴ in oxidative PPMs encouraged us to explore the proposed chemistry. For instance, Klausen^{14d} and Ouchi^{14c} individually developed highly efficient oxidative PPMs for their customized boron-containing polymers using organoboron oxidation

chemistry.¹⁵ Herein, we report an exhaustive Baeyer-Villiger (BV) post-modification as the first example developed by the DOP approach. This BV post-modification provides a general method to prepare a wide range of synthetically challenging homopolymers, statistical, and block copolymers of VAc.

Results and discussion

Initial attempts using classical BV protocols

Pioneering efforts¹⁶ to bring BV oxidation into the field of PPM suffered from a lack of reactivity and/or significant chain scission. Conventional BV oxidation conditions¹⁰ appeared to be destructive and incompatible with ketone-containing polymers. To obtain more mechanistic details, we decided to re-investigate this transformation using PMVK as a substrate.¹⁷

We first evaluated the influence of temperature and reaction time using a commercial PMVK sample (Fig. 1 and Table S2†). The BV oxidations of PMVK were conducted using a typical protocol of chloroform as a solvent and *m*-chloroperoxybenzoic acid (mCPBA) as an oxidant. Although higher conversions were obtained with prolonged periods at elevated temperatures, the molar mass of the polymers decreased significantly. Noticeably, our kinetic studies revealed that the BV post-modification proceeded rapidly during the early stage, but became sluggish after 24 h. Consistent with the earlier investigations,¹⁶ our results also suggested that the standard BV oxidation conditions were not efficient enough to complete the proposed post-modification of PMVK. Other oxidants such as hydrogen peroxide and peracetic acid were also evaluated but inferior results were obtained.

Unsuccessful attempts at the translation of small-molecule protocols to PMVK

A small-molecule model using 3-hexylundecan-2-one as a substrate was established at the outset of this study. A large number of high-yielding conditions from the literature were screened and modified (Table S1†). Unfortunately, the direct translation of small-molecule protocols to the post-modification of PMVK completely failed (Fig. 2 and Table S3†). The M_n of the polymers decreased significantly with the use of either acids or bases (Fig. 2a and b). In addition, the use of alternative oxidants such as peracetic acid (PAA), trifluoroperoxyacetic acid (TFPAA), and magnesium monoperoxyphthalate hexahydrate (MMPP) gave even worse results (Fig. 2c).

The failure of the translation of the small-molecule model to PMVK suggests that the reactivity of a molecule with a single functional group such as 3-hexylundecan-2-one is quite different from that of PMVK. For a polymeric substrate, the electronic and steric interactions between functional groups can significantly affect its reactivity and possibly induce additional side reactions. Therefore, a small-molecule model would not always be able to guide the development of synthetic methods for polymers and other macromolecules.

We speculated that multiple side reactions could be responsible for the unsuccessful BV oxidation of PMVK. For

example, acid-induced radical generation¹³ which is reported to be able to initiate even at low temperatures could cause significant chain scission. In addition, oxidative decomposition¹² instigated by excessive oxidants, or Aldol-type condensations¹¹ promoted by acid or base could also complicate the proposed PPM. A combination of a literature survey and our preliminary results suggested that a comprehensive evaluation of PMVK under BV conditions was required. Accordingly, we turned our focus to the DOP approach in the following studies.

Development of the BV oxidation of commercial PMVK homopolymers

We first identified that the combination of carbon-13 and proton nuclear magnetic resonance spectroscopy (^{13}C and ^1H NMR) was a reliable method to quantitatively characterize both PMVK and its product after BV oxidation. Errors relating to C–H decoupling of ^{13}C NMR were evaluated and calibrated by ^1H NMR prior to use.

The effect of solvent was first investigated under a set of standard conditions (Table 1). Less polar solvents generally gave higher conversions while polar solvents were found to be problematic. Dichloromethane and chloroform, two common solvents for BV oxidation, were not suitable for the corresponding PPM due to both significant polymer degradation and only moderate reaction rates. Surprisingly, the optimal solvents

were found to be halogen-substituted aromatic solvents such as fluorobenzene, chlorobenzene and 1,2,4-trichlorobenzene, which are rarely used in BV oxidation. Their improved performance may be partially attributed to the enhanced stability of these solvents to oxidative conditions. Among the solvents tested, 1,2,4-trichlorobenzene was found to be optimal in terms of both conversion and M_n . The BV post-modification proceeded smoothly in the first 8 h, but the M_n of the functionalized polymers declined with prolonged periods. We conjectured that the accumulation of *m*-chlorobenzoic acid was likely the cause of this phenomenon.

We speculated that a “precise” buffer could perhaps maintain the pH of the reaction mixture within a narrow window where polymer degradation would not occur. Indeed, even a subtle deviation from the “ideal” pH range could potentially induce chain scission. Initial efforts using various aqueous buffers were unsuccessful. Control experiments indicated that excessive water affected both the reaction rate and molar mass in a negative manner. Gratifyingly, an extensive screening (>700 experiments) of inorganic salts and organic additives revealed that hexamethyldisiloxane (TMS)₂O (Tables S5–S7†) was able to buffer the system effectively. We conjectured that (TMS)₂O

slowly reacted with the *m*-chlorobenzoic acid accumulating during the oxidation to form a neutral trimethylsilyl *m*-chlorobenzoate species. Further suppression of chain scission by drying the commercial mCPBA reagent provided an optimal BV protocol for the exhaustive functionalization of PMVK. The optimal condition was obtained in Table 1, entry 22. Further experiments indicated that 4.0 equiv. of mCPBA was not required. Indeed, 1.2 equiv. of mCPBA was sufficient to complete the reaction, although a slower rate was observed.

Exhaustive BV oxidation of commercial PMVK homopolymers

With the first exhaustive functionalization condition in hand, we then conducted a BV oxidation of commercial PMVK on a preparative scale. In addition to ^1H NMR and ^{13}C NMR, the resulting polymer was fully characterized by size exclusion chromatography (SEC), Fourier transform infrared spectroscopy

(FT-IR), differential scanning calorimetry (DSC), and thermogravimetric analysis (TGA).

The ^1H NMR and ^{13}C NMR spectra of the polymer samples before and after oxidation are displayed in Fig. 3. The peak at $\delta = 4.87$ ppm was assigned to the protons attached to carbon **b'** of the post-modified polymer (Fig. 3a, bottom). Meanwhile, the peaks at $\delta = 2.3$ – 2.7 ppm, corresponding to the protons attached to the carbon **b** of PMVK, disappeared after the oxidation (Fig. 3a, top). These results indicated that the BV oxidation completely transformed the PMVK homopolymer into a PVAc homopolymer. The ^{13}C NMR spectra also provided additional evidence. In Fig. 3b, the carbonyl signal of the ketone of PMVK ($\delta = 210.2$ ppm) disappeared completely after the oxidation, while a carbonyl signal corresponding to an ester appeared at 170.4 ppm. In addition, the conversion of PMVK to PVAc was further confirmed by FT-IR.

The M_n and \bar{D} of the resulting PVAc polymer **5a** were obtained by SEC (Fig. 4a). A slightly higher M_n and a similar \bar{D} were obtained after functionalization. The SEC traces indicated that our protocol successfully suppressed chain scission and cross-linking without affecting the molar mass and \bar{D} . Meanwhile, glass transition temperature (T_g) data was collected using differential scanning calorimetry (DSC) (Fig. 4b). The T_g of PVAc **5a** obtained by the exhaustive BV oxidation was close to the T_g of the commercial PVAc sample. In contrast, the T_g of PMVK **3a** was slightly lower. Furthermore, the thermogravimetric analysis (TGA) of this sample after oxidation displayed a two-staged curve, which is analogous to that of PVAc (Fig. 4c). The initial degradation stage possibly relates to the elimination reaction of the side groups while the second stage may relate to the degradation of the polymer backbone. As a comparison, the TGA of the original PMVK sample exhibited a one-stage curve.

Exhaustive BV oxidation of statistical copolymers of MVK and various monomers

Although PVAc-derived copolymers are highly valuable, many PVAc copolymers, in particular those involving more activated monomers (MAMs), are rarely accessible by conventional copolymerization approaches.^{8a} Indeed, copolymerization cannot occur effectively since VAc and MAMs have disparate reactivity ratios.⁸ Encouraged by our success using PMVK homopolymers, we expected that our exhaustive BV post-

modification would provide a general solution for the synthesis of poly(VAc-co-MAM)s.

Firstly, we prepared a number of PMVK-co-PSs with differing MVK/St feed ratios (20/80, 50/50, and 80/20) under AIBN-initiated free radical polymerization. The reactivity ratios of MVK and St monomers ($r_{\text{MVK}} = 0.29$, $r_{\text{St}} = 0.35$)^{8a} indicate that PMVK-co-PS copolymers favor a statistical distribution. As expected, almost identical MVK/St ratios (28/72, 51/49 and 75/25, respectively) were obtained in the resulting copolymers. Subsequently, the prepared PMVK-co-PS copolymers were functionalized using the BV protocol developed for the PMVK homopolymers. Unexpectedly, it was observed that the rates of BV oxidation for PMVK-co-PS copolymers were higher than of the PMVK homopolymers. The enhanced rates appeared to be proportional to the percentages of styrene units within the PMVK-co-PSs. Following the same trend, the rates of chain scission and cross-linking also increased. Gratifyingly, with careful tuning of the reaction temperature, a set of exhaustive modification conditions for PMVK-co-PS were achieved at 45 °C (MVK/St = 75/25), 40 °C (MVK/St = 51/49), and 35 °C (MVK/St = 28/72), respectively (Table S10†). Under these optimized conditions, the M_n and \bar{D} were well controlled (Fig. 5). The reactivity differences between the PMVK homopolymers and PMVK-co-PS copolymers can be tentatively attributed to the fact that phenyl groups are less electron-withdrawing than acetyl and acetoxy groups. Mechanistically, the reaction rate of BV oxidation can be affected by the electronic properties of the migrating group. As a comparison, the direct copolymerization of VAc and St was also conducted. It was found that only 1% of the VAc monomer copolymerized while 94% conversion of St was obtained. Accordingly, the resulting copolymer was predominately composed of St. Besides PVAc-co-PS, PVAc copolymers with other MAMs such as acrylonitrile (AN), and methyl acrylate (MA) were also successfully prepared. Under the optimal BV conditions of 50 °C and 24 hours, PMVK-co-PAN and PMVK-co-PMA copolymers were fully converted to their corresponding PVAc-co-PAN and PVAc-co-PMA copolymers, respectively. No obvious chain scission or cross-linking were observed in the SEC traces (Fig. 5). All of the prepared statistical copolymers were thoroughly characterized. The “comonomer” ratios in the functionalized copolymers were consistent with the ratios of the starting copolymers (Tables S10 and S12†). Analysis of NMR spectral data (Fig. S4–S8†) confirmed that nearly all MVK units were converted to VAc units. FT-IR, DSC, and TGA data (Tables S11 and S13†) further supported the NMR spectra result.

Exhaustive BV oxidation of block copolymers of MVK and various monomers

In addition to the synthesis of statistical copolymers, the synthesis of block copolymers of VAc and MAMs remains challenging as well.¹⁸ Encouraged by our success in the synthesis of statistical poly(VAc-co-MAM)s, we anticipated that our BV post-modification strategy could be expanded to the synthesis of PVAc block copolymers with MAMs. Firstly, we prepared a number of PMVKs and poly(MAM-*b*-MVK)s *via* RDRP techniques. Although the atom transfer radical polymerization

(ATRP) of vinyl ketone monomers^{16a} is presently inaccessible, Wooley's RAFT protocol^{9f} offered us an effective method to synthesize narrow-dispersed PMVKs and PMVK block copolymers. Unfortunately, none of our established BV protocols for the statistical copolymers were compatible with the post-modification of narrow-dispersed PMVK homopolymers. Significant degradation of the polymer architecture occurred in all cases (Table S8†). We speculated that the degradation was most likely caused by the end-group of the RAFT polymers. Indeed, this hypothesis was later verified by the fact that a RAFT-derived polymer without a sulfur-based end group¹⁹ performed well using our BV protocol (Table S8†).

Previous studies indicated that sulfonic acid might be generated by the oxidation of the sulfur-based end-groups in the RAFT polymers.²⁰ Although TMS₂O was unable to buffer the more acidic –SO₃H group, we speculated that another additive might neutralize both *m*-chlorobenzoic acid and the additional sulfonic acid. Significant efforts at using common bases as a buffer met with little success since the pH of the reaction mixture changed dynamically. Indeed, a fluctuating pH, no matter if higher or lower, could be detrimental to the PPM. Gratifyingly, *t*-butyl carbamate and urea were later identified as the most effective additives after a laborious screening (Tables 2 and S9†). With a modified procedure using 0.2 equiv. of urea as an additive, the PMVK homopolymer prepared by RAFT was nearly quantitatively transformed into a PVAc polymer without obvious chain scission or cross-linking. The structural integrity of the resulting PVAc polymer was verified by ¹H and ¹³C NMR (Fig. S3†), and FT-IR. Furthermore, the MALDI-TOF MS (matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy) spectrum indicated a spacing of 86.1 which is consistent with the molar mass of a VAc repeating unit (Fig. S13†).

The modified BV protocol using the urea additive was further applied to the synthesis of PVAc block copolymers. Two di-block copolymers, poly(methyl methacrylate)-*block*-poly(methyl vinyl ketone) (PMMA-*b*-PMVK, $M_n = 14.0$ kDa, PMMA/PMVK = 7.7/6.3) and poly(ethyl acrylate)-*block*-poly(methyl vinyl ketone) (PEA-*b*-PMVK, $M_n = 13.9$ kDa, PEA/PMVK = 8.6/5.3), and one “ABA”-type tri-block copolymer, PMVK-*b*-PMA-*b*-PMVK ($M_n = 20.0$ kDa, PMVK/PMA/PMVK = 5.2/10.3/4.5), were synthesized by sequential RAFT polymerization. Subsequently, these three PMVK block copolymers were completely functionalized by the urea-modified BV protocol, with PMMA-*b*-PVAc, PEA-*b*-PVAc, and PVAc-*b*-PMA-*b*-PVAc being obtained without apparent degradation (Fig. 6 and Fig. S9–S11†). Notably, all of these copolymers were prepared using nearly identical conditions, and thereby the careful tuning of conditions for different MAMs is not required. This is distinct from the methods using switchable RAFT agent^{7b} and dual RDRP agents²¹ where the choice of polymerization parameters and RDRP techniques were important.^{18b}

Scalable one-pot synthesis of PVAc-co-PS and its improved performance over PVAc adhesive

To streamline the preparation of poly(VAc-co-MAM)s, we developed a one-pot copolymerization/exhaustive BV post-

modification procedure (Fig. 7, top). This convenient and scalable process allows us to synthesize PVAc-co-PS on a gram scale from MVK and St monomers directly without the purification of the PMVK-co-PS precursor. Noticeably, the use of 1,2,4-trichlorobenzene as a solvent for copolymerization was crucial for this process. Although the comprehensive properties of PVAc-co-PS **10** are yet to be investigated, this copolymer has exhibited an improved performance over the standard PVAc adhesive in our preliminary tests, especially when applied in aqueous conditions at elevated temperatures. The adhesive strength of PVAc-co-PS was maintained after 12 h of heating at 80 °C in water while that of regular PVAc was lost in 10 min under identical conditions (Fig. 7, bottom).

Conclusions

Baeyer–Villiger oxidation, a historically important transformation in small-molecule organic chemistry, has now emerged to be an efficient PPM reaction for PMVK and its copolymers. Initial unsuccessful attempts on a small-molecule model led us to develop and re-investigate the BV oxidation directly on PMVK polymers. After the elucidation of multiple factors affecting reaction kinetics and side reactions, a set of unique BV oxidation conditions have been developed and are able to completely functionalize PMVK and its copolymers without obvious chain scission or cross-linking.

With this unique BV post-modification method in hand, we successfully prepared a broad array of poly(VAc-co-MAM) statistical copolymers that are rarely accessed by direct copolymerization. In addition, a number of PVAc di-block and tri-block copolymers with narrow molecular weight distributions were synthesized using this post-modification method. A gram-scale one-pot process was additionally developed to demonstrate the potential of a scalable production of such copolymers. The material properties and potential applications of the prepared poly(VAc-co-MAM) copolymers will be reported in due course.

In addition, we recognize that re-investigating a reaction using polymer substrates could be a valuable approach for the development of other PPM reactions, particularly when the direct translation of small-molecule protocols has failed. By applying this approach, the post-modifications of other commodity polymers such as poly(acrylic acid) and polyketones are currently being investigated in our laboratory.
