High-performance protonic ceramic fuel cell cathode using protophilic mixed ion and electron conducting material†

Protonic ceramic fuel cells (PCFCs) are attractive energy conversion devices for intermediate-temperature operation (400–600 °C), however widespread application of PCFCs relies on the development of new high-performance electrode materials. Here we report the electrochemical and protophilic properties of a self-assembled nanocomposite, Ba$_{0.5}$Sr$_{0.5}$(Co$_{0.7}$Fe$_{0.3}$)$_{0.6875}$W$_{0.3125}$O$_3$–d (BSCFW) consisting of a disordered single perovskite and an ordered double perovskite phase, as a PCFC cathode material. BSCFW shows thermodynamic and kinetic protonic behaviour conducive to PCFC application with favourable proton defect formation enthalpy (∆H = −35 ± 7 kJ mol$^{-1}$) comparable to existing proton conducting electrolyte materials. BSCFW presents an excellent polarization resistance (R$_p$ of 0.172(2) Ω cm$^2$ at 600 °C and a high power density of 582(1) mW cm$^{-2}$ through single-cell measurement, which is a comparable performance to current state-of-the-art cathode materials. BSCFW exhibits good chemical and thermal stability against BaZr$_{0.1}$Ce$_{0.7}$Y$_{0.1}$Yb$_{0.1}$O$_3$–d (BZCYYb) electrolyte with a low R$_p$ degradation rate of 1.0(1) × 10$^{-6}$ Ω cm$^2$ min$^{-1}$. These performance and stability figures represent an advance beyond those of Ba$_{0.5}$Sr$_{0.5}$Co$_{0.7}$Fe$_{0.3}$O$_3$–d (BSCF), which is unstable under the same conditions and is incompatible with the electrolyte material. Our comprehensive characterization of the protonic properties of BSCFW, whose performance and stability are ensured via the interplay of the single and double perovskite phases, provides fundamental understanding that will inform the future design of high-performance PCFC cathodes.

The first report of high-temperature proton conductivity in oxide materials by Iwahara and co-workers in the 1980s garnered significant research interest for developing PCOs based on barium-zirconates and -cerates as electrolyte materials.⁷–⁹ Aliovalent-doped BaCe$_{1-x}$Zr$_x$O$_{3-δ}$ (0 < x < 1) have demonstrated high proton conductivity overcoming the major issues such as poor sinterability of BaZr$_{0.2}$O$_{3-δ}$ and low proton conductivity of BaCe$_{0.8}$O$_{3-δ}$ under practical operating conditions.⁷–¹¹ A barium zirconate-cerate co-doped with Y and Yb, BaZr$_{0.1}$Ce$_{0.7}$Y$_{0.1}$Yb$_{0.1}$O$_{3-δ}$ (BZCYyb), is reported with high ionic conductivity (~0.01 S cm$^{-1}$ in a humidified O$_2$ atmosphere), and excellent tolerance to sulfur poisoning and coking while BZCYyb with A-site barium deficiency showed chemical instability under both CO$_2$ and H$_2$S atmosphere.¹² However, despite such performance from the electrolyte, the limiting factor that prevents the widespread application of PCFCs is the limited availability of cathode materials with high activity and/or stability.

Generally, mixed ionic (O$^{2-}$) and electronic conductors (MIECs) have been used as the cathode material for conventional SOFC systems because of their excellent electronic conductivity and catalytic activity for the oxygen reduction.

Introduction

Amongst the various type of fuel cells, ceramic fuel cells have been extensively studied as eco-friendly alternative energy devices as a result of high energy conversion efficiency and continuous production of electricity without pollutant emissions.¹ The high operating temperature (>800 °C) of conventional O$^{2-}$-conducting ceramic fuel cells (solid oxide fuel cells, SOFCs), however, leads to serious issues such as chemical inter-diffusion and high thermal stress.²–⁵ Protonic ceramic fuel cells (PCFCs) using proton-conducting oxides (PCOs) are promising candidates for intermediate to low temperature operation (400–600 °C) because of the relatively high ionic conductivity and low activation energy for H$^+$ transport compared with O$^{2-}$-conducting oxides under the same operating conditions.⁶

Department of Chemistry, Materials Innovation Factory, University of Liverpool, 51 Oxford Street, Liverpool, L7 3NY, UK. E-mail: m.j.rosseinsky@liverpool.ac.uk
† Electronic supplementary information (ESI) available. See DOI: 10.1039/d1ta07113k
reaction. However, for MIECs with poor proton conductivity, electrochemical activity is localized to the interface between cathode and electrolyte, as protons diffuse from the PCO electrolyte to the cathode material in order to generate electricity. Triple conducting oxides (TCOs), that allow simultaneous transport of H\(^+\), O\(^2-\) and e\(^-\), with high chemical stability are required to effectively extend the electrochemically active sites to the entire surface of the cathode, and two different approaches have been used to increase the electrochemical performance of TCOs. The first approach is to dope various aliovalent elements (Co, Fe, Sc, Y) into pure proton-conducting electrolyte to increase oxygen-ion conductivity. The trivalent cations (Co and Fe) doped into BaZr\(_x\)Ce\(_{1-x}\)O\(_3\) significantly improve its catalytic properties as a PCFC cathode by activating electronic conduction while maintaining existing ionic conductivity. The second approach is to target existing MIEC materials with protophilic properties. This approach has the advantage that the material is already well-studied and its reaction mechanisms of O\(^2-\) and e\(^-\) are understood. Several researchers have investigated the protonic properties of typical MIEC perovskite-related materials, such as BaCoO\(_3\), which exhibit excellent electrochemical properties.

Among those BaCoO\(_3\)-based materials, Ba\(_{0.5}\)Sr\(_{0.5}\)Co\(_{0.8}\)Fe\(_{0.2}\)-O\(_{1-\delta}\) (BSCF) exhibits excellent electrochemical performance as a SOFC cathode. However, BSCF has been limited for use as an air electrode material because of its chemical instability under PCFC operating conditions (e.g., after hydration treatment) and degradation of the electrochemical performance below 650 °C in humidified air. We previously reported the self-assembled dynamic perovskite composite material, Ba\(_{0.5}\)Sr\(_{0.5}\)Co\(_{0.7}\)Fe\(_{0.3}\)-O\(_{1-\delta}\) (BSCFW), as an SOFC cathode. By incorporating W\(^6+\) into BSCF, BSCFW self-assembles into a composite where the interplay between a majority phase of stable oxygen-stoichiometric and electronically conducting double perovskite (DP), and a relatively minor phase of highly electro-catalytically active MIEC single perovskite (SP), ensures a combination of low polarization resistance and high chemical stability.

Here we report the high electrochemical performance of BSCFW as a PCFC cathode material with comprehensive characterization of protonic properties. The thermodynamic protonation enthalpy of BSCFW is evaluated by thermogravimetric analysis (TGA). The electrochemical performance of BSCFW as a PCFC cathode is examined through single-cell tests. Our findings highlight the excellent performance of the perovskite composite BSCFW and detailed characterization of the material provides insight and understanding towards the development of more efficient high-performance PCFC electrode materials.

**Experimental**

**Synthesis of electrolyte and electrode powders**

The solid-state reaction method was used to synthesize Ba\(_{0.5}\)Sr\(_{0.5}\)Co\(_{0.7}\)Fe\(_{0.3}\)-O\(_{1.0}\) and Ba\(_{0.5}\)Sr\(_{0.5}\)Co\(_{0.7}\)Fe\(_{0.3}\)W\(_{0.3}\)-O\(_{1.0}\) (BSCFW). Stoichiometric amounts of BaCO\(_3\) (99.995%), SrCO\(_3\) (99.994%), Co\(_2\)O\(_3\) (99.9%), Fe\(_2\)O\(_3\) (99.99%), and WO\(_3\) (99.9%) were weighed and ball milled in 15 mL propan-2-ol for 14 h with ZrO\(_2\) balls (10 mm diameter) using a Fritsch Pulverisette 7 Planetary Mill (350 rpm). The milled powder was dried and calcined at 700 °C for 6 h and 900 °C for 8 h with heating and cooling rates of 5 °C min\(^{-1}\) in air. The calcined BSCFW powder was pressed into 10 mm diameter pellet and sintered at 1200 °C for 12 h in a zirconia crucible. The relative density of sintered BSCFW pellet is 94%. BaZr\(_{0.1}\)Ce\(_{0.7}\)Y\(_{0.1}\)Yb\(_{0.1}\)-O\(_{3-\delta}\) (BZCYYb) powder was synthesized by the solid-state reaction. Stoichiometric amounts of BaCO\(_3\) (99%, Sigma Aldrich), CeO\(_2\) (99.9%, Sigma Aldrich), ZrO\(_2\) (99%, Alfa Aesar), Y\(_2\)O\(_3\) (99.99%, Alfa Aesar), and Yb\(_2\)O\(_3\) (99.9%, Alfa Aesar) were mixed by the ball milling process, followed by sintering at 1200 °C for 12 h in air.

**Preparation of samples for SEM and XRD analysis**

BSCFW-BZCYYb mixtures were sintered at 950 °C in air for 4 h, to investigate the chemical reactivity between the BSCFW and BZCYYb. The chemical reactivity of BSCFW and BZCYYb powders was checked by an X-ray diffractometer (Panalytical X’Pert Pro Bragg–Brentano geometry laboratory X-ray diffractometer with Co K\(_\alpha\) radiation, \(\lambda = 1.78898 \) Å). Synchrotron X-ray diffraction data of powder samples were recorded on Beamline I11 with a wide-angle position sensitive detector (\(\lambda = 0.826596(10) \) Å) at Diamond Light Source with samples loaded in borosilicate capillaries. The microstructures and cross-section images of the NiO-BZCYYb/BZCYYb/BSCFW single cell were observed using scanning electron microscopy (Hitachi S4800).

**Fabrication of single-cell**

The NiO-BZCYYb anode-supported cell was fabricated for fuel cell durability and performance. NiO-BZCYYb supported cells were fabricated by the drop-coating method to form the electrolyte layer. The NiO-BZCYYb hydrogen electrode was prepared by a mixture of NiO and BZCYYb (weight ratio of 6.5 : 3.5) after being ball-milled (5 mm balls, 100 rpm) for 24 h in ethanol. The BZCYYb suspension was applied to the NiO-BZCYYb support by drop-coating, followed by drying in air and co-sintering at 1400 °C for 4 h. The diameter of the single cell after sintering is 1.025 cm (shown in Fig. S1†). The calcined BSCFW powder was blended with a binder ( Heraeus V006) at a weight ratio of 1 : 0.7 for air electrode slurries. Air electrode slurries were screen-printed onto the surface of the BZCYYb electrolyte and were finally sintered at 950 °C in air for 1 h.

**Thermogravimetric analysis**

The concentration of protonic defects was determined by thermogravimetric analysis (TGA). To remove all water from the
structure, the powders (60–70 mg) were heated to 800 °C in dry air and held until thermal equilibrium was reached. The weight changes of samples under dry (Fig. S4a†) and wet air (PH2O = 0.023 atm, Fig. S4b†) were collected every 100 °C from 800 °C to 400 °C with a 2 h stabilization time at each temperature. TGA data were logged using a Q500 device from TA. Measurements were carried out on samples in platinum crucibles under dry air and wet air saturated by bubbling a constant air with a flow rate of 60 mL min⁻¹ through water at 25 °C. The difference of sample weight in dry and hydrated conditions at various temperatures is interpreted as the water uptake in BSCFW.

**Electrochemical performances**

The preparation procedure of the symmetrical cells began with pressing 0.6 g BZCYYb into 10 mm diameter pellets that were sintered at 1400 °C for 14 h in air with a heating rate and cooling rate of 2 °C min⁻¹ and 3 °C min⁻¹, respectively. The cathode slurry was screen printed onto both sides of the BZCYYb electrolyte pellet with an Aremco Screen Printer (model 3230, from Aremco) and fired in air at 950 °C for 1 h. After firing, silver electrodes were adhered to both faces of the symmetrical cell and heated at 600 °C for 1 h with a heating rate 3 °C min⁻¹. The symmetrical cell was held at 600 °C under the 3 vol% H2O-containing air with a flow rate of 20 mL min⁻¹, collecting the impedance spectra every 30 min for a total time of 60 h. For single-cell tests, Ag wires were attached at the cathode and anode side using Ag paste as a current collector. The NiO-BZCYYb anode-supported single-cell was sealed fully onto one end of the alumina tube using a ceramic adhesive (Aremco, Ceramabond 552). Humidified H2 (3 vol% H2O-containing H2) was applied to the anode side as a fuel through a water bubbler with a flow rate of 200 mL min⁻¹, while dry air was supplied as an oxidant with a flow rate of 100 mL min⁻¹ to the cathode during the single cell test. The cell operational stability test was carried out at 600 °C using BZCYYb with a constant 0.6 V potential applied for 8 h. Impedance spectra and I–V curves were acquired with Solartron 1260 frequency response analyzer in combination with a Solartron 1287 potentiostat. The resistance is determined by using the fitting tool in the software ZView v.3.2b (Scribner Associates).

**Results and discussion**

The powder X-ray diffraction (XRD) patterns of phase pure cathode Ba0.5Sr0.5(Co0.7Fe0.3)0.6875W0.3125O3 (BSCFW) and electrolyte BaZr0.1Ce0.7Y0.1Yb0.1O3–δ (BZCYYb) materials and...
their composite powders are presented in Fig. 1a. Compatibility between BSCFW and BZCYyb is investigated by heating the mixtures at 950 °C for 4 h. Fig. 1a shows there is no reaction between BSCFW and BZCYyb, indicating that BSCFW is chemically compatible with BZCYyb under these processing conditions. As shown in the fits against synchrotron XRD data (Fig. 1b, c and S2†), the lattice parameters of BSFCW do not significantly change between dry (\(a_{\text{DP}} = 3.98593(5) \text{ Å}, a_{\text{DP}} = 8.01198(4) \text{ Å}\)) and humidified air (3 vol%) at 300 °C (\(a_{\text{DP}} = 3.98357(10) \text{ Å}, a_{\text{DP}} = 8.01115(7) \text{ Å}\)). BSCFW, stabilized due to the self-assembly effect by incorporating \(\text{W}^{6+}\) doping, shows excellent chemical stability after exposure to 3 vol% \(\text{H}_2\text{O}\) in air for 1 h at 300 °C, while BSCF powder treated under the same conditions decomposed, forming \(\text{Co}_3\text{O}_4\) as a secondary phase (Fig. S3†). Moreover, the thermal expansion coefficient (TEC) difference between BSCFW (15 × 10⁻⁶ K⁻¹)²⁹ and BZCYyb (100–500 °C: 14.2 × 10⁻⁶ K⁻¹, 600–700 °C: 5.5 × 10⁻⁶ K⁻¹), indicating there is probably structure transformations or phase change in BZCYyb at ~500–600 °C)²⁹ is smaller (5.6% at 500 °C) than that between BSCF (approximately 20 × 10⁻⁶ K⁻¹)²⁹ and BZCYyb (40.8% at 500 °C), suggesting BSCFW exhibits superior mechanical compatibility with the electrolyte material compared to BSCF, which will minimize or avoid cell degradation, delamination or fracture.²⁵,²³,₂₂,₂₁

To determine the thermodynamic protonic properties of BSCFW, the extent of \(\text{H}_2\text{O}\) uptake into BSCFW was measured by thermogravimetric analysis (TGA) in the temperature range of 400–800 °C. The mass of the material was recorded as a function of temperature under dry (\(P_0 = 0.19 \text{ atm}, \text{balanced N}_2\)) and under humidified synthetic air (\(P_0 = 0.023 \text{ atm}\)). When exposed to humidified air (3 vol% \(\text{H}_2\text{O}\)) under an isothermal condition (sample held for 2 h in 100 °C steps in the range 400–800 °C), the BSCFW sample absorbed water due to the hydration reaction as described in Kröger–Vink notation below [eqn (1), Fig. S4†].

\[
\text{H}_2\text{O(gas)} + V_0^- + O_0^+ \leftrightarrow 2\text{OH}^-_0
\]  

(1)

Thus, the equilibrium constant (\(K_{\text{OH}}\)) for the hydration reaction can be expressed as,

\[
K_{\text{OH}} = \frac{[\text{OH}^-_0]^2}{P_{\text{H}_2\text{O}}[V_0^-][O_0^+]}
\]  

(2)

where \([\text{OH}^-_0]\), \([V_0^-]\), and \([O_0^+]\) are, respectively, the proton, oxygen vacancy, and oxygen concentrations of the sample in the hydrated state. Following the previous study of BSCFW, the oxidation state of B-site cations Co, Fe and W are +2/+3, +3 and +6 respectively.²⁹ Then, the BSCFW composition \(\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.5}\text{W}_{0.5}\text{Fe}_{0.5}\text{O}_{2.5}\) is approximated as \(\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.5}\text{W}_{0.5}\text{Fe}_{0.5}\text{O}_{3.4}\) (while keeping the total chemical stoichiometry of B-site unchanged, \(B = \text{Co}^{2+}/3^{+} + \text{W}^{6+}\)). Thus, the relevant reactions in BSCFW for vacancy creation and the water uptake reaction are given as

\[
\text{Fe}_2\text{O}_3 + 2\text{B}^+_0 + \text{O}_0^- \rightarrow 2\text{Fe}^+_0 + \text{V}^-_0 + 2\text{BO}_2
\]  

(3)

From TGA data, only \([\text{OH}^-_0]\) could be obtained while both \([V_0^-]\) and \([O_0^+]\) are unknown. Under oxidising conditions, the acceptor (Fe³⁺)-doped perovskites can be oxidized in the process of consuming oxygen vacancies and generating electron holes.

\[
\frac{1}{2}\text{O}_2 + \text{V}_0^- \leftrightarrow \text{O}_0^- + 2h^+
\]  

(4)

Considering the overall electro-neutrality, then based on eqn (1), (3) and (4) above, eqn (5) could be obtained:
The ohmic resistance ($R_{\text{ohmic}}$) including the contribution from the instrument and electrolyte is subtracted (the original impedance data is shown in Fig. S8†). The ASR of the cathode material is determined by the total resistance which is the sum of $R_1$ and $R_2$ (shown in the equivalent circuit diagram) (b) ASR of the symmetrical cell in 3 vol% water-containing air showing a 205 min break-in period after which the ASR stabilised and increases with a decay rate of $1.0(1) \times 10^{-9}$ cm$^2$ min$^{-1}$. (c) Impedance spectra plot of the symmetrical cell in Fig. 3b at $t = 205$ min (after break-in period) and after the 60 h test ($t = 3925$ min). (d) Impedance spectra of the single cell (BSCFW/BZY/C15/BZY) measured under open-circuit condition. A reduced scale is displayed to show detail at higher temperature (full-scale plot is shown in Fig. S9†). (e) $I$–$V$ curve (open symbols) and corresponding power density curves (filled symbols) of the BSCFW-BZY single cell in the 500–650 °C temperature range.

$$2[V'O] + [OH'O] + p = [Fe''']$$

in which $[Fe''']$ is the concentration of Fe on B-site ([Fe$'''$] = 0.21) and $p$ is the unknown hole concentration. Note there is also a constraint for the number of oxygen sites to sum to 3.

$$[V'O] + [OH'O] + [O'O] = 3$$

Using the above eqn (5) and (6), and as some studies reported, the hole concentration $p$ is negligible.$^{34,35}$ Therefore the unknown $[V'O]$ and $[O'O]$ can be expressed as $[V'O] = \frac{1}{2}([Fe'''] - [OH'O])$ and $[O'O] = \frac{1}{2}(6 - [OH'O] - [Fe'''])$, respectively.

Then the eqn (2) now could be expressed as

$$K_{\text{OH}} = \frac{4[OH'O]^2}{P_{\text{H}:O}([Fe'''] - [OH'O])(6 - [OH'O] - [Fe'''])} \quad (7)$$

Therefore, the equilibrium constant ($K_{\text{OH}}$) could be solved from known parameters. The proton uptake reaction is a thermally activated process, so the enthalpy of proton defect formation ($\Delta H$) for BSCFW can be determined from the slope of the Arrhenius plot of equilibrium constants ($K_{\text{OH}}$) at different temperatures (Fig. 2a) using the following Van’t Hoff equation,$^{36}$

$$\ln(K_{\text{OH}}) = \frac{-\Delta H}{RT} + \frac{\Delta S}{R} \quad (8)$$

where $R$, $T$, and $\Delta S$ are the universal gas constant, absolute temperature and entropy, respectively. For comparison, $\Delta H$ values of state-of-the-art PCOs are presented in Fig. 2b (specific TGA results are shown in Fig. S4†). The more negative values of $\Delta H$ (i.e., more exothermic) indicate that the hydration reaction is more favourable because of the relationship between the dissolved hydroxyl group and the lattice oxygen.$^{36,37}$ According to Sabatier’s principle, the bond strength between the catalytic material and the reactant must be optimized for the ideal catalytic reaction. (i.e., not too strong or too weak bonding with reactants).$^{38}$ In the temperature range of 400–800 °C, the $\Delta H$ of proton defect formation for BSCFW is $-35 \pm 7$ kJ mol$^{-1}$, which is lower than the typical proton-conducting electrolyte materials BZY solid solutions ($-94$ kJ mol$^{-1}$ to $-66$ kJ mol$^{-1}$),$^{39,40}$ but is comparable to the reported cathode materials for PCFC (BSFZ, $-70$ kJ mol$^{-1}$;
performance of a single cell with a configuration of BSCFW/BZCYYb/NiO-BZCYYb. Generally, the measured impedance spectra of a single cell are used to describe total resistances associated with components such as electrode and electrolyte. The intercept with the real axis at high frequencies represents the ohmic resistance which mainly originates from the electrolyte, whereas the difference between the high- and low-frequency intercepts with the real axis indicates the sum of the electrode polarization resistance particularly from the cathode. As expected from the favourable protonic kinetic and thermodynamic properties presented by BSCFW, a small $R_p$ of 0.172(2) $\Omega$ cm$^2$ and a maximum power density of 0.582(1) W cm$^{-2}$ were obtained at 600 °C (Fig. 3d and e) from the single cell measurement. Fig. S6† shows the cross-section scanning electron microscopy image of the cell after the single cell test. There is no evidence of delamination or change of microstructure of the BSCFW cathode (Fig. S6b and c†).

The operational stability of the cell using BSCFW as cathode material was also examined at 600 °C for 8 h with a constant voltage of 0.6 V applied to the cell. For the cell stability test, 3 vol% H$_2$O-containing H$_2$ with a flow rate of 200 mL min$^{-1}$ was supplied to the NiO-BZCY721 anode while air with a flow rate of 100 mL min$^{-1}$ was supplied to the BSCFW cathode. Two different electrolytes (BZCY721 and BZCYYb) were used to preliminarily examine their influence on the stability of cell. Note that the cell durability depends not only the cathode–electrolyte compositional combinations, but also anode, working gas, temperature and the applied voltage. More detailed evaluation with longer tests is required. As shown in Fig. S7† the power density of the cell using BZCY721 electrolyte decreased slightly (at the rate of 2.2(1) × 10$^{-5}$ W cm$^{-2}$ min$^{-1}$), which is lower that reported for LSCF-BZCY cell (La$_{0.5}$Sr$_{0.5}$Co$_{O.8}$O$_{1.9}$ cathode – BZCY electrolyte, approximately 3.3 × 10$^{-7}$ W cm$^{-2}$ min$^{-1}$, Table S2†). In addition, the power density decay rate of the cell using BSCFW cathode and BZCYYb electrolyte is 3.0(2) × 10$^{-4}$ W cm$^{-2}$ min$^{-1}$ (Fig. S7†), which is larger than that using BZCY721 electrolyte since the high Ce : Zr ratio (7 : 1) of BZCYYb increases the instability of the cell.†

Fig. 4 presents a comparison of $R_p$ for BSCFW against representative PCFC cathodes materials. According to Steele et al., the total $R_p$ of cell components (electrolyte, anode, and cathode) should be below 0.50 $\Omega$ cm$^2$ to ensure high power densities, with targets of 1 kW dm$^{-3}$ and 1 kW kg$^{-1}$. Assuming that 30% of the total cell $R_p$ is attributed to the electrolyte (i.e., a typical value of 0.15 $\Omega$ cm$^2$), an adequate performance is obtained from a PCFC if the electrode’s $R_p$ is less than 0.35 $\Omega$ cm$^2$. Notably, the $R_p$ measured from the BSCFW single cell gives a value of 0.172(2) $\Omega$ cm$^2$, which is less than half the recommended value and meets the requirement for efficient operation of a PCFC. Also, BSCFW shows a power density of 0.426(1) W cm$^{-2}$ even at 550 °C, which is higher than the required power density of 0.25 W cm$^{-2}$ for efficient operation (Table 1 and Fig. 4). Such efficient performance in the intermediate-to-low temperatures regime (~600 °C) enables cost-effective manufacturing by widening the choice of materials (e.g., metallic interconnects, non-ceramic seals) and eliminating major performance degradation.†

Conclusions

BSCFW, a self-assembled dynamic perovskite composite cathode, shows excellent chemical stability in contact with humidified air and the solid electrolyte (BZCYyb) at high temperatures, and electrochemical stability under PCFC operating conditions with a symmetrical cell showing a \( R_p \) degradation rate of \( 1.0(1) \times 10^{-6} \) Ω cm² min⁻¹ over more than 60 h at 600 °C. A single-cell test showed operational stability over 8 h, with a power density decay rate of \( 2.2(1) \times 10^{-5} \) W cm⁻² min⁻¹. These initial stability tests give decay rates less than those found for LSCF electrodes in equivalent single cell configurations and require more detailed evaluation with longer tests. This performance is a significant improvement over BSCF, which was not stable under the same conditions and its TE mismatch with BZCYyb prevented symmetrical cell testing. Thermodynamically, BSCFW has a favourable enthalpy value (ΔH) of proton defect formation (−35 ± 7 kJ mol⁻¹) comparable to leading proton-conducting oxides. Such favourable protonic properties highlight the potential of BSCFW as a PCFC cathode material with high efficiency for operation at low temperatures (e.g. 550 °C). Our identification of the self-assembled nanocomposite BSCFW as a high-performance PCFC cathode material, and comprehensive characterisation of thermodynamic behaviour provides fundamental scientific insight for the rational design of more efficient electrode materials for high-performance PCFCs.

Data availability

Underlying data is available at http://datacat.liverpool.ac.uk/id/eprint/1499.

Author contributions

JK and DH designed and conducted the material synthesis, characterisation and electrochemical measurements and prepared the first draft of the manuscript. HN assisted with construction and operation of single-cell measurements. RF and BL assisted with TGA measurements. LD, TM, RC participated in the design of the experiment and provided assistance with data analysis and revision of the manuscript. All authors contributed to the discussion of the results and approved the final version of the manuscript. MJR directed the research.

Conflicts of interest

There are no conflicts to declare.
