5,15-Bis(triisopropylsilylethynyl)tetrabenzoporphyran (TIPS-H2BP) gave a one-dimensionally extended columnar packing motif. The single crystal field-effect transistor of TIPS-H2BP exhibited clearly better hole mobility (2.16 cm2 V−1 s−1) than its metal complexes (ca. 0.1 cm2 V−1 s−1), with efficient charge transport through π−π stacking along the tetrabenzoporphyran units.

The charge transport in organic semiconductors is achieved by the π orbital overlapping of the conjugated molecules along the direction of carrier flow. Therefore, organic semiconducting materials with a rigid and planar π-system have great potential to provide suitable packing to increase the π orbital overlap.1–4 Due to the large and rigid π-system, tetrabenzoporphyrrins (BPs) are promising candidates as efficient p-type semiconducting materials.5,6 However, BP itself is hardly soluble in organic solvents, resulting in difficulty in its direct solution deposition. In addition, the solubility is an important factor not only for the solution-processable device fabrication but also for achieving the large-scale synthesis by conventional organic chemistry together with easy purification using column chromatography. Although these factors, including rigidity and solubility, are likely a trade-off relationship, several molecules perfectly satisfy these requirements. For example, 6,13-bis(triisopropylsilylethynyl)pentacene (TIPS-Pen), which is a benchmark compound as an efficient organic semiconducting material, has proven to be quite successful, despite the fact that the pentacene itself is almost insoluble in common organic solvents.7 Taking advantage of the improved solubility by the introduction of TIPSethynyl groups, the solution sharing with a micropillar-patterned blade gave a hole mobility up to 11 cm2 V−1 s−1,8 achieving clearly better hole mobility than pristine pentacene.

For BPs as well, recent synthetic efforts have solved the solubility problem by using the “precursor method”, in which a soluble precursor compound, 1,4:8,11:15,18:22,25-tetraethano-29H,31H-tetrabenzo[b,g,l,q]porphyran (CP), can be quantitatively converted to BP by a thermally induced retro-Diels–Alder reaction with heating at 150–200 °C for several minutes.6,9 Importantly, the retro-Diels–Alder reaction releases only ethylene molecules as gaseous byproducts. Thus, no purification process is required to obtain pure compounds, if the corresponding precursors are sufficiently pure. The charge-carrier mobility of BP polycrystalline film obtained via the precursor method was evaluated for the first time by Aramaki, exhibiting a hole mobility of 0.017 cm2 V−1 s−1.10 The hole mobility was then slightly improved to 0.07 cm2 V−1 s−1, while the value was still low.11 Recently, the substituent effect was evaluated to obtain better charge transport property by controlling the packing orientation of BP. It was found that 5,15-bis(triisopropylsilylethynyl)-BP (TIPS-H3BP) with reasonable solubility for solution-processed organic thin film transistors formed two types of packing motifs: columnar motif using a drop-casting method and brickwork motif using a dip-coating method.12 The drop-casting films with the columnar motif showed low hole mobility (0.027 cm2 V−1 s−1), although such a columnar motif is also known to exhibit efficient charge transport properties. On the other hand, the brickwork motif has two dimensionally extended π-stacking. The maximum hole mobility of dip-coating films reached 1.1 cm2 V−1 s−1, which was approximately 14 times higher than pristine free-base BP (0.07 cm2 V−1 s−1). This disparity in charge transport property derived from different packing motifs prepared using drop-casting and dip-coating methods turned our attention to single-crystal field-effect transistors (SCFETs), which are able to unveil the intrinsic charge transport property of organic
semiconducting materials due to ordered arrangement of molecules, free of grain boundaries and minimized defects. The obtained maximum hole mobility of TIPS-H2BP in the above report implied that functionalized BP derivatives could be candidates for efficient organic semiconducting materials. For further structural fine-tuning of BP, the potential of TIPS-H2BP as a simple prototype is necessary to be evaluated by using the single crystal. In this study, single crystals of TIPS-H2BP and its metal complexes were prepared on a substrate, and the molecular orientation in the single crystal was explored in detail. Then, the relationship between the molecular orientation and charge transport property was investigated by preparing SCFETs.

TIPS-H2BP and the zinc(II) and copper(II) complexes (TIPS-ZnBP and TIPS-CuBP) were synthesized by following the previous reports (Fig. 1). Then, their crystals were grown by drop-casting the toluene solution on the octadecyltrichlorosilane (OTS) modified Si/SiO2 surface. It was found that slow evaporation of the drop-casted toluene solution gave isolated and thin ribbon-shaped single crystals on Si/SiO2/OTS substrates (Fig. 2). Importantly, the changing of interfacial color in the polarized optical microscope (POM) images indicated that they were single crystals. Narrow ribbon-shaped crystals of TIPS-H2BP similar to the case of TIPS-CuBP were also observed. However, out-of-plane X-ray diffraction (XRD) and transmission electron microscopy (TEM) analyses indicated that the molecular orientations in these crystals were the same (vide infra). Indeed, the crystal grew having a different shape probably because of the slightly different surface energy on the substrate. Here, the order of ease of crystal formation was as follows: TIPS-H2BP > TIPS-ZnBP > TIPS-CuBP. Specifically, single crystals of TIPS-CuBP suitable for SCFETs were hardly obtained on a Si/SiO2/OTS substrate, usually giving a fiber-like structure (Fig. S1, ESI†).

Before examining the molecular orientation of single crystals on a substrate, the bulk single crystal structures for each BP derivative were analyzed in order to establish a referential basis for further discussion. Those single crystals were prepared from toluene solutions, although the X-ray analysis had already been done with single crystals obtained from a different solvent system in the previous report. In fact, solvents showed no significant effect on their packing structures. Briefly, a large TIPS-H2BP core (Fig. 3a and b) formed a one-dimensionally extended columnar π-stacking motif with the plane-to-plane distance of BP of ca. 3.3 Å (Fig. 3c). TIPS-H2BP molecules stacked orthogonally in the packing, alternately possessing a

planar TIPS-H$_2$BP molecule (Fig. 3a) and the one with two TIPSethynyl groups bent from the BP plane sigmoidally (Fig. 3b). It is evident that the well-ordered alignment of TIPS-H$_2$BP facilitates the intermolecular charge transport in the column. BP backbones of TIPS-ZnBP$^{19}$ and TIPS-CuBP$^{20}$ are similar to TIPS-H$_2$BP. However, molecules in the single crystal form a triad-like structure in which the molecules are stacked orthogonally.$^{17}$ In the triad-like structure, TIPS-ZnBP and TIPS-CuBP also have the plane-to-plane distance of ca. 3.3 Å, while the triad units are packed parallel to provide one-dimensional slip-stacked structures. In addition, a planar TIPS-ZnBP or TIPS-CuBP molecule is sandwiched by the respective metal complexes with sigmoidally bent TIPSethynyl groups in the triad-like structure. As a result, long-range molecular orientation is missing in the cases of TIPS-ZnBP and TIPS-CuBP, in contrast with that observed in TIPS-H$_2$BP.

To shed light on the molecular orientation of single crystals on a substrate, out-of-plane XRD analysis was performed (Fig. 4 and Fig. S2, ESI†). In the case of TIPS-H$_2$BP (Fig. 4a), the intense peaks at 2θ = 5.16° with a d-spacing of 17.1 Å together with peaks at 2θ = 6.10° (d-spacing = 14.5 Å) and at 2θ = 6.22° (d-spacing = 14.2 Å) were well-consistent with the simulated [001], [010], and [011] diffractions of the one-dimensional columnar structure (Fig. 3c), respectively, according to the crystallographic data for the bulk crystal. These results support the fact that the one-dimensional columnar packing in parallel to the substrate was grown through the π-π stacking direction of TIPS-H$_2$BP. Note that a peak at 4.66°, which corresponds to [001] of the brickwork motif,$^{12}$ was not observed. Similarly, the peaks at 2θ = 5.02° (d-spacing = 17.6 Å) and at 2θ = 5.77° (d-spacing = 15.3 Å) for TIPS-ZnBP are in good agreement with the simulated [001] and [010] diffractions of the TIPS-ZnBP columnar structure, respectively (Fig. 4b). In the case of TIPS-CuBP, small peaks at 2θ = 5.03° (d-spacing = 17.6 Å) and at 2θ = 5.82° (d-spacing = 15.2 Å) which correspond to [001] and [010], respectively, could be observed (Fig. 4c), while less number of single-crystals on the substrate resulted in the overall weak peak intensity of the XRD pattern. As described above, a fiber-like structure also formed on the substrate together with ribbon-shaped crystals (Fig. S1, ESI†). Rigid π-systems could form the crystalline nanofibers.$^{21,22}$ Thus, these crystalline fibers account for the peaks at 2θ = 4.87° and 2θ = 5.16° which are not consistent with the simulated patterns of the one-dimensional columnar packing.

In order to confirm the molecular arrangements in the ribbon-shaped crystals, TEM images and their corresponding selected area electron diffraction (SAED) patterns were collected from an individual ribbon-shaped crystal (Fig. 5). The observed bright diffraction spots demonstrated the high-quality of crystallinity. Here, the SAED pattern could be indexed with its single crystal structure, while the SAED patterns for TIPS-H$_2$BP and TIPS-ZnBP are not complete. It was found that the preferred crystal growth directions of TIPS-H$_2$BP, TIPS-ZnBP, and TIPS-CuBP were expected to be [100], [−111], and [−111], respectively (Fig. 3c–e), which are in good agreement with the morphologies predicted through the Bravais-Friedel-Donnay-Harker (BFDH)$^{23-25}$ method (Fig. 5). Thus, SAED patterns and TEM analysis together with XRD measurement indicated that the growth direction of the ribbon-shaped crystals on the substrate was guided by π-π interactions, creating a one-dimensionally extended packing motif as a charge-carrier transport.

Finally, the charge transport property of the single crystals was evaluated by fabricating bottom-gate-top-contact organic field-effect transistors using the “gold layer glue technique”.$^{26}$ Briefly, gold source and drain electrodes were placed on the crystals which were grown by drop-casting the toluene solution on the Si/SiO$_2$/OTS substrate. The effective channel length and width were measured by microscopy (Fig. S3, ESI†).

The ribbon-shaped crystals of TIPS-H$_2$BP exhibited an average value of 1.16 cm$^2$ V$^{-1}$ s$^{-1}$ with 15 devices (Fig. 6a and d), giving the maximum hole mobility of 2.16 cm$^2$ V$^{-1}$ s$^{-1}$ with a threshold voltage $V_{th}$ of 15.6 V and on/off ratio $I_{on}/I_{off}$ of $6.1 \times 10^2$ (Fig. S4, ESI†). In the previous report, the one-dimensional columnar structure of TIPS-H$_2$BP prepared using
the drop-casting method exhibited the hole mobility of 0.027 cm$^2$ V$^{-1}$ s$^{-1}$. Thus, the maximum hole mobility obtained in this study is approximately 80 times higher than that obtained using the drop-casting method. This result supported the fact that the molecular orientation of TIPS-H$_2$BP is preferable to SCFETs, with the charge transport through π-π stacking of BP units in the one-dimensional column. In addition, the efficient charge transport reflected the feature of single crystals free of grain boundaries and with minimized defects. It should be noted that nearly identical curves were observed after 10 cycles (Fig. S3, ESI†), suggesting the good bias-stress stability of SCFETs based on ribbon-shaped crystals of TIPS-H$_2$BP. Here, SCFET devices based on TIPS-H$_2$BP often showed the hole carried on operation mode especially for the device which exhibited a high hole mobility (Fig. S4, ESI†), indicating that the transport channel already formed even without gate bias ($V_G = 0$ V). This is probably due to the high hole density of TIPS-H$_2$BP. The holes not only filled the trap states, but also the excess holes became free carriers, forming a conducting channel even though at $V_G = 0$ V. Moreover, the decreased trap states would facilitate carrier transport, thus improving the mobility of TIPS-H$_2$BP.\(^\text{27}\)

On the other hand, the ribbon-shaped crystals of the metal complexes, TIPS-ZnBP and TIPS-CuBP, showed clearly lower hole mobilities compared with TIPS-H$_2$BP (Fig. 6b, c, e, f and Fig. S4, ESI†), although those values were much higher than the ones prepared using the spin-coating method ($1.1 \times 10^{-5}$ cm$^2$ V$^{-1}$ s$^{-1}$ for TIPS-ZnBP and $5.6 \times 10^{-3}$ cm$^2$ V$^{-1}$ s$^{-1}$ for TIPS-CuBP).\(^\text{17}\) The maximum hole mobility of 0.12 cm$^2$ V$^{-1}$ s$^{-1}$ (average values of 0.05 cm$^2$ V$^{-1}$ s$^{-1}$ with 12 devices) with a threshold voltage $V_{th}$ of 6.6 V and on/off ratio $I_{on}/I_{off}$ of $7.6 \times 10^5$ for TIPS-ZnBP, while TIPS-CuBP showed the maximum hole mobility of 0.16 cm$^2$ V$^{-1}$ s$^{-1}$ (average values of 0.14 cm$^2$ V$^{-1}$ s$^{-1}$ with 4 devices) with a threshold voltage $V_{th}$ of 3.0 V and on/off ratio $I_{on}/I_{off}$ of $1.1 \times 10^5$. This result is rationalized by the fact that charge transport is suppressed in the cases of TIPS-ZnBP and TIPS-CuBP because of their triad-like structures (Fig. 3), clearly indicating that the metalation had negative effects on the charge transport property.

Note that the I–V characteristics for the TIPS-ZnBP device seem suppressed at high gate voltage, and the linear portion of the TIPS-H$_2$BP device shows current crowding. Although these reasons are not clear at this moment as the mechanisms are very complex, the carrier-density-dependent mobility and contact resistance are known to be two important factors which cause nonideal characteristics.\(^\text{28–31}\) Here, the gate-dependence saturation mobility extracted from I–V curves is shown in Fig. S6 (ESI†). Most OFET devices of TIPS-H$_2$BP showed the mobility with gate voltage independency (Fig. S6a, ESI†). However, a few devices exhibited decreased mobility with increased gate voltage (Fig. S6c, ESI†), which may be attributed to the charge trapping induced non-ideal behaviors.\(^\text{32}\) Distinctly, the I–V characteristics for all the TIPS-ZnBP devices showed a typical “double-slope” shape or “kink” with the mobilities shaking upwards and downwards (Fig. S6b and d, ESI†) at different gate voltages.\(^\text{28}\) Regarding the single-crystal nature of our devices, these “double-slope” phenomenon may be caused by the disorder of the interface, which means that the charges are more tightly attracted toward the interface at high gate voltages.\(^\text{33,34}\) Since the nonideality could affect the calculation for the mobility, further analysis will be done to unveil the reason for the nonideality. This effort should contribute to providing an important clue to improving the mobility of BP derivatives.

In summary, SCFETs of TIPS-H$_2$BP and its metal complexes were fabricated and their charge transport properties were evaluated. TIPS-H$_2$BP exhibited the best mobility ($2.16$ cm$^2$ V$^{-1}$ s$^{-1}$) among the BP derivatives employed in this study. XRD and TEM analyses unveiled that the long-range one-dimensional columnar structure of TIPS-H$_3$BP contributed the high charge transport property. It should be noted that the deviation between the maximum and average hole mobilities of TIPS-H$_3$BP would stem from the quality of single crystals, meaning that finding optimized conditions for single crystal formation could improve the charge transport property. More importantly, recent synthetic efforts are providing a variety of BP derivatives.\(^\text{6,35–37}\) Considering that TIPS-H$_2$BP shows excellent stability, elaborately-designed BP derivatives have great potential to be promising semiconducting materials. We believe that fine-tuning of the BP structure enables a significant improvement in the charge transport property.
